Outer membrane proteins related to iron metabolism Growth of gonococci and meningococci under iron-limiting conditions leads to the increased production of a variety of outer membrane or periplasmic proteins, collectively termed Irps (iron repressed proteins) (Norqvist et al., 1978). Consistent with the notion that levels of available iron are low in mammalian tissue and fluids, studies of seroconversion following disease indicate that Irps are expressed *in vivo* (Ferreiros et al., 1994). Irps are involved in iron uptake and their expression is coordinately regulated by the action of the iron-dependent regulatory protein Fur (Thomas and Sparling, 1996). Gonococci and meningococci express surface proteins engaged in specific uptake of iron from human transferrin, lactoferrin, and hemoglobin, and, in most cases, proteins found in these two species in each uptake system are structurally and functionally related (Schryvers and Stojiljkovic, 1999). Uptake from transferrin and lactoferrin involves expression of two large proteins, a lipoprotein (Tbp2 and LbpB) and a TonB dependent integral membrane protein (Tbp1 and LbpA), which act in concert to bind their respective ligand (Pettersson et al., 1994). In both systems, expression of the TonB dependent integral membrane proteins is required for function, while that of the lipoprotein is not (Anderson et al., 1994; Pettersson et al., 1998a).

Only 50% of gonococcal strains produce a functional lactoferrin receptor (Biswas and Sparling, 1995), and, as such, the ability to utilize lactoferrin as an iron source is not necessary for gonococcal infection. In contrast, transferrin receptor activity appears to be essential since mutants lacking Tbp1/2 are incapable of colonization in the human urethral challenge model (Cornelissen et al., 1998). Given their surface exposure and expression *in vivo*, meningococcal Irps have been examined for their abilities to engender bactericidal or opsonic antibodies (Lissolo et al., 1995; Ala'Aldeen and Borriello, 1996; Lehmann et al., 1999). Like other surface-exposed molecules, transferrin binding proteins display heterogeneity, which arises due to genetic exchange (Rokbi et al., 1997; Legrain et al., 1998), but such diversity may not automatically preclude their utility as protective immunogens since broadly cross-reactive antibodies against Tbps have also been reported to restrict growth under conditions of iron limitation by virtue of blocking the interaction with transferrin (Ala'Aldeen, 1996).

Other membrane proteins Rmp is a highly conserved, reduction modifiable outer membrane protein that is found only in pathogenic neisseriae (Wolff and Stern, 1995). It is so named because its migration in SDS-PAGE is altered following treatment with reducing agents and was previously designated as Protein III (PIII) in gonococci and the class 4 protein in meningococci. Although mutants lacking Rmp have no discernible phenotypes, the protein does co-purify with the Por proteins (Wetzler et al., 1992b). In addition, antibodies directed against Rmp appear to block the bactericidal activity of antibodies directed toward other outer membrane proteins (Munkley et al., 1991), which may account for the observation that Rmp antibodies are associated with an increased susceptibility to gonococcal infection (Plummer et al., 1993).

Several other neisserial outer membrane proteins have been described. Some of these proteins appear to be both highly conserved and surface exposed. NspA is a conserved membrane protein that is reported to elicit protective antibody responses against *N. meningitidis* serogroups A, B, and C in mice (Martin et al., 1997). Although originally found in meningococci, it has also recently been shown to be expressed by *N. gonorrhoeae* strains (Plante et al., 1999).

Lipo-oligosaccharide Lipopolysaccharide (LPS) is a major component of the outer membrane of Gram-negative bacteria. The LPS of enteric bacteria such as *E. coli* consists of a lipid A moiety, a core oligosaccharide, and a repeating O-antigen polysaccharide. In contrast, the corresponding molecule of the pathogenic *Neisseria* spp. lacks the repeating O-antigen polysaccharides and is therefore termed lipo-oligosaccharide (LOS) (Mintz et al., 1984; Yamasaki et al., 1994). Differences in LOS composition appear to account for the difference in M_r. The oligosaccharide component consists of 1) a partially conserved and highly substituted basal oligosaccharide that branches at a heptose residue; 2) a linear segment consisting of $(hexose)_n$ residues that determines the length of the oligosaccharide; and 3) terminal sequences that are similar to those of glycosphingolipids (Griffiss et al., 1988; Mandrell et al., 1988). The resemblance of the lactoneoseries glycolipids in gonococcal (Yamasaki et al., 1994) and meningococcal (Tsai et al., 1998) LOS to human glycolipids appears to represent a form of host mimicry that may play a role in immune evasion (Moran et al., 1996). Gonococci expressing these LOS forms appear to be selected for *in vivo* and may have reduced infective doses (Schneider et al., 1991, 1995). Differences in the chemical composition of individual oligosaccharides relate to their ability to inhibit the killing of serum-sensitive strains of gonococci (Griffiss et al., 1987). *N. meningitidis* releases large amounts of the potent LOS through blebs or lysis. The oligosaccharide of neisserial LOS can be bound by host cell-expressed lectins and, therefore, might also contribute to bacterial adhesion (Apicella et al., 1986; Porat et al., 1995) and invasion (Song et al., 2000d).

Gonococci have the ability to produce a variable set of the oligosaccharide components of LOS at a high frequency. This variation occurs primarily due to phase variable expression of tandemly arrayed glycosyl transferase genes that ensue from slipped strand mispairing within poly-G tracts (Yang and Gotschlich, 1996). The lactoneoseries glycolipids in gonococcal LOS are also able to become modified *in vivo* by sialylating the oligosaccharide with host-derived CMP-*N*-acetyl neuraminic acid (CMP-NANA) (Nairn et al., 1988; Parsons et al., 1989). The enzyme responsible for this modification, sialyl transferase, is of gonococcal origin. The sialylation of the LPS results in the conversion of a serum-sensitive organism to one that is serum-resistant (Parsons et al., 1989) and is one of several mechanisms responsible for this phenomenon in gonococci. The sialylated

LPS appears to be rapidly lost after growth *in vitro* in the absence of CMP-NANA and may explain the type of resistance referred to as unstable serum resistance (Ward et al., 1970; Wetzler et al., 1992a). Curiously, sialylation *in vitro* prior to urethral challenge in men has been reported to reduce infectivity (Schneider et al., 1996). Meningococcal serogroup B and C strains are able to endogenously sialylate LOS since they have sialyl transferase and produce CMP-NANA as a substrate for capsule biosynthesis (Tsai et al., 1998). In contrast to other Gram-negative species, meningococcal mutants lacking LOS are viable (Steeghs et al., 1998). This remarkable finding may be attributable to compensatory changes in the phospholipid composition.

Immunoglobulin M (IgM) class antibodies directed against LPS epitopes are responsible for the complement-dependent bactericidal activity of normal human serum for serum-sensitive strains of *N. gonorrhoeae* (Apicella et al., 1986). The LPS from serum-resistant strains also contains bactericidal epitopes; however, normal human serum often lacks antibodies to these particular epitopes (Schneider et al., 1985). Nevertheless, antibodies to these epitopes are present in convalescent serum samples from patients with disseminated infections (Rice and Kasper, 1977).

Fimbriae (pili) Fimbriae (pili) are hairlike filamentous appendages emanating several micrometers from the bacterial cell surface. Fimbriae have been found on the surface of *N. gonorrhoeae* (Jephcott et al., 1971; Swanson et al., 1971), *N. meningitidis* (DeVoe and Gilchrist, 1975; McGee et al., 1977), and the nonpathogenic *Neisseria* spp., including *N. perflava* and *N. elongata* (Wistreich and Bakter, 1971; Frøholm et al., 1973; Bøvre et al., 1977). A PCR-based screen detected homology to the conserved N-terminal region of the pilus expression locus PilE in 12 out of 15 *Neisseria* species investigated, including all human commensal isolates (Aho et al., 2000).

Neisserial pili are ordered arrays of polymerized protein subunits termed pilin, with a molecular weight that varies between strains in the range of 16–22 kDa (Robertson et al., 1977; Brinton et al., 1978; Buchanan, 1978). Pili from *N. gonorrhoeae* and *N. meningitidis* are antigenically and structurally similar (Hermodson et al., 1978; Olafson et al., 1985; Potts and Saunders, 1988). However, meningococcal pili can be divided into two classes: those cross-reacting with the SM1 monoclonal antibody that recognizes a conserved epitope in gonococcal pili (class I), and those not showing this cross-reactivity (class II). The pili demonstrated on a number of commensal *Neisseria* spp. are homologous to the class II pili of *N. meningitidis* (Aho et al., 2000). The neisserial prepilins at short leader sequences and proximal 30 amino acids (Meyer et al., 1984; Potts and Saunders, 1988) show a high degree of homology with pilins of other Gram-negative human pathogens including *P. aeruginosa* (Strom and Lory, 1986), *Vibrio cholerae* (Faast et al., 1989), enterotoxigenic *E. coli* (ETEC) (Giron et al., 1994), and enteropathogenic *E. coli* (EPEC) (Giron et al., 1991), as well as opportunistic pathogens in the genera *Eikenella* (Tønjum et al., 1993) and *Moraxella* (Frøholm and Sletten, 1977; Tønjum et al., 1991). Collectively, this family of surface appendages has been termed type IV pili (Ottow, 1975) or Tfp (Wolfgang et al., 1998b).

These related pilus colonization factors appear to be essential for infectivity and disease. Pili mediate the attachment of *N. gonorrhoeae* to a wide range of different cell types, including tissue culture cells (Swanson, 1973; Heckels, 1989), vaginal epithelial cells (Mardh et al., 1975), fallopian tube epithelium (Ward et al., 1974), and buccal epithelial cells (Punsalang and Sawyer, 1973). Pili also mediate the attachment of *N. meningitidis* to nasopharyngeal cells (Stephens and McGee, 1981). Evidence for the critical roles of gonococcal and meningococcal pili can be found in the invariable recoveries of piliated organisms from primary cultures (Jyssum and Lie, 1965; Kellogg et al., 1986; Swanson et al., 1987) and the capacities of these structures to undergo antigenic variation (Tinsley and Heckels, 1986; Swanson et al., 1987). Pili appear to be multifunctional organelles. In addition to adherence, their expression is associated with other phenotypes that may be relevant to the host-parasite interaction. Pilus expression is correlated with high level (sequence-specific) competence for DNA transformation with frequencies of transformation being reduced 1000-fold in nonpiliated mutants (Sparling, 1966; Frøholm et al., 1973; Seifert et al., 1990; Zhang et al., 1992; Drake and Koomey, 1995; Freitag et al., 1995; Tønjum et al., 1995b; Drake et al., 1997). The consensus DNA uptake sequence recognized (5′-GCCGTCTGAA) is distributed throughout the gonococcal and meningococcal genomes (Goodman and Scocca, 1988).

Pilus expression is also associated with multicellular behavior. Bacterial autoagglutination (independent of that associated with Opa proteins) is a pilus-dependent phenomenon (Swanson et al., 1971). Although flagella and motility in liquid media are absent in *Neisseria* species, a form of bacterial surface translocation termed "twitching motility" is only displayed by piliated organisms (Henrichsen, 1975b; Swanson, 1978; Wolfgang et al., 1998a). In *P. aeruginosa*, twitching motility is proposed to be a consequence of pilus retraction (Bradley, 1980) and mutants that retain piliation but have lost twitching motility have been shown to carry mutations in a gene designated *pilT* (Whitchurch et al., 1991). Likewise, neisserial PilT mutants do not display twitching motility (Wolfgang et al., 1998b), and laser tweezer analysis of gonococci supports the notion that twitching motility is a consequence of pilus retraction (Merz et al., 2000).

Neisserial pilus expression is subject to both phase and antigenic variation. Gonococcal pilus variation results from homologous recombination between a single complete pilin gene or expression locus (*pilE*) and multiple partial pilin gene copies or silent alleles (*pilS*) (Haas and Meyer, 1986; Swanson et al., 1986; Koomey et al., 1987), and an analogous mechanism is thought to operate in meningococcal pilus variation (Aho and Cannon, 1988; Perry et al., 1988; Blake et al., 1989). Antigenic variation results from the unidirectional transfer of genetic information from the variant-encoding *pilS* genes to the active expression locus. The pilin amino acid changes reflect the nucleotide changes in *pilE*, which result from nonreciprocal RecA-dependent recombination events with numerous silent loci, *pilS*. The most convincing results show that productive pilin gene rearrangements in *N. gonorrhoeae* mainly arise by gene conversion and not by transformation (Zhang et al., 1992). The frequency of phase variation (on–off) from p^+ to p^- (10^{-3}) is much higher than reversion from p^- to p^+ (10^{-6}) (Swanson et al., 1987; Swanson and Koomey, 1989). The expression of pili is therefore often lost on repeated nonselective subculture. The high-frequency changes in the primary amino acid sequence of the pilin subunit alter pilus expression and aid in adjusting attachment abilities and the avoidance of the host immune response. The frequently occurring antigenic variation may result in phase variation, and loss of fimbriation may occur. Cultivating *N. gonorrhoeae*, *N. meningitidis*, and *N. elongata* in special growth conditions such as pellicle formation and selective subculture based on the observation of colony morphology will maintain pilus expression

(McGee et al., 1979; Swanson et al., 1987; Swanson and Koomey, 1989).

The fimbriae are produced and exported to the surface by the action of a multi-component machinery homologous to type II secretion systems (Tønjum and Koomey, 1997). A number of genes encoding products involved in neisserial pilus biogenesis have been identified (Tønjum and Koomey, 1997). By chromosomal mapping (Dempsey et al., 1995), it has become clear that these genes are distributed throughout neisserial genomes. The machinery dedicated to pilus biogenesis comprises, in addition to the pilin subunit itself, cytoplasmic and cytoplasmic membrane components as well as periplasmic and outer membrane components. A locus carrying the genes *pilF*, *pilD*, and *pilG* related to pilus biogenesis encodes cytoplasmic and cytoplasmic membrane components. Mutants failing to express functional PilD, PilF, or PilG were nonpiliated and showed over a 1000-fold decrease in frequencies of competence for natural transformation (Freitag et al., 1995; Tønjum et al., 1995b). Based on homology to *P. aeruginosa* PilD, the neisserial PilD is thought to function as a prepilin peptidase and methylase of the first amino acid in the mature protein (Strom et al., 1991; Freitag et al., 1995; Tønjum et al., 1995b). PilD is the only component engaged in pilus biogenesis that to date has a defined function (Nunn and Lory, 1991). The role of PilF is still obscure, but its identity with other related molecules (Pugsley, 1993; Sandkvist et al., 1995) and evidence from studies of its homologues in *P. aeruginosa* suggests that it may function as an ATPase or kinase (Turner et al., 1993). The deduced amino acid sequence of PilG reveals the absence of a signal sequence and three membrane spanning domains, which indicates it is a cytoplasmic membrane protein. The exact functional role of PilG remains to be established, but it has been proposed that the homologous PilC in *P. aeruginosa* may be needed for optimal localization or stabilization of PilD (Koga et al., 1993; Tønjum et al., 1995b). Gonococcal PilT, a protein homologous to PilF and belonging to a large family of molecules sharing a highly conserved nucleotide binding domain motif, has been shown to be dispensable for pilus biogenesis but essential for twitching motility and competence for genetic transformation (Wolfgang et al., 1998b).

Outer membrane components engaged in pilus biogenesis characterized to date are PilQ, PilP, and PilC. The PilQ protein, which is essential for type IV pilus assembly, is a member of the secretin family (see above) (Russel, 1998). The common functions served by the secretin homologues appear to involve the translocation of large, macromolecular complexes across the outer membrane. PilQ of the pathogenic neisseriae forms a multimer composed of 10–12 subunits that is resistant to SDS and heating (Newhall et al., 1980a), and the conserved C-terminal residues are necessary for expression of the multimerized form and function in pilus extrusion (Drake and Koomey, 1995; Tønjum et al., 1998). The meningococcal PilQ protein is constitutively expressed in abundant amounts. Analysis of the quaternary structure of meningococcal PilQ by transmission electron microscopy and self-rotation analysis suggest that PilQ is organized as a ring of 12 identical subunits (Collins et al., 2001, 2003). The *pilP* gene, immediately upstream of *pilQ*, encodes a lipoprotein that is predicted to be localized to the outer membrane, and $PilP^-$ mutants are nonpiliated (Drake et al., 1997). It seems that PilP is required for stable expression of the multimerized form of PilQ. Gonococcal $PilP^-$ as well as $PilQ^-$ mutants release PilC (Drake et al., 1997). PilQ and PilC may interact during the terminal stages of pilus biogenesis (Drake et al., 1997; Wolfgang et al., 2000).

The presence or absence of fimbriae is of no taxonomic value in the genus, but is indirectly important because of the use of the associated property competence for natural transformation in qualitative and semiquantitative assays (see below) (Bøvre and Hagen, 1981; Tønjum et al., 1995b).

Secreted proteins *N. meningitidis* and *N. gonorrhoeae* produce IgA1-protease, which degrades and inactivates immunoglobulin of the IgA1 subtype found in mucosal secretions and serum (Koomey and Falkow, 1987).

Peptidoglycan The peptidoglycan composition of those species of *Neisseria* that have been analyzed is typical of other Gram-negative bacteria. The peptidoglycans of *N. gonorrhoeae* and *N. perflava* belong to chemotype 1 and are composed of muramic acid, glucosamine, alanine, diaminopimelic acid, and glutamic acid in an approximate molar ratio of 1:1:2:1:1, respectively (Martin et al., 1973; Hebeler and Young, 1976). The percentage of peptide cross-linking in gonococcal peptidoglycan was found to be approximately 41%, which is relatively high for a Gram-negative bacterium (Rosenthal et al., 1980). *N. gonorrhoeae* and *N. flava* peptidoglycans are extensively O-acetylated (Martin et al., 1973; Blundell and Perkins, 1981). O-acetylated peptidoglycan is more resistant to lysozyme and other human peptidoglycan hydrolases (Rosenthal et al., 1980; Blundell and Perkins, 1981), and this resistance to hydrolases might enable gonococci to persist *in vivo* or potentiate the biological effects in pathogenesis of peptidoglycan *in vivo*.

Polysaccharides Several *Neisseria* sp. are known to produce polysaccharide capsules and exopolysaccharides. The acidic and hydrophilic capsular polysaccharides provide the surface charge and humid environment that are critical for survival of the bacteria in aerosol droplets. Serogrouping of *N. meningitidis* is based on antigenic differences in capsular polysaccharides, and presently recognized serogroups include A, B, C, H, I, K, L, X, Y, Z, W135, and 29E (Frasch, 1989). The capsular polysaccharide may be a homopolymer or a heteropolymer composed of a monosaccharide-glycerol, disaccharide, or trisaccharide repeating unit. 1,2-Diacylglycerols have been identified as components of meningococcal capsular polysaccharides (Gotschlich et al., 1981). It has been postulated that the presence of these hydrophobic moieties may be responsible for the association of the capsular polysaccharide with the outer membrane of the meningococcus, giving rise to the structure recognized as a capsule. The disease-associated serogroup A capsule is composed of mannoseamine-phosphate, while the disease-associated serogroups B, C, Y, and W-135 all have sialic acid in their capsular polysaccharide. Sialic acid-containing polysaccharides confer resistance to host complement-mediated attack mechanisms (Jarvis and Vedros, 1987). *N. meningitidis* serogroup B strains are a predominant cause of meningococcal disease in the developed world. The serogroup B polysaccharide is a homopolymer of alpha-2,8 polyneuraminic acid and is poorly immunogenic, probably because of immunotolerance resulting from cross-reactivity between this polysaccharide and polysialic acid expressed on host neural cell adhesion molecules (NCAMs) (Finne et al., 1983). *N. meningitidis* serogroup B capsular polysaccharide is also chemically and immunologically identical to capsular polysaccharide in *E. coli* K-1 and surface polysaccharide found in a large proportion of *Moraxella nonliquefaciens* strains (Bøvre et al., 1983; Krambovitis et al., 1987).

The genes encoding all the enzymes necessary for capsular polysaccharide biosynthesis in *N. meningitidis* serogroup B are located on a 5-kb DNA fragment within the chromosomal capsule (*cps*) gene cluster (Frosch et al., 1989). It contains genes encoding enzymes required for capsular polysaccharide biosynthesis in the cytoplasm, for phospholipid substitution, and for the production of proteins whose function is the translocation of polysaccharide across the inner and outer bacterial cell membranes. The full-size capsular polysaccharide with a phospholipid anchor is synthesized intracellularly, and the lipid modification is a strong requirement for translocation of the polysaccharide to the cell surface (Frosch and Müller, 1993). Regulation of capsule expression is shown to be performed through slipped strand mispairing of a polyC stretch in the *siaD* gene (Hammerschmidt et al., 1996).

It seems evident that the capsule of *N. meningitidis* functions as a virulence factor, since the virulence of this organism depends, in part, on the antiphagocytic properties of its capsule (Masson and Holbein, 1983). In general, meningococcal capsular polysaccharides are immunogenic in humans; antibodies directed against the capsule are bactericidal. However, serogroup B capsular polysaccharide is poorly immunogenic in humans, possibly because of its similarity to sialic acid moieties in human tissues. Furthermore, the serogroup A and C capsules are poorly immunogenic in infants and young children (Lieberman, 1996). *N. gonorrhoeae* does not have a capsule that can be confirmed by electron microscopy, using India ink (Melly et al., 1979) or wheat germ agglutinin (Frasch, 1980). However, *N. gonorrhoeae* produces a high-molecular-weight extracellular polyphosphate (Noegel and Gotschlich, 1983), and a similar polyphosphate is also produced by *N. meningitidis*, *N. lactamica*, *N. sicca*, and *N. flava* (Noegel and Gotschlich, 1983). It has been postulated that the extracellular polyphosphate may serve the function of a capsule in gonococci.

N. perflava possesses a novel system for the synthesis of a glycogen-like polysaccharide. The mechanism involves the transfer of the glucosyl moiety of sucrose to a 1,4-α-D-glucan by the enzyme amylosucrase (Okada and Hehre, 1974). A similar D-glucan is produced by *N. polysaccharea* (Riou et al., 1986), *N. canis*, *N. cinerea*, *N. cuniculi*, *N. denitrificans*, *N. sicca*, and *N. subflava* (MacKenzie et al., 1977, 1978a, b, c) when grown on a medium containing sucrose. A galactosamine polymer has been isolated from the cell walls of *N. sicca* (Adams and Chaudhari, 1972; Wagner et al., 1973). The function of this polymer is presently unknown.

Some bacterial species produce a starch-like polysaccharide from sucrose that stains dark blue-purple to black with iodine. Among the *Neisseria* spp., *N. polysaccharea*, *N. subflava* biovar perflava, *N. mucosa*, *N. sicca*, and *N. flavescens* produce polysaccharide from sucrose. This test is invaluable for differentiating between strains of *N. meningitidis* (polysaccharide-negative) and *N. polysaccharea* (polysaccharide-positive); as many as 25% of organisms identified as nontypable *N. meningitidis* strains were found to be *N. polysaccharea* when tested for polysaccharide production.

Colony morphology and cultural characteristics Colony morphology varies with the species and ranges from small smooth, transparent, butyrous colonies to wrinkled, dry, adherent colonies (Catlin, 1978; Swanson and Koomey, 1989). Colony morphology has been particularly useful in characterization of *N. gonorrhoeae* and *N. elongata*, since agglutinating and aggregating bacterial properties display various forms of colony consistency and edge, as well as spreading and/or corroding growth (Kellogg et al., 1963; Reyn et al., 1971; Swanson and Koomey, 1989). The autoagglutination of bacterial cells into multicellular aggregates induces clumping in broth and variations in colony morphology that can be observed in oblique light in a dissecting stereoloupe/microscope (Juni and Heym, 1977). Important components affecting autoagglutination are pilus expression, opacity proteins, and LPS. Colonies of cells expressing pili and opacity proteins are wrinkled and well defined with a clear edge, while colonies from non-piliated cells have a less defined edge and are smoother and more glistening (Swanson and Koomey, 1989; Koomey et al., 1991). Opaque and transparent variants of the colony types have been described (Swanson, 1978). The autoagglutinating colonies are typically isolated from the urethra of infected males and the cervix of females (see review by James and Swanson, 1978; Swanson et al., 1987). The autoagglutination properties can be camouflaged in strains expressing a capsule.

Colonies of *N. meningitidis* are larger than those of gonococci (≥1.0 mm in diameter) and are smooth and moist with a glistening surface and entire edge (Morello and Bonhoff, 1980). The colony morphology of meningococci is difficult to distinguish, probably due to the capsule giving rise to mucoid colonies. Colonies of *N. lactamica* closely resemble those of meningococci, but may be less moist and smaller (Morello and Bonhoff, 1980). Some strains of *N. lactamica* produce a yellow pigment (Hollis et al., 1969). A yellowish green pigment is also produced by *N. subflava*, *N. flavescens*, and *N. sicca*. *N. elongata* may also have a slight yellow tinge due to pigment production. Pigmentation of neisseriae varies with growth conditions, and quantitative analysis of the extracted pigment indicates that it is of little taxonomic value (Berger, 1961a; Hoke and Vedros, 1982c).

Nutrition and growth conditions *Neisseria* species other than *N. meningitidis* and *N. gonorrhoeae* will grow on plain nutrient agar at 35–37°C. *N. meningitidis* requires mineral salts, lactate, a few amino acids, and glutamic acid as a carbon source (Reyn, 1974; Catlin, 1978). Cystine is required by approximately 10% of the strains (Catlin, 1978), and some strains can be adapted to grow with ammonium salts as the sole nitrogen source (Jyssum, 1959). *N. gonorrhoeae* is more fastidious and requires glutamine for primary isolation of approximately 20% of strains and co-carboxylase for 1% of strains (Reyn, 1974). Several defined media have been developed for growth of *N. gonorrhoeae* (Catlin, 1973; LaScolea and Young, 1974; Wong et al., 1980b). Iron is an essential growth factor for *N. gonorrhoeae* (Kellogg et al., 1963) and its availability in culture media influences the virulence of both meningococci and gonococci (Payne and Finkelstein, 1975). The optimal temperature for growth of *Neisseria* spp. is 35–37°C with a range of 22–40°C, except for *N. meningitidis* and *N. gonorrhoeae*, which grow poorly or not at all below 30°C. A high relative humidity (50%) is beneficial to the growth of all species, and CO_2 (3–10%) is required for the growth of gonococci and enhances the growth of meningococci on solid media. After many passages, laboratory strains become less fastidious in their growth requirements than fresh isolates. See Catlin (1977) for a detailed review of gonococcal nutritional requirements.

N. meningitidis and *N. gonorrhoeae* do not survive long after the cessation of growth, and decreases in viability appear to be related to cellular lysis (autolysis) (Morse and Bartenstein, 1974). Several peptidoglycan-degrading enzymes have been described in *N. gonorrhoeae*, including D-alanine carboxypeptidase (or endopeptidase) (Davis and Salton, 1975; Chapman and Perkins, 1983),

N-acetylmuramyl-L-alanine amidase (Hebeler and Young, 1976), transglycosylase (Rosenthal, 1979; Sinha and Rosenthal, 1980), exo-*N*-acetyl-glucosaminidase (Chapman and Perkins, 1983), and endo-*N*-acetylglucosaminidase (Gubish et al., 1982; Chapman and Perkins, 1983). It is likely that some of these enzymes normally have a biosynthetic role in cell growth, but that under nongrowth conditions (i.e., no cell wall biosynthesis) enzyme activity results in peptidoglycan hydrolysis.

Metabolism and biochemistry *Neisseria* species produce oxidase and catalase, carbonic anhydrase, and nitrite reductase, but do not produce thymidine phosphorylase, nucleoside deoxyribosyl transferase, or thymidine kinase (Table BXII.β.76).

Carbohydrate metabolism *Neisseria* species do not catabolize many carbohydrates and some species (*N. cinerea*, *N. flavescens*, and *N. elongata*) are asaccharolytic. Glucose is the only carbohydrate that can be used as an energy source by *N. gonorrhoeae* and is apparently the only monosaccharide that is used by the other saccharolytic species.

Neisseria species produce acid from carbohydrates by oxidation, not fermentation. Because these species are oxidative and produce less acid from carbohydrates such as glucose, maltose, fructose, and sucrose than do fermentative organisms, and because they also produce ammonia from peptones (which may neutralize acid produced from carbohydrates), acid production must be determined in a medium with a low protein/carbohydrate ratio and a sensitive indicator such as phenol red (Knapp, 1988).

Phosphoglucose isomerase (Pgi) in *E. coli* is a dimeric enzyme that catalyzes the reversible isomerization of glucose-6-phosphate and fructose-6-phosphate in glycolysis (Froman et al., 1989; Fraenkel, 1992). In *E. coli* there is a single *pgi* gene, and Pgi appears to be dispensable because strains lacking it are also able to grow on glucose minimal media, apparently utilizing glucose primarily by the pentose phosphate shunt (Fraenkel, 1992). Expression analysis in starch gel electrophoresis and isoenzyme analysis revealed the presence of two distinct isoforms of Pgi in *N. meningitidis* and *N. gonorrhoeae*. Indeed, Southern blot analysis of *N. meningitidis* and *N. gonorrhoeae* chromosomal DNAs and the complete genome sequences confirmed that there are two complete *pgi* genes on different parts of the chromosomes in pathogenic *Neisseria* (Tønjum et al., 1994). This gene duplication may be significant since Pgi expression in other bacteria has been implicated in pathogenicity (Tung and Kuo, 1999).

Tricarboxylic acid cycle *Neisseria* species have a functional tricarboxylic acid cycle (Holten, 1975). All tricarboxylic acid cycle enzymes, except a soluble pyridine nucleotide-dependent malate dehydrogenase, have been detected in *N. gonorrhoeae* and *N. meningitidis* (Jyssum, 1960). Instead of the pyridine nucleotide-dependent malate dehydrogenase, *N. gonorrhoeae* and *N. meningitidis* possess a flavine adenine dinucleotide (FAD)-dependent malate oxidase (Holten, 1976b). A similar enzyme is present in the other *Neisseria* spp. (Holten, 1976b) in spite of the observation that these species also have a pyridine nucleotide-dependent malate dehydrogenase (Holten and Jyssum, 1974).

N. gonorrhoeae lacks a glyoxylate bypass (Holten, 1976b). With the exception of *N. elongata*, *Neisseria* spp. do not oxidize acetate in the absence of other substrates, providing additional evidence for the absence of a glyoxylate bypass (Holten, 1976b). Indirect evidence of acetate oxidation in the absence of other substrates suggests that *N. elongata* may have a glyoxylate bypass (Holten, 1976b, 1977).

Amino acid metabolism The biosynthesis of amino acids by *Neisseria* spp. appears to occur by pathways similar to those in other microorganisms. *Neisseria* species vary widely with respect to their amino acid requirements. In general, the nonpathogenic *Neisseria* species are able to grow in a defined medium containing one to five amino acids (McDonald and Johnson, 1975), while the amino acid requirements of the pathogenic species are more complex (Catlin, 1973). *N. gonorrhoeae* exhibits an absolute requirement for cysteine (or cystine) (Catlin, 1973). Strains of *N. gonorrhoeae* often require one or more amino acids in addition to cysteine for growth in a chemically defined medium (Janik et al., 1976). Amino acid requirements have been used to differentiate among isolates (auxotyping) for epidemiologic purposes (Carifo and Catlin, 1973) or for identification by genetic transformation by returning auxotrophic strains to phototrophy (Juni and Heym, 1980). Auxotyping data have also demonstrated that the requirement for certain amino acid biosynthesis in *N. gonorrhoeae* is associated with spontaneous mutations in the genes encoding enzymes involved in the biosynthesis of amino acids (Lerner et al., 1980; Shinners and Catlin, 1982).

Amino acids can be used as energy and carbon sources by many *Neisseria* spp. via their oxidation by the tricarboxylic acid cycle (Holten, 1976a). Glutamate, proline, and to a lesser extent aspartate are the preferred amino acids (McDonald and Johnson, 1975; Pillon et al., 1982). Glutamate dehydrogenase is a key enzyme in the catabolism of glutamate and proline, and all *Neisseria* species contain two forms of glutamate dehydrogenase (Holten, 1973; Holten and Jyssum, 1973). The NAD-dependent enzyme serves a catabolic function, and the NADP-dependent enzyme serves an anabolic function, depending on the needs of the cell (Holten, 1973).

Electron transport *Neisseria* spp. characteristically have high cytochrome *c* oxidase activity (Jurtshuk and Milligan, 1974). The oxidation of tetramethyl-*p*-phenylendiamine by this cytochrome provides the basis for the oxidase test used in the identification of members of the genus *Neisseria*.

Proteolytic enzymes The degradation of proteins or peptides requires specific enzymes. *Neisseria* species possess aminopeptidases that are capable of hydrolyzing L-amino-acid-β-naphthylamide derivatives of various amino acids (D'Amato et al., 1978). *N. meningitidis* can be distinguished from *N. gonorrhoeae* by the presence of *N*-γ-glutamyl aminopeptidase (D'Amato et al., 1978). However, some of the nonpathogenic species (*N. mucosa*, *N. sicca*, and all biovars of *N. subflava*) also produce *N*-γ-glutamyl aminopeptidase (Riou et al., 1982).

N. gonorrhoeae and *N. meningitidis* express a highly specific IgA protease that cleaves human IgA of the IgA1 subclass (Plaut et al., 1975; Koomey and Falkow, 1984). This enzyme is an important virulence factor in that its production promotes bacterial immune evasion. Each isolate of *N. gonorrhoeae* and *N. meningitidis* produces only one of two distinct types of IgA protease (Mulks et al., 1980). The two types of IgA protease can be distinguished by their specificity for two different peptide bonds in the hinge region of human IgA1 (Mulks and Knapp, 1987). The type I protease cleaves the proline-serine bond at position 237/238 in the IgA1 hinge region (Mulks et al., 1980), while the type 2 protease cleaves the proline-threonine peptide bond at position 235–236 (Plaut et al., 1975). The IgA protease is an extracellular enzyme that is secreted throughout exponential growth (Pohlner et al., 1987). The gene encoding IgA protease in *N. gonorrhoeae* was cloned, inactivated, and reintroduced into *N. gonorrhoeae* to

obtain an IgA protease negative mutant (Koomey et al., 1982). Gonococcal IgA protease has also been suggested to play a role in adherence and invasion processes (Lorenzen et al., 1999).

Periplasmic proteins The gonococcal periplasm is very similar to that of *E. coli* (Judd and Porcella, 1993). Several proteinases that are disulfide oxidoreductases, termed DsbA, are located in the periplasmic space (Jose et al., 1996). These autotransporters are subjected to secretion across the inner membrane in a Sec-dependent manner followed by self-directed passage and release through the outer membrane (Maurer et al., 1997). The periplasmic meningococcal superoxide dismutase C catalyzes the conversion of the superoxide radical anion to hydrogen peroxide, preventing the production of toxic hydroxyl free radicals (Wilks et al., 1998).

Iron The free iron concentration in the human and other eucaryotic hosts is extremely low and cannot support sustained microbial growth. Therefore, *Neisseria* species rely on mechanisms for obtaining growth-essential iron from their host. The pathogenic neisseriae are capable of satisfying their iron requirements with human iron-binding proteins such as transferrin and lactoferrin (see iron-regulated outer membrane proteins).

Oxygen requirements *Neisseria* species are generally considered to consist of aerobic and facultatively anaerobic organisms. *N. gonorrhoeae*, however, has been isolated from body sites where anaerobes usually are found, suggesting that *N. gonorrhoeae* can grow under reduced oxygen tension. *N. gonorrhoeae* will also grow *in vitro* under oxygen tension suitable for anaerobes (Kellogg et al., 1983). Nitrite is toxic to *N. gonorrhoeae*, so that the reduction of nitrite is only observed at low concentrations (Knapp and Clark, 1984). The addition of subtoxic concentrations of nitrite to the medium enables gonococci to grow under anaerobic conditions to a level comparable to that observed aerobically (Knapp and Clark, 1984). Gonococcal nitrate reductase is a constitutive enzyme that is synthesized under aerobic conditions in the absence of nitrite (Knapp and Clark, 1984). Since nitrite is present in biological fluids, the ability to grow aerobically or anaerobically by anaerobic nitrite respiration may be one of the factors responsible for the diversity of body sites from which gonococci can be isolated. Nitrite is reduced by all *Neisseria* spp. isolated from humans, with the possible exception of some serogroups of *N. meningitidis*, and some strains of *N. lactamica*, *N. cinerea*, and *N. polysaccharea* (Morse and Knapp, 1987).

N. gonorrhoeae grown *in vitro* under anaerobic conditions expresses several new outer membrane proteins (Clark et al., 1987). The presence of antibodies in serum samples from patients with gonorrhea that react with one or more of the anaerobically induced proteins suggests that gonococci grow anaerobically *in vivo* (Clark et al., 1988).

Carbon dioxide requirements *N. gonorrhoeae* and *N. meningitidis* both require an increased CO_2 tension for isolation from clinical specimens (Tuttle and Scherp, 1952; Griffin and Racker, 1956). Gaseous CO_2 can be replaced by the addition of bicarbonate to the medium (Talley and Baugh, 1975). Little is known about the CO_2 requirements of the nonpathogenic *Neisseria* spp. The enzymes known to be involved in the assimilation of CO_2 by *Neisseria* spp. are carbonic anhydrase, which appears to be located in the cytoplasmic membrane (MacLeod and DeVoe, 1981), and phosphenolpyruvate carboxylase (Jyssum and Jyssum, 1962; Holten and Jyssum, 1974).

Genetics

Transformation Transformation is the binding, uptake, and chromosomal integration of naked DNA. Many neisserial species are constitutively competent throughout their entire life cycle (Table BXII.β.77). DNA uptake in *Neisseria* spp. is dependent on the presence of a 10-basepair specific DNA uptake sequence (DUS, 5′-GCCGTCTGAA) (Goodman and Scocca, 1988). Genome sequencing shows that the pathogenic *Neisseria* contains approximately 1900 copies of the DNA uptake sequence (Parkhill et al., 2000; Tettelin et al., 2000) and that this sequence is found very infrequently in the genomes of other organisms. Some reports have claimed that most DUSs are located as inverted repeats downstream of open reading frames throughout the genome, serving as putative transcriptional regulators (Smith et al., 1999a). However, it has recently been shown that many of the genes engaged in genome maintenance harbor DUSs within their open reading frames. Genome-wide analysis of DUS representation in the coding sequences of *N. meningitidis* has indeed demonstrated that the group of genes engaged in DNA repair, recombination, restriction–modification, and replication exhibited the highest rate of DUSs among all designated gene groups (Davidsen and Tønjum, personal communication). A genome-wide overrepresentation of the *H. influenzae*-specific DUS was also found in the genome maintenance genes of this bacterial species. The biased distribution of the respective DUS within sequences encoding genome maintenance genes of the phylogenetically divergent *N. meningitidis* and *H. influenzae* is evidence for fundamental evolutionary prioritization and conservation. However, the complete role of DUS in this context is yet to be unraveled.

The expression of natural competence may vary since it is associated with type IV pilus expression in most species (Bøvre and Frøholm, 1971, 1972; Swanson et al., 1971; Frøholm et al., 1973). Therefore, it is often critical to perform selective culture passages to maintain pilus expression; nonselective subcultures should be minimized to avoid loss of pilus expression and thus a loss of competence. The transformation yield, however, is higher in early phases of growth, before autolysis of bacteria occurs in the culture and causes inhibition of transformation by

exogenous DNA due to saturation of DNA binding sites with residual autologous DNA.

Many reports strongly suggest that transformation is the genetic mechanism that contributes the most to the large amount of horizontal gene transfer taking place in the *Neisseria* (Feil et al., 1996; Koomey, 1998). Transformation takes place most often between closely related species, but also between more distantly related ones, contributing to species diversity and fitness for survival. Furthermore, transformation represents an invaluable tool in the study of specific determinants by virtue of the ease with which strains carrying defined mutations in chromosomal genes can be constructed.

Competence for genetic transformation provides a unique tool for measuring genetic distances for classification and identification purposes, since the relative efficiency of transformation depends on the degree of DNA homology as well as on DNA uptake sequences (Albritton et al., 1986). The widespread occurrence of natural competence for genetic transformation among *Neisseria* spp. has enabled the use of this method for critical classification schemes and strain identification (see also chapter on the *Moraxellaceae*) (Bøvre, 1965, 1980; Bøvre et al., 1977). In the 1950s, Henriksen made observations causing subdivision of bacterial groups into species of *Neisseria*, *Moraxella*, and other genera (Henriksen, 1952). These early studies demonstrated that it was possible to show relatedness of bacterial strains because of the ability of their DNAs to undergo genetic recombination, provided that at least one of these strains was competent for genetic transformation (Henriksen, 1952; Leidy et al., 1956; Catlin and Cunningham, 1961; Bøvre, 1964). This procedure involved quantitative transformation of streptomycin-resistance markers and has later been applied in many neisserial species (Table BXII.β.77). Juni and co-workers developed another useful and easy-to-perform transformation assay for distinction of species (Juni and Janik, 1969; Juni, 1972, 1990). This technique involved transformation of auxotrophic bacterial strains to prototrophy, using crude lysates of bacterial cells as transforming DNA. The use of lysates as transforming DNA greatly facilitates the practical application of this method. To establish nutritional transformation assays it is necessary to isolate nutritionally defective mutants of the competent strain, and also to design a minimal or defined medium on which transformants of the nutritionally deficient mutants can grow and thus demonstrate that transformation has taken place. For example, *N. gonorrhoeae* strains grow on a simple sodium lactate–mineral medium with ammonium chloride as the nitrogen source, no growth factors being required (Juni, 1974). Metabolic markers in transformation can give an increased opportunity for discrimination between closely related strains. However, this approach may in some cases be of reduced utility due to a relatively higher frequency of divergence occurring in these genes.

Conjugation Several neisserial conjugative plasmids have been described (see Plasmids and Antibiotic susceptibility).

Recombination The plasticity of the neisserial genomes for large and small genome rearrangements demands highly facilitated DNA recombination and repair systems. High-frequency recombination events may be RecA-dependent, such as gene conversion and homologous recombination, or RecA-independent, such as replicative DNA slippage. Indeed, a number of recombination genes have been identified in *Neisseria* (Carrick et al., 1998; Salvatore et al., 2002; Skaar et al., 2002). However, an inducible DNA repair and recombination response (SOS response) has not been identified in *Neisseria* (Black et al., 1998).

Consequences of natural transformation, recombination, and spontaneous mutation on phylogenetic sequence analyses of* Neisseria *species The pattern of nucleotide sequence variation within genes shows that species within the genus *Neisseria* can be assigned to five phylogenetic groups, but that sequence divergence within *N. meningitidis* and closely related species is inconsistent with a bifurcating tree-like phylogeny and is better represented by an interconnected network (Smith et al., 1999a). New data indicate that although the human commensal *Neisseria* species can be separated into discrete groups of related species, the relationships both within and among these groups, including those reconstructed using 16S rDNA sequences, have been distorted by interspecies recombination events (Smith et al., 1999a). The sequence data indicate that there has been a history of interspecies recombination within selected genes of the human *Neisseria* species, which has obscured the phylogenetic relationships between the species (Feil et al., 1996). The neisseriae are therefore polyphyletic species, most probably due to the frequent DNA exchange and recombination events, both intragenomic and subsequent to transformation, taking place in these species. One consequence of the high spontaneous mutation and recombination rates detected and horizontal gene transfer is that the bifurcating phylogeny that can be inferred for other genetic bacterial entities are not valid for genus *Neisseria*, except for very closely related strains reflecting short-term genetic distance and exchange.

Among the neisseriae, the limitations of 16S rDNA based phylogeny are demonstrated due to 1) the high level of horizontal gene transfer, 2) high frequency and variability of mutation rates, as well as 3) high frequencies of gene duplication (and extinction) occurring in bacteria with high numbers of repetitive genetic elements of various kinds, such as those demonstrated by the genome sequences of the pathogenic *Neisseria* (Parkhill et al., 2000; Tettelin et al., 2000). Any phylogeny created depends on the gene chosen for analysis, and no deep evolutionary tree can be determined for the neisseriae due to the continuously high spontaneous mutation rate and recombination including incorporation of DNA from other species. If an analysis is performed that does not force the data into a tree-like phylogeny (split decomposition), then a network phylogeny can be obtained with all genes examined to date, although the precise network will differ from gene to gene.

Genomics The complete genome sequences of meningococcal isolates of both *N. meningitidis* serogroup A Z2491 and *N. meningitidis* serogroup B strain MC58 have been published, and the genomes are 2.2 and 2.3 Mbp in size, respectively (Parkhill et al., 2000; Tettelin et al., 2000). These genomes have a little over 2000 open reading frames, with 83% of each genome being coding sequence, which is the lowest percentage coding sequence among the intact bacteria so far sequenced. The mol% G + C is variable and some low mol% G + C regions are associated with open reading frames predicted to code for surface structures. Several partial genes and pseudogenes have been identified that represent the C-terminal portion of upstream genes; these may allow variation by the use of alternate C-termini. Approximately 1900 copies of the *Neisseria* uptake sequence are present throughout the genome. A comparison of the two genome sequences reveal 91.2% similarity with one inversion of

955 kb being the major difference. However, two inversion events have occurred, both of which center around the origin of replication. Repeat arrays are present near the points of inversion. A related bacteriophage has been identified in each genome, although in different positions. Three major islands of horizontal DNA transfer have been identified in the genomes; most of these contain genes encoding proteins involved in pathogenicity. However, the most notable feature of these genomes is the presence of many hundreds of repetitive elements, ranging from short repeats, positioned either singly or in large multiple arrays, to insertion sequences and gene duplications of 1 kb or more. Many of these repeats appear to be involved in genome fluidity and antigenic variation. *N. meningitidis* contains more genes that undergo phase variation than any pathogen studied to date, a mechanism that controls their expression profiles and contributes to the evasion of the host immune system.

The genome sequence of *N. meningitidis* serogroup C strain FAM18 and *N. gonorrhoeae* strain F1090 are almost completed. The genome of *N. gonorrhoeae* is approximately 2.1 Mbp with a prediction of around 2000 open reading frames and 2000 uptake sequences. Approximately 30% of the gonococcal genome is repetitive DNA with 6000 repeats less than 2 kb in size. Comparisons show that it has approximately 95% conservation with the *N. meningitidis* isolate Z2491 with one large rearrangement. Of the two isolates sequenced to date, the serogroup A Z2491 isolate was more similar in gene order to the sequenced gonococcal isolate than it was to the MC58 variant sequenced.

Plasmids and transposons Plasmids in *Neisseria* spp. have attracted considerable attention because of their potential role in virulence and association with antibiotic resistance. Beta-lactamase plasmids have been identified in *N. gonorrhoeae* and *N. meningitidis* and have been associated with resistance to penicillin and other beta-lactam antibiotics (Roberts, 1989). Several beta-lactamase-conferring plasmids have been described; these nonconjugative plasmids range in size from 2.9 to 4.4 mDa and share considerable homology with each other (Dillon and Young, 1989; Pagotto et al., 2000; Pagotto and Dillon, 2001).

Two types of larger nonconjugative plasmids have been described in *Neisseria* spp. The 24.5-mDa plasmid carries no detectable markers for antibiotic resistance. However, it efficiently mobilizes itself and the beta-lactamase plasmids between strains of gonococci. A 25.2-mDa conjugative plasmid has been described in isolates of *N. gonorrhoeae* and *N. meningitidis* (Morse et al., 1986; Knapp et al., 1988). This plasmid carries tetracycline resistance and was formed by the transposition of the TetM determinant onto the 24.5 conjugative plasmid. The 25.2-mDa plasmid will also mobilize beta-lactamase plasmids and has an extended host range (Roberts and Knapp, 1988a, b). A group of plasmids that are genetically related to the enteric plasmid RSF1010 and range in size from 4.9 to 9.4 mDa has been described in *N. meningitidis*, *N. mucosa*, *N. subflava*, and *N. sicca* (Pintado et al., 1985; Rotger et al., 1986; Facinelli and Varaldo, 1987). Some of these plasmids confer resistance to sulfonamide alone, whereas others specify resistance to sulfonamide, streptomycin, and penicillin (Rådstrøm et al., 1992). Many *Neisseria* spp. contain cryptic plasmids, i.e., plasmids with no measurable phenotype. The 2.6-mDa plasmid from *N. gonorrhoeae* is present in auxotypes of *N. gonorrhoeae*, except those strains that require proline, citrulline, and uracil (Dillon and Pauze, 1981). Some strains of *N. meningitidis*, *N. lactamica*, *N. mucosa*, and *N. cinerea* carry plasmids that are homologous to the gonococcal 2.6-mDa plasmids (Ison et al., 1986) and that are not homologous with this plasmid (Aalen and Gundersen, 1985; Prere et al., 1985).

Conjugal transfer of genetically modified plasmids to appropriate gonococcal recipients has been most useful for research purposes (Eisenstein et al., 1977; Kupsch et al., 1996).

Phages A nontransducing bacteriophage has been isolated for *N. subflava* biovar perflava (Stone et al., 1956; Phelps, 1967). Evidence for the existence of a prophage can be found in the analysis of the pathogenicity island of the *N. meningitidis* serogroup A strain Z2491 (Klee et al., 2000).

Bacteriocins *N. meningitidis* and *N. gonorrhoeae* may release bacteriocins during growth (Kingsbury, 1966; Flynn and McEntegart, 1972; Senff et al., 1976; Allunans and Bøvre, 1996; Allunans et al., 1998). On average, 0.8% of gonococcal strains were reported bacteriocin producers (Lawton et al., 1976). In systemic meningococcal strains and isolates from healthy carriers of Norwegian origin, the overall reported frequency varied from 1.5% to 2.8% (Andersen et al., 1987; Allunans and Bøvre, 1996). While a high frequency of bacteriocin producers (13.5%, systemic strains) coincided with the peak incidence of the ongoing epidemic in Norway in 1975, the involvement of bacteriocins in meningococcal epidemiology and disease remains unclear.

Habitats The principal habitats of those *Neisseria* spp. isolated from humans are the mucous membrane surfaces. Similarly, for domestic and experimental animals the mucosal surfaces of the oropharynx are the principal habitats. Only *N. meningitidis* and *N. gonorrhoeae* are considered to be primary pathogens of humans. Other *Neisseria* species isolated from humans have been reported to be responsible for disease, e.g., *N. mucosa* (Berger et al., 1974), *N. flavescens* (Branham, 1930), and *N. subflava* (Lewin and Hughes, 1966), but it is generally considered that these species are opportunists that rarely cause infection. The species isolated from animals other than humans have caused infections, possibly as primary pathogens (*N. iguanae*) or as opportunists, also in humans (*N. weaveri* and *N. canis*) (Hoke and Vedros, 1982b; Anderson et al., 1994). These species are generally part of the normal flora of their respective animal hosts, but may have a broader host range as indicated by the isolation of *N. mucosa* from marine mammals (Vedros et al., 1973).

N. meningitidis strains are carried as normal flora in the oro- and nasopharynx of adults and children. The prevalence of *N. meningitidis* carriage varies geographically (Holten et al., 1978; Knapp and Koumanis, 1999). It has been suggested that *N. meningitidis* may occur more frequently in adults with gonorrhea and in homosexual men. Fewer than 1% of children are colonized by *N. meningitidis* during the first 4 years of life; the carriage rate increases after this age.

N. lactamica colonizes the throats of children more frequently than adults (Holten et al., 1978). *N. lactamica* colonizes the throats of as many as 4% of infants to a peak of 21% in children 18–24 months; colonization by *N. lactamica* then declines to 2% by age 14–17 years (Holten et al., 1978; Blakebrough et al., 1982; Knapp and Koumanis, 1999). It is estimated that 59% of children have been colonized by *N. lactamica* at least once by the age of 4 years. This pattern of colonization may reflect the fact that young children may drink large volumes of milk. Among *Neisseria* species, strains of *N. lactamica* are unique in their ability to use lactose; this characteristic may enhance populations of *N. lactamica* in the throats of younger children. Unlike *N. gonorrhoeae*

and *N. meningitidis*, *N. lactamica* has not been implicated as a primary pathogen, although it may be an opportunistic pathogen. The other commensal *Neisseria* species are normal inhabitants of the oro- or nasopharynx. These species are occasionally isolated from other sites but are not considered to be normal flora of sites other than the throat.

Because strains of the commensal *Neisseria* species rarely grow on selective media used to isolate *N. meningitidis* and *N. gonorrhoeae*, the prevalence of these species must be determined on a medium that does not contain colistin, the antibiotic incorporated in neisserial selective medium to inhibit the growth of the commensal species. It therefore was not possible to accurately determine the carriage rate of commensal *Neisseria* species in the early 1900s studies (Berger, 1961a). Most studies of the prevalence of *Neisseria* spp. were performed with nonselective media, e.g., blood agar, which neither inhibited the growth of other bacterial species nor permitted differentiation between colonies of *Neisseria* and related species. Thus, it is probable that the carriage rates of some species (*N. cinerea*, *N. polysaccharea*, and *N. lactamica*) were underestimated because these species occur in relatively small numbers and were probably overgrown by either non-neisserial species or the sucrose-positive *Neisseria* species (*N. subflava* biovar perflava, *N. sicca*, and *N. mucosa*). Furthermore, in these studies, strains were identified with acid detection tests that were not appropriate for the detection of the relatively small amounts of acid produced by *Neisseria* species, and additional differential tests now used to accurately identify commensal *Neisseria* species were unknown.

Some studies have been performed using selective differential media that inhibited the growth of non-neisserial species and selected for commensal *Neisseria* spp., by differentiating either between the asaccharolytic species or among several different groups of species.

The commensal *Neisseria* species have been determined to colonize the throats of adults as follows: *N. sicca*, 45%; *N. perflava*, 40%; and *N. subflava*–*N. flava*, 11% (Stechmann and Berger, 1964). It must be remembered that because nitrate reduction was not used as a differential test for the identification of *Neisseria* species at that time, strains of *N. mucosa* were not recognized by these authors. Although not verifiable, it is reasonable to assume that *N. mucosa* strains were present in the throats of these individuals. Thus, in this study, strains of *N. mucosa* were identified as either *N. sicca* or *N. perflava*, and the prevalences of these latter species were overestimated by the inclusion of strains of *N. mucosa* in their numbers (Berger and Miersch, 1970). Using a selective medium at a later time, Berger found that asaccharolytic strains, i.e., strains that do not produce detectable acid from glucose, maltose, sucrose, or fructose, accounted for 15% of all neisserial isolates, but, because nitrate reduction was not used to differentiate between *N. cinerea* and *M. catarrhalis* until a few years later, the relative colonization rates of these individual species were not given.

Pathogenicity Among the *Neisseria* and related species, only *N. gonorrhoeae* is always considered to be pathogenic and cause disease; *N. gonorrhoeae* is not considered to be normal flora under any circumstances. *N. gonorrhoeae* strains may infect the mucosal surfaces of urogenital sites (cervix, urethra, rectum) and the oro- and nasopharynx (throat), causing symptomatic or asymptomatic infections. Gonococcal infections of the urogenital sites are more frequently symptomatic than asymptomatic; however, asymptomatic infections may occur. Gonococcal infections of the oro- and nasopharynx and the rectum may be asymptomatic more frequently than symptomatic. The prevalence of gonorrhea varies geographically (Lind, 1990; van der Heyden et al., 2000).

N. meningitidis causes epidemic meningitis in many parts of the world such as sub-Saharan Africa. Certain types of *N. meningitidis* are usually associated with meningitis. Of a total of 13 serogroups of *N. meningitidis*, strains belonging to the serogroups A, B, C, and W-135 have most frequently been associated with epidemics. Group A strains have been associated with most epidemics, whereas group B, C, W-135, and Y strains have caused sporadic epidemics. Strains of *N. meningitidis* may be carried as normal flora in the throat or nasopharynx. Between 3% and 30% of healthy persons in nonepidemic geographic areas may be asymptomatic carriers of *N. meningitidis*, i.e., meningococci have colonized their throats without causing disease. The carrier state may persist for many months. *N. meningitidis* may be considered as part of the oral normal flora particularly in crowded human settings, such as child care facilities and military camps. *N. meningitidis* is a major cause of bacterial meningitis and septicemia worldwide. From its commensal state in the pharyngeal mucous membrane, *N. meningitidis* may opportunistically disseminate to the bloodstream and, in the absence of bactericidal serum activity, cause sudden onset of disease. Systemic meningococcal disease affects primarily small children and adolescents, often leading to neurological sequelae or a fatal outcome. Despite the unique disease manifestations associated with *N. meningitidis* and *N. gonorrhoeae*, many of their basic strategies for successful colonization of their exclusive human hosts are highly conserved.

The ability of *N. meningitidis* to inflict damage on its host is correlated with adherence to mucosal epithelial cells in the nasopharynx and further invasion of subepithleial tissues and blood vessels (Nassif, 1999; Hardy et al., 2000). The most important virulence factors contributing to disseminated disease are pili, IgA1 protease, LOS, outer membrane proteins, and capsule polysaccharides (Poolman et al., 1995). *N. meningitidis* releases large amounts of the potent LOS through blebs or lysis. Meningococcal LOS exerts its impact on pathogenesis by facilitating close attachment to and inducing a potent cytokine response in host cells, mainly through TNF-α and interleukin-1 (Brandtzæg, 1995).

N. gonorrhoeae and *N. meningitidis* can cause conjunctivitis, and epidemics of gonococcal ophthalmia occur in developing countries (Koch, 1883; Myerhoff, 1911; Maxwell-Lyons and Amies, 1949). "Gonococcal" eye infection was common in Egypt even after the introduction of antimicrobial agents (Maxwell-Lyons and Amies, 1949). For example, in one study, conjunctival scrapings from children with trachoma and conjunctivitis contained intracellular diplococci. The Gram-negative bacterial strains isolated resembled *N. gonorrhoeae* in growth characteristics and sugar utilization patterns but could not be typed as gonococci. The colony morphology resembled that of meningococci more than that of gonococci. The DNA of the Egyptian isolates was cleaved by the restriction enzyme *Hae*III, like that of *N. meningitidis* but not like that of *N. gonorrhoeae*. The frequency of transformation of a temperature-sensitive mutant of *N. gonorrhoeae* to the ability to grow at the non-permissive temperature was 5–10 fold lower when DNA from two of the Egyptian isolates or from two *N. meningitidis* strains was used for transformation than when DNA

from two *N. gonorrhoeae* strains was used (Mazloum et al., 1986). One of the Egyptian isolates exhibited 68–73% DNA relatedness to *N. gonorrhoeae* DNA and 57–63% DNA relatedness to *N. meningitidis* DNA. The Egyptian isolates were therefore thought to be a variant of *N. gonorrhoeae*, which Mazloum et al. (1986) termed "*N. gonorrhoeae* subsp. *kochii*". 16S rDNA analysis confirmed "*N. gonorrhoeae* subsp. *kochii*" as an intermediate between *N. gonorrhoeae* and *N. meningitidis*.

Other *Neisseria* species are considered to be commensals; they colonize the host without causing disease. Strains of these species are normal flora in the throat and appear to be opportunistic pathogens; they may cause infections although they are not routinely associated with specific types of infections or infections of specific sites. Most *Neisseria* species have been isolated occasionally from blood, cerebrospinal fluid, abscesses, etc., but no consistent association between any species and syndrome has been established that would warrant designating any of these species as pathogens. Some infections caused by commensal *Neisseria* species have occurred in persons who have deficient immune systems and who therefore may be predisposed to infections with organisms that would not normally cause disease.

Antibiotic susceptibility Neisserial species are naturally susceptible to most antibiotics active against Gram-negative bacteria. The antibiotic susceptibilities are monitored through disk diffusion or agar dilution methods. However, antibiotic resistance is now widespread among the pathogenic neisseriae, more so in *N. gonorrhoeae* than in *N. meningitidis*, and occurs as both chromosomally mediated resistance to a variety of agents and plasmid-mediated resistance to penicillins (penicillinase/beta-lactamase producing strains) and to tetracycline (Dillon et al., 1983; Mendelman et al., 1988; Rice and Knapp, 1994). Penicillin resistance due to changes in the genes encoding PBPs is acquired through horizontal gene transfer by transformation (Spratt et al., 1992). Penicillin insensitivity in neisserial species is associated with changes in penicillin-binding protein PBP-2 occurring by horizontal gene transfer (Spratt, 1988; Spratt et al., 1989; Maggs et al., 1998). Resistance to fluoroquinolones in *N. gonorrhoeae* has already emerged and resistance to narrow-spectrum cephalosporins in *N. meningitidis* and *N. gonorrhoeae* is emerging (Fox and Knapp, 1999). Spectinomycin resistance in *N. gonorrhoeae*, due to point mutations in the gene encoding the ribosomal protein S12, and chloramphenicol-resistant *N. meningitidis* strains are increasing problems (Galimand, 1999, 2000). Sulfonamide resistance due to changes in the gene encoding dihydropteroate (*dhps*) was acquired through transformation (Rådstrøm et al., 1992). Comprehensive antibiotic susceptibility data are not available for commensal *Neisseria* spp. Generally, the commensal *Neisseria* spp. have been reported to be susceptible at least *in vitro* to penicillin, ampicillin, and tetracycline, although some strains may possess the TetM determinant. Strains of *N. cinerea*, however, appear to exhibit uniformly decreased susceptibility or resistance to erythromycin when tested by procedures for *N. gonorrhoeae* (Knapp and Koumanis, 1999).

Sulfonamide resistance is predominant in the *N. meningitidis* ET-5 complex, a distinctive group of genetically closely related clones that has been responsible for an epidemic of meningococcal disease in Norway since the mid-1970s. Clones of the *N. meningitidis* ET-5 complex have been identified as the causative agents of recent outbreaks and epidemics in many parts of the world. Analysis of sulfonamide susceptibility of isolates of the ET-5 complex from various geographic sources showed that there was no difference in resistance according to geographic source of the isolates, demonstrating that sulfonamide resistance is an essentially invariant property of clones of the ET-5 complex (Caugant et al., 1989).

Antigens and vaccines Vaccines directed against the polysaccharide capsule are available for four of the five pathogenic meningococcal serogroups (A, C, Y, W), but these vaccines offer only short-duration protection, may induce tolerance after repeated immunization, and are ineffective in infants. New conjugate polysaccharide vaccines against serogroups A, C, W-135, and Y are now available. The meningococcal C glycoconjugate vaccine currently available is approximately 70% effective for 15–17 year olds. The challenge remains in finding an effective vaccine against meningococci that express the serogroup B polysaccharide, as the sialic acid parts of this capsule mimic carbohydrates found in human fetal nervous tissue and other tissues (Bøvre, 1980). This problem is exacerbated by the continual variation of meningococcal protein antigens generated by both mutation and recombination. It is likely that vaccines directed against these molecules will become less effective with the passage of time.

Antigenic variation of surface components such as fimbriae, Opa, and LPS precludes their being relevant vaccine candidates. Other noncapsular vaccine candidates are being sought, but many are variable and give weak protection. The descending order of preference for a protein vaccine candidate employed by some manufacturers is: 1) secreted, 2) outer membrane, 3) lipoprotein, 4) periplasmic, 5) integral membrane. The genome projects have opened up new approaches in the search for new vaccine candidates. The entire genome sequence of a virulent serogroup B strain (MC58) was used to identify vaccine candidates. A total of 350 candidate antigens were expressed in *E. coli*, purified, and used to immunize mice. The sera allowed the identification of proteins that are surface exposed, that are conserved in sequence across a range of strains, and that induce a bactericidal antibody response, a property known to correlate with vaccine efficacy in humans. Among the candidates identified were four lipoproteins, two outer membrane proteins, a membrane protein, murein lytic transglycolase, HtrA serine protease, an autotransporter, and members of the iron transport system (Pizza et al., 2000). Other multiple component approaches including exploiting class I outer membrane proteins, pilin, and LOS conjugates are being pursued. Targeting the semi-conserved section of the pilus had produced some degree of cross-reactivity and an LOS conjugate had induced antibody production. In some animal models, however, the production of bactericidal antibodies may not be necessary to give protection. On the other hand, the detection of bactericidal and opsonophagocytic antibodies in mice may not guarantee that the same will be induced in the human host.

Enrichment and Isolation Procedures

Details of the isolation and processing of *Neisseria* species from humans have been provided by Morello and Bonhoff (1980) and Bartlett and Finegold (1978). In brief, specimens considered to yield pure cultures (blood, spinal fluid, urethral pus, joint fluid) are plated on prewarmed or room temperature chocolate agar (blood agar heated to 80–90°C to rupture the blood cells) and incubated at 36–37°C for a minimum of 48 h in 3–10% CO_2

atmosphere having high humidity. Specimens from body sites that may contain contaminants (cervix, oropharynx) are plated on modified Thayer–Martin medium (Martin et al., 1974) or New York City medium (Faur et al., 1973) and incubated as above. Selective media for *N. meningitidis* and *N. gonorrhoeae* contain four antimicrobial agents—vancomycin, 3–4 μg/ml; colistin, 7.5 μg/ml; trimethoprim, 5 μg/ml; and nystatin, 13.5 μg/ml—to inhibit Gram-positive bacteria, Gram-negative bacteria including commensal *Neisseria* spp., swarming *Proteus* species, and fungi, respectively. Nasopharyngeal samples may be inoculated onto chocolate and blood agar media. Generally, only morphology, Gram stain, oxidase reaction, and acidification of certain sugar media (particularly glucose, maltose, lactose, and sucrose) are used for routine identification. Immunofluorescence is often used for the gonococci and serological grouping by means of agglutination tests for the meningococci. Other *Neisseria* species from humans or animals can be isolated on Mueller–Hinton agar with or without 3% defibrinated sheep blood; once obtained in pure culture they can be identified by the characteristics listed in Table BXII.β.76.

Transport The best method for preserving viable organisms is the inoculation of specimens directly onto a nutrient medium and incubation at 35–37°C in a CO_2-enriched atmosphere immediately after collection. If specimens must be transported and it is not possible to incubate the inoculated media immediately before transport, it is more important to place the inoculated plates in a CO_2-enriched atmosphere than to incubate them at 35–37°C. Inoculated media may be held at room temperature in a CO_2-enriched atmosphere either in a candle extinction jar or commercial CO_2-generating zip-lock bags for up to 5 h without considerable loss of viability. If specimens must be transported through very high or low temperatures, the samples should be transported in a Styrofoam container. Transport of clinical samples is still often performed in semisolid non-nutritive, charcoal-containing transport media, but this method is inferior to the use of a nutrient transport system in a CO_2-enriched atmosphere. If specimens must be transported a long distance, the inoculated media should be incubated for 18–24 h before being transported, and the specimen should arrive within 48 h.

Maintenance Procedures

Isolates should be subcultured every 18–24 h to maintain maximum viability. A neisserial isolate will usually survive for no longer than 48 h in culture, although some isolates may survive for 72–96 h. *N. meningitidis* and *N. gonorrhoeae* are particularly sensitive to cold temperatures and autolysis (Morse and Bartenstein, 1974) and therefore need to be subcultured frequently. Frequent subculturing may lead to the loss of important factors such as fimbriae unless piliated colonies are picked, as observed in a stereomicroscope.

The best method of long-term preservation is by lyophilization in a rich broth (e.g., trypticase soy broth) containing 6% lactose, with storage of the vials at 4°C (Heckly, 1961). For long-term storage in −70°C or liquid nitrogen the bacteria are resuspended in broth containing 20% glycerol or 10–50% serum (Morello and Bonhoff, 1980). The loss of cells during freezing may be minimized by rapid freezing of the specimen in an ethanol bath containing dry ice.

Direct detection in clinical specimens Direct nonculture tests are available for detecting *N. meningitidis* and *N. gonorrhoeae.* Commercial latex agglutination tests and coagglutination tests are used to detect meningococcal polysaccharide capsular antigens in body fluids such as spinal fluid. These kits contain polyvalent antibodies against the serogroups A, C, Y, and W135 and a separate reagent for serogroup B that also detects the cross-reacting *E. coli* K1 antigen. Antigen detection should always be performed along with Gram staining and culture. Direct detection of nucleic acids can be performed by PCR and other amplification techniques (Crotchfelt et al., 1997; Backman et al., 1999; Palmer et al., 2003). Relevant target DNAs for these assays are 16S rDNA, *porA* (Ni et al., 1992), IS1106, and the gene encoding CtrA, which is involved in the excretion of capsular polysaccharide (Porritt et al., 2000). Amplifying the gene encoding SiaD can provide species and serogroup identification in the same assay (Borrow et al., 1997). A direct nucleic acid detection of 16S ribosomal RNA from *N. gonorrhoeae* with a chemiluminescence-enhanced probe assay is useful for the direct detection of gonococci in clinical samples (Granato and Franz, 1990). More recently, a ligase chain reaction-based nucleic acid amplification has provided increased sensitivity in detecting *N. gonorrhoeae* in clinical samples (Hook et al., 1997).

Procedures for Testing Special Characters

Initial identification of neisseriae is based on observing Gram-negative diplococci (except for *N. elongata* and *N. weaveri* cells, which are short rods) taken from the colonies that are oxidase positive when tested with tetramethyl-*p*-phenylendiamine (Kovãcs, 1956). Another routine test used in initial identification is the production of acid from glucose, maltose, lactose, and sucrose, either by inoculation of cystine trypticase agar supplemented with 1% sugar or by measuring preformed enzymes in a rapid sugar fermentation tests (Table BXII.β.76) (Knapp, 1988). *N. lactamica* is the only neisserial species that possesses a typical β-galactosidase that is produced constitutively and will hydrolyze the chromogenic substrate *o*-nitro-phenyl-β-D-galactopyranoside (ONPG). Rapid methods, such as RapidNE or Quad-FERM (Bio-Merieux, Vitek, France), permit the detection of acid from neisseriae within 4 h. However, since many of the reactions in different neisserial species are identical, other phenotypic tests are needed for rapid, presumptive identification. All *Neisseria* species except *N. elongata* are catalase positive when tested with 3% hydrogen peroxide and observing the prompt evolution of bubbles of gas. The superoxol test is analogous to the catalase test, but is performed with a 30% hydrogen peroxide solution (Arko and Odugbemi, 1984). This reagent is most useful in differentiating between *N. gonorrhoeae* (strongly positive), *N. cinerea* (weakly positive), and *Kingella denitrificans* (superoxol negative). The biochemical reactions with the least variability among the species are the nitrate/nitrite reduction test (Cowan, 1974) and the synthesis of polysaccharide from 5% sucrose. The latter test employs bacteria grown on heart infusion agar containing 5% sucrose; after incubation for 2 days the colonies are tested with Lugol's iodine solution diluted 1:4 and the immediate development of a blue color indicates a positive reaction.

The presence of carbonic acid anhydrase is assayed as described by Berger and Issi (1971) and Berger and Piotrowski (1974). The test is performed by determining the minimum inhibitory concentration (MIC) of acetezolamide for cultures grown on heart infusion agar (Difco) containing 5% bovine serum. The cultures are incubated under an air atmosphere and

also under air +10% CO_2. In general, if the MIC for an air-grown strain is approximately 32 mg/ml or lower, the strain produces carbonic anhydrase; this is confirmed by finding a much higher MIC for the strain when grown under 10% CO_2. The confirmation is especially important when the MIC is borderline (e.g., 16–62 mg/ml), as may occur, for example, with some strains of *N. elongata*.

Molecular strain typing The nature of gonococcal infection as a sexually transmitted disease, the rapid course of meningococcal disease, and the capacity of some serogroups to cause large-scale epidemics necessitate the use of sensitive, reliable, and rapid typing methods of characterizing strains. Because of the high plasticity of the neisserial genomes, the choice of typing methods is dependent on the epidemiological questions to be answered and on the population genetics of the organism under investigation. With highly clonal populations comprising independent non-recombining lineages such as gonococci and serogroup A meningococci, ribotyping, multilocus enzyme electrophoresis (MLEE), pulsed-field gel electrophoresis (PFGE), multilocus sequence typing (MLST), and PCR with short primers for random arbitrary polymorphism detection (RAPD) or with other gene-based primers each provides a constant measure of the relationship among strains (Yakubu et al., 1999). A more restricted portfolio of molecular methods, such as PFGE, MLEE, and MLST, is appropriate for the investigation of strains of the less clonal *N. meningitidis* serogroup B and C from localized outbreaks.

The worldwide spread of distinct ET types of *N. meningitidis* has been defined by MLEE (Caugant et al., 1989). However, MLST (Maiden et al., 1998) has been introduced to improve the resolution of bacterial isolates and contributed to the identification and tracking of the spread of virulent or drug-resistant pathogens. In MLST the nucleotide sequences of 450–500 bp of at least seven nonselected housekeeping genes are determined, revealing all of the variation at each locus. Sequences that differ at even a single nucleotide are assigned as different alleles. The large number of alleles at each of the different loci provides the ability to distinguish billions of different allelic profiles. It is extremely unlikely that two unrelated isolates would have the same allelic profile. The relatedness of isolates is displayed as a dendrogram constructed using the matrix of pair-wise differences between their allelic profiles; the pattern of nucleotide sequence variation within genes clearly resolves the major meningococcal lineages known to be responsible for invasive meningococcal disease around the world. MLST exploits the unambiguous nature and electronic portability of nucleotide sequence data for the characterization of organisms (Maiden et al., 1998). With this method the strain associations obtained are consistent with clonal groupings previously determined by MLEE. The advantage of MLST over other molecular typing methods is that sequence data are truly portable between laboratories, permitting expanding global databases for each species to be utilized on a World Wide Web site, thus enabling the exchange of molecular typing data for global epidemiology via the Internet (Enright and Spratt, 1999).The need for a method like MLST is clearly demonstrated by *N. meningitidis*, which is constitutively competent for transformation, is highly recombinogenic, and has an increased spontaneous mutation rate, representing an unusual challenge for DNA repair mechanisms to handle genome instability. MLST analysis of more than 100 isolates of *N. meningitidis* indicates that 1) identical alleles are disseminated among genetically diverse isolates, with no evidence for linkage disequilibrium, 2) different loci give distinct and incongruent phylogenetic trees, and 3) allele sequences are incompatible with a bifurcating treelike phylogeny at all loci (Holmes et al., 1999). These observations are consistent with the hypothesis that meningococcal populations consist of organisms assembled from a common gene pool, with alleles and allele fragments spreading independently, together with the occasional importation of genetic material from other species (Feil et al., 1996, 2000, 2001). Further, they support the view that recombination is an important genetic mechanism in the generation of new meningococcal clones and alleles. Consequently, for anything other than the short-term evolution of *N. meningitidis*, some researchers state that a bifurcating treelike phylogeny is not an appropriate model (Holmes et al., 1999).

Recombinational exchanges in relatively diverse species such as *Neisseria* spp. are very likely to introduce multiple polymorphic nucleotide sites, whereas point mutation results in only a single polymorphism. MLST analysis of seven housekeeping genes in a large number of meningococcal isolates (n = 126) reveals that a single nucleotide site in a meningococcal housekeeping gene is at least 80-fold more likely to change as a result of recombination than as a result of mutation (Feil et al., 1996), This per-site recombination/mutation parameter value is estimated to be 10–50-fold for *E. coli* and approximately 50-fold for *Streptococcus pneumoniae*, another naturally competent species.

Differentiation of the genus *Neisseria* from other genera

The genus *Neisseria* contains mostly cocci. Distinguishing cocci from short rods by microscopic observation alone may sometimes be difficult, and a reliable test that can be applied in doubtful cases is to culture the organisms in the presence of subinhibitory levels of penicillin: rod-shaped organisms form long, stringy cells, whereas cocci retain their coccal morphology. It should be noted that *N. elongata* and *N. weaveri*, the rod-shaped species in the genus *Neisseria*, produce long cells by this method (Bøvre and Holten, 1970; Andersen et al., 1993).

Table BXII.β.75 of the chapter on the family *Neisseriaceae* lists other characteristics that differentiate the genus *Neisseria* from other members of the family. The rod-shaped species *N. elongata* and *N. weaveri* can be distinguished from acinetobacters by their oxidase positive reaction and from the rod-shaped moraxellae by their ability to reduce nitrite. They can be distinguished from kingellae by their generally larger and more opaque colonies and frequent inability to produce acid from glucose; more specifically, they differ from *K. kingae* by being nonhemolytic, from *S. indologenes* by being indole negative, and from *K. denitrificans* by failing to reduce nitrate (although some exceptional nitrate-positive *N. elongata* strains have been found).

Strains of the genus *Neisseria* can be differentiated from related genera such as *Kingella* and *Eikenella* as well as the more distantly related genera *Moraxella* and *Acinetobacter* by cellular morphology, catalase, production of acid from glucose, and nitrite reduction (Table BXII.β.78).

Taxonomic Comments

Classification of the neisseriae into defined species is the subject of intense studies and has been in a state of continuous flux for the last four decades (see reviews by Henriksen, 1976; Bøvre and Hagen, 1981; Vedros, 1981; Tønjum et al., 1995b). The high frequency of horizontal gene transfer among the neisseriae obscures the phylogenetic relationships and species definitions in

TABLE BXII.β.78. Differentiation of the species of the genus *Neisseria* from other genera of the *Neisseriaceae* and two genera of *Moraxellaceae*[a]

Characteristic	*Neisseria*	*Kingella*	*Eikenella*	*Moraxella*	*Acinetobacter*
Cell morphology:					
Cocci	+	−	−	+	−
Rods	+[b]	+	+	+	+
Oxidase test	+	+	+	+	−
Catalase test	+	−	−	+	+
Acid from glucose	(+)	+	−	−	(+)
Nitrite reduction	+	+	+	(+)	−
True waxes present in cell wall	−	−	−	(+)	D
Mol% G + C of DNA	46–58	47–55	56–58	40–48	38–47

[a]Symbols: +, positive for the majority of strains of each species; (+), positive for all strains of the majority of species, only one strain known to be negative; D, positive and negative strains about equally represented. Data compiled from Hollis et al. (1969), Catlin (1978), Bøvre and Hagen (1981), Hoke and Vedros (1982a).

[b]Only two species, *N. elongata* and *N. weaveri*, consist of rods.

this genus. The degree of genetic relatedness between *N. gonorrhoeae* and *N. meningitidis* is extremely high. Kingsbury et al. (1969) found by thermal stability of hybrid DNA duplexes that the two species had at least 80% similarity in their nucleotide sequences, and the DNA–DNA hybridization studies by Hoke and Vedros (1982c) indicated a relatedness of 93%. More recently performed subtractive hybridization analysis and genome sequencing data indicate that the genome sequence similarity among the pathogenic neisseriae is higher than 96% (Tinsley and Naissif, 1996), which has been confirmed by the complete genome sequences (Parkhill et al., 2000; Tettelin et al., 2000). On purely genetic grounds, the two species therefore should be considered as subspecies of a single species. Yet, *N. meningitidis* and *N. gonorrhoeae* cause distinctly different kinds of clinical infections, and from a practical viewpoint it seems desirable to continue to consider these organisms as separate species.

Lactose-positive strains of organisms resembling *N. meningitidis* were recognized as early as 1934 (Jessen, 1934), but were largely ignored until the report by Hollis et al. (1969). *N. lactamica* showed a close relationship to *N. meningitidis* by transformation studies and to the other "true neisseriae" by DNA–DNA hybridization, cellular fatty acid composition, and mol% G + C values (Bøvre et al., 1972; Hoke and Vedros, 1982a, c).

The close relationships between all of the "true neisseriae" have been demonstrated consistently by a variety of techniques (see Bøvre, 1980; Bøvre and Hagen, 1981; Hoke and Vedros, 1982a, c). Of particular interest have been the similarities among *N. flava*, *N. perflava*, and *N. subflava*. It is difficult to differentiate these three species by cultural and biochemical reactions, and in the eighth edition of *Bergey's Manual* they were incorporated in the single species *N. subflava* (Reyn, 1974). This close similarity is supported by DNA–DNA hybridization and genetic transformation studies (Hoke and Vedros, 1982a), as well as by 16S rDNA sequence analysis (Fig. BXII.β.62). Although a high level of DNA relatedness between *N. sicca* and the *N. subflava* group has been found (Hoke and Vedros, 1982a), biochemical distinction between *N. perflava* and *N. sicca* has also been reported (Berger and Catlin, 1975). Further confusion in the classification of these chromogenic neisseriae has been added by the finding of identical lipopolysaccharides in *N. subflava* and *N. canis* (Johnson et al., 1976).

New species in genus *Neisseria* since the last edition of *Bergey's Manual of Systematic Bacteriology* (1984) are *N. polysaccharea* (Riou and Guibourdenche., 1987), *N. macacae*, *N. iguanae*, *N. weaveri*, *N. animalis*, and *N. dentiae* . The last four of these all have mammalian hosts other than humans.

Although the species *N. elongata* consists of rod-shaped cells, genetic transformation studies have shown that *N. elongata* has very high genetic affinities to the coccal species of *Neisseria* (Bøvre and Holten, 1970; Bøvre et al., 1977) and has no affinities to other genera of the family *Neisseriaceae* except a low affinity to *Kingella kingae*. *N. elongata* possesses carbonic anhydrase, which is characteristic of the "true neisseriae", and also possesses a fatty acid composition similar to other neisserial species (Jantzen et al., 1974; Hoke and Vedros, 1982c). The evidence shows that the rod-shaped *N. weaveri* belongs in the genus *Neisseria*, most closely related to *N. elongata*, *N. flavescens*, and *N. animalis*.

The taxonomic status of the previous "false neisseriae", that is the animal species *N. caviae*, *N. ovis*, and *N. cuniculi*, as well as *M. catarrhalis*, has been reassigned to the *Moraxellaceae* (Rossau et al., 1989; Pettersson et al., 1998b). These species were previously considered as a group within the *Neisseria* spp., because they share several phenotypic characteristics (Henriksen, 1976; Bøvre, 1984a). They are listed and described in the article on the genus *Moraxella* in this *Manual*.

Acknowledgments

Stimulating discussions with Kjell Bøvre, Michael Koomey, and Bertil Pettersson are deeply appreciated. We are grateful for the receipt of *N. dentiae* strains from P.H. Sneath. The information provided in the first version of *Bergey's Manual of Systematic Bacteriology* (1984) by N.A. Vedros is greatly acknowledged.

Differentiation of the species of the genus *Neisseria*

Neisseria species are relatively inert biochemically, but those activities and characteristics that are of determinative value are shown in Table BXII.β.76.

List of species of the genus Neisseria

1. **Neisseria gonorrhoeae** (Zopf 1885) Trevisan 1885, 106[AL] (*Merismopedia gonorrhoeae* Zopf 1885, 54.)
go.nor.rhoe' ae. Gr. n. *gonorrhoeae* gonorrhoea; M.L. gen. n. *gonorrhoeae* of gonorrhoea.

Common name: gonococcus.

The biochemical characteristics are as described for the genus and as listed in Table BXII.β.76. Primary isolation is made on chocolate agar at temperatures of 35–36°C under an atmosphere containing 3–10% CO_2 and high relative humidity. Minimum growth temperature, 30°C. At 48 h, colonies are 0.6–1.0 mm in diameter, opaque, grayish white, raised, finely granular, glistening, and convex. They become mucoid with further incubation. The cocci are arranged in pairs. Primarily found in gonorrhea (purulent venereal discharges), oropharyngeal infection, anorectal infection, endometritis, conjunctivitis, and disseminated gonococcal infection. Also found in blood, the conjunctiva, petechiae, pharynx, and cerebrospinal fluid. Found only in humans.

The mol% G + C of the DNA is: 49.5–53.3 (T_m, chromatography).

Type strain: ATCC 19424, CCUG 26876, CIP 79.18, DSM 9188, NCTC 8375.

GenBank accession number (16S rRNA): X07714.

This species shows very high genetic relatedness to *N. meningitidis* (Tinsley and Nassif, 1996; Fig. BXII.β.62). *"N. kochii"* is considered to be a subspecies of *N. gonorrhoeae* and has no independent taxonomic status.

2. **Neisseria animalis** Berger 1960, 160[AL]
an.i.mal' is. L. n. *animal* animal; L. gen. n. *animalis* of an animal.

Typical diplococci. Colonies are smooth, round, graywhite. Produces acid from saccharose, no acid from fructose and maltose (which is positive for *N. sicca* and *N. perflava*, the other saccharose-positive *Neisseria*) (Berger, 1962). Isolated from the throats of guinea pigs. Appears to be closely related to *N. denitrificans* (Fig. BXII.β.62).

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 14678, CCUG 808, CIP 72.15, NCTC 10212.

GenBank accession number (16S rRNA): AJ239288.

3. **Neisseria canis** Berger 1962, 455[AL]
ca' nis. L. gen. n. *canis* of the dog.

The cells are typical diplococci, rarely tetrads. Colonies are smooth, butyrous, with a light yellowish tinge. Absorption peaks of the extracted pigment are similar to those of *N. lactamica* (Hoke and Vedros, 1982c). The cellular fatty acids are similar to those of the "true" neisseriae. Carbonic anhydrase is produced (Berger and Issi, 1971). Other characteristics are listed in Table BXII.β.76. Isolated from the throats of cats (Berger, 1962) and as an opportunist in a cat-bite wound of a human (Hoke and Vedros, 1982b).

The mol% G + C of the DNA is: 49.6 (T_m).

Type strain: ATCC 14687, CIP 103347, LMG 8383, NCTC 10296.

GenBank accession number (16S rRNA): L06170.

16S rDNA sequence analysis of the type strain suggests that this species is more closely related to genus *Kingella* than to *Neisseria* spp.

4. **Neisseria cinerea** (von Lingelsheim 1906) Murray 1939, 283[AL] (*Micrococcus cinereus* von Lingelsheim 1906, 396.)
ci.ne' re.a. L. fem. adj. *cinerea* gray.

The cocci are plump and arranged in pairs or more often in scattered clusters. Colonies are small (1.0–1.5 mm in diameter), grayish white with entire edges, and slightly granular. The percentage of fatty acids having a chain length of over 16 carbon atoms is similar to that of the other neisseriae (Hoke and Vedros, 1982c). Carbonic anhydrase is produced (Berger and Issi, 1971). Other characteristics are listed in Table BXII.β.76. Found in the nasopharynx of humans. Opportunistic pathogen (e.g., newborn ocular infections) (Bourbeau et al., 1990).

The mol% G + C of the DNA is: 49.0–50.9 (T_m, Bd).

Type strain: ATCC 14685, CCUG 2156, CIP 73.16, DSM 4630, LMG 8380, NCTC 10294.

5. **Neisseria denitrificans** Berger 1962, 455[AL]
de.ni.tri' fi.cans. L. prep. *de* away from; L. n. *nitrum* soda; M.L. n. *nitrum* nitrate; M.L. v. *denitrifico* to denitrify; M.L. part. adj. *denitrificans* denitrifying.

The percentage of fatty acids with chain length over 16 carbon atoms and the fatty acid profile are similar to those of the "true" neisseriae (Hoke and Vedros, 1982c). Carbonic anhydrase is produced (Berger and Issi, 1971). Other characteristics are as listed in Table BXII.β.76. Isolated from the throats of guinea pigs.

The mol% G + C of the DNA is: 55.6 (T_m).

Type strain: ATCC 14686, CCUG 2155, CIP 72.16, NCTC 10295.

GenBank accession number (16S rRNA): L06173, M35020.

6. **Neisseria dentiae** Sneath and Barrett 1997, 915[VP] (Effective publication: Sneath and Barrett 1996, 357.)
den' ti.ae. M.L. fem. gen. sing. n. *dentiae* of (Dr.) Dent; named for Vija E. Dent (Mrs. Pratley) in recognition of her pioneering work on neisserias from dental plaque.

Cells are small cocci about 1 µm in diameter, arranged mainly as diplococci with occasional tetrads, but without diplobacilli. Nonmotile. No endospores. Growth is aerobic with optimal temperature close to 35°C. No growth under anaerobic conditions. Colonies on horse blood agar are round transparent and domed, without obvious yellow pigment, about 1 mm in diameter after 24 h growth at 35°C. No hemolysis on horse blood; weak hemolysis on sheep

blood is occasionally found. Oxidase positive. Catalase positive. Indole negative. Gelatin negative. Nitrate negative. Most strains reduce nitrite. Found in dental plaques of domestic cows. Resembles *N. animalis*, *N. canis*, and *N. iguanae* phenotypically, but is distinguished from the first two by being positive for acidification of gluconate, D-glucose, and usually D-fructose, and from the third by lacking predominant tetrad arrangement and distinct α-hemolysis and by growing on nutrient agar and usually acidifying D-fructose. May have impact on dental microbiology because members of the genus *Neisseria* rapidly utilize oxygen and this may contribute to the anaerobic microenvironment found in dental plaques.

The mol% G + C of the DNA is: not determined.

Type strain: V33, SHI/3848, ATCC 700276, CIP 106968.

GenBank accession number (16S rRNA): AF487709.

16S rDNA sequence analysis shows highest homology to *N. canis* (as for the other neisseriae from animal habitats other than humans).

7. **Neisseria elongata** Bøvre and Holten 1970, 73[AL]
e.lon′ga.ta. L. fem. part. adj. *elongata* elongated, stretched out.

Rods, short and slender, ~0.5 μm in diameter, often arranged as diplobacilli or in short chains. A marked elongation effect of sublethal concentrations of penicillin occurs during growth, with formation of very long filaments. Often fimbriated. Colonies on blood agar are shiny and low convex with an entire edge, ~2–3 mm in diameter after 48 h of incubation. The colonies are semi-opaque to grayish white with a yellowish tinge due to pigment production. Older colonies may attain a diameter of 4–5 mm and often show granular spreading zones around the periphery, or the colonies become irregular in outline with spreading projections. The colony texture is usually clay-like and coherent, and the growth mass when collected is lumpy and difficult or impossible to disperse. No hemolysis occurs. Agar corrosion with a peripheral groove and a central pit is often observed under the colony. The spreading and corrosion are related to the presence of fimbriae on the cells; nonfimbriated or less fimbriated variants give rise to colonies that are often smaller, nonspreading, and noncorroding. Optimal growth temperature 33–37°C. Capable of growing weakly on blood agar under anaerobic conditions. Grows on simple peptone media. The specific growth requirements are not known.

Capsules are not formed. Nonmotile. Oxidase positive. Usually acid is not formed from glucose, but some strains may form small amounts of acid. Nitrite reducing, but usually not nitrate reducing (see below). Catalase activity is usually not detectable but may be positive or weakly positive in some strains. No liquefaction of coagulated serum or gelatin occurs. Urease negative. Phenylalanine is not produced except for weak reactions observed with some strains. Carbonic anhydrase is produced (Berger and Issi, 1971). Highly sensitive to penicillin. The species lacks true cellular waxes (Jantzen et al., 1976) and contains heptose (Jantzen et al., 1976). Other characteristics are listed in Table BXII.β.76. Isolated from the pharynx of healthy individuals and from cases of pharyngitis. Also isolated from bronchial aspirates, pus from perimandibular abscesses, blood cultures during endocarditis, and from the urinary tract. So far recorded only from human sources. Considered as a largely harmless parasite.

The mol% G + C of the DNA is: 53.0–53.5 (T_m).

Type strain: ATCC 25295, CCUG 2043, CCUG 2130 A, CIP 72.27, LMG 5124, NCTC 10660.

GenBank accession number (16S rRNA): L06171.

The cells are frequently competent in genetic transformation and can be identified by transformation. The competence is apparently associated with the fimbriated state (Bøvre and Holten, 1970; Bøvre et al., 1977). There is a distinct genetic affinity by transformation between *N. elongata* and the coccal species of the "true" neisseriae. The species also fits in with the "true" neisseriae with respect to cellular lipid and carbohydrate composition and the characteristics of glycolytic enzymes (see reviews by Bøvre, 1980; Bøvre and Hagen, 1981).

The species is genetically somewhat heterogeneous (Bøvre et al., 1972) and it is now proposed to consist of three subspecies: *Neisseria elongata* subsp. *elongata*, *Neisseria elongata* subsp. *glycolytica*, and *Neisseria elongata* subsp. *nitroreducens*.

Another subspecies, "*N. elongata* subsp. *intermedia*", was proposed by Berger and Falsen (1976). This subspecies presently has no standing in nomenclature. It is catalase positive and immunologically distinct from the type strain of the elongata. It may possibly be identical to the subsp. *glycolytica*.

a. **Neisseria elongata** *subsp.* **elongata** Bøvre and Holten 1970, 73[AL]

Oxidase positive, aerobic, nonmotile, rod-shaped bacterium. No acid production from glucose or other carbohydrates. Catalase negative. Urease, indole, and motility negative. Nitrite reducing. Differs from subsp. *glycolytica* and subsp. *nitroreducens* by showing no acidification of glucose media and being catalase negative.

The mol% G + C of the DNA is: 56 (T_m).

Type strain: ATCC 25295, CCUG 2043, CCUG 2130 A, CIP 72.27, LMG 5124, NCTC 10660.

GenBank accession number (16S rRNA): L06171.

b. **Neisseria elongata** *subsp.* **glycolytica** Henriksen and Holten 1976, 480[AL]
gly.co.ly′ti.ca. Gr. *glyko-* from Gr. *glykys* sweet; Gr. adj. *lyticus* dissolving; M.L. fem. adj. *glycolytica* meant to indicate an ability to attack glucose.

Oxidase positive, aerobic, nonmotile, rod-shaped bacterium. Nitrite reducing. Catalase positive. Urease, indole, and motility negative. No acid production from carbohydrates. Differs from elongata by being catalase positive, by causing a weak acidification of glucose media, and by forming colonies with a smooth texture. Quantitative genetic transformation data show identity reactions between subsp. *elongata* and subsp. *glycolytica*, and they are also indistinguishable in terms of fatty acid composition (Bøvre et al., 1977).

The mol% G + C of the DNA is: 56 (T_m).

Type strain: ATCC 29315, CCUG 6508, CIP 82.85, NCTC 11050.

Although subspeciation of *N. elongata* subsp. *elongata* and *N. elongata* subsp. *glycolytica* has been proposed based

on differences in glycolytic properties (Henriksen and Holten, 1976), genetic and other evidence for subspeciation are rather weak. In fact, Bøvre et al. (1977) has reported general species identification of the glycolytic strain 6171/75 ATCC 23915 with the type strain M2 = ATCC 25295 by genetic transformation. They found DNA homology of up to 86% between the glycolytic strain (6171/75) and the type strain (M2) by quantitative streptomycin resistance transformation.

c. **Neisseria elongata** *subsp.* **nitroreducens** Grant, Brenner, Steigerwalt, Hollis and Weaver 1990, 2596[VP]
nit.ro.re' du.cens. Gr. *nitroreducens* the agent that reduces nitrate.

Oxidase positive, aerobic, nonmotile, rod-shaped bacterium. Reduction of nitrate and nitrite with no gas formation. Negative reactions for catalase, urease, indole, and motility; and no acid production from carbohydrates. Differences from subsp. *elongata*: reduces nitrate and sometimes causes a weak acidification of glucose media. Differences from *N. elongata* subsp. *glycolytica*: catalase negative, reduces nitrate. Found in throat or sputum and from blood, with many of the systemic isolates being associated with endocarditis. Rarely occurring, but can cause serious human infections (Hofstad et al., 1998). The fact that it is found in association with endocarditis and other systemic diseases differentiates it from the other *N. elongata* subspecies.

The mol% G + C of the DNA is: 55–58 (T_m).

Type strain: B109, ATCC 49377, CCUG 30802, CIP 103511, NCTC 12736.

N. elongata biovar nitroreducens was previously termed CDC group M-6. By the hydroxyapatite method, DNAs from the M-6 strains showed an average of 78% relatedness to M-6 reference strain B1019 in reactions at 60°C and 73% relatedness in reactions at 75°C (Grant et al., 1990). This organism is biochemically similar to *Kingella denitrificans* and displays a cellular fatty acid profile consistent with CDC groups M-5 and EF-4 as well as with *N. elongata*. The relatively high mol% G + C content of DNA supported the establishment of this subspecies. 16S rDNA sequence analysis show high similarities among the three subspecies of *N. elongata* (Fig. BXII.β.62).

8. **Neisseria flavescens** Branham 1930, 849[AL]
fla.ves' cens. L. v. *flavus* to become golden yellow; L. part. adj. *flavescens* becoming golden yellow.

The characteristics are as described for the genus and as listed in Table BXII.β.76. Cocci in pairs and tetrads. Colonies are smooth and opaque with golden yellow pigment. Nitrate and nitrite reducing. Synthesis of polysaccharide positive (iodine test). Found in cerebrospinal fluid of patients with meningitis and in cases of septicaemia. Rare (Branham, 1930; Wertlake and Williams, 1968). Found in the pharynx of humans (rare).

The mol% G + C of the DNA is: 46.5–50.1 (T_m, Bd, chromatography).

Type strain: ATCC 13120, CCUG 345, CCUG 17913, CIP 73.15, LMG 5297, NCTC 8263.

GenBank accession number (16S rRNA): L06168.

9. **Neisseria iguanae** Barrett, Schlater, Montali and Sneath 1994b, 852[VP] (Effective publication: Barrett, Schlater, Montali and Sneath 1994a, 201.)
i.gu' an.ae. M.L. fem. gen. sing. n. *iguanae* of the iguana lizard; from Sp. fem. n. iguana.

Cells are small cocci about 0.8 μm in diameter, largely arranged as diplococci but show numerous tetrads in culture. Nonmotile. Surface colonies grown on 5% sheep or horse blood agar are nonpigmented, round, transparent, domed, about 1 mm in diameter after 72 h at 35°C with marked zones of α-hemolysis. Oxidase positive, catalase positive, urease and deoxyribonuclease negative. Weak acidity usually from glucose, sucrose, and gluconate. Strongly positive for alkaline phosphatase. Gluconate positive. Strongly positive for alkaline phosphatase 2. No endospores. Aerobic growth, no growth under anaerobic conditions. Mesophilic. Grows between 25°C and 37°C. Chemoorganotrophic. May be isolated from the oral cavity of healthy lizards. Associated with septicemia and abscesses in iguanid lizards (*Iguana iguana* and *Cyclura cornuta*).

The mol% G + C of the DNA is: 50.8–52.0 (T_m).

Type strain: ATCC 51483, NVSL 85737.

10. **Neisseria lactamica** Hollis, Wiggins and Weaver 1969, 72[AL]
lac.ta.mi' ca. L. n. *lac* milk, from *lactose* milk sugar; L. adj. *amicus* fond of; M.L. fem. adj. *lactamica* fond of lactose.

The characteristics are as described for the genus and as listed in Table BXII.β.76. Cocci arranged in pairs. Colonies are small, smooth, translucent, slightly butyrous, and often have a yellowish tinge. Primary isolation is made on chocolate agar at temperatures of 35–36°C under an atmosphere containing 3–10% CO_2 and high relative humidity. Minimum growth temperature 30°C. At 48 h, colonies are 0.6–1.0 mm in diameter, opaque, grayish white, raised, finely granular, glistening, and convex. They become mucoid with further incubation. The only *Neisseria* species that produces acid from lactose. Primarily found in the nasopharynx, most commonly found in children and young teenagers. Rarely pathogenic, but has been identified as a possible cause of meningitis.

The mol% G + C of the DNA is: 49.5–53.3 (T_m, chromatography).

Type strain: ATCC 23970, CCUG 5853, CIP 72.17, DSM 4691, NCTC 10617.

GenBank accession number (16S rRNA): AJ239286.

Genetic transformation, DNA–DNA hybridization, and 16S rDNA sequence analysis have indicated a close relationship between *N. lactamica*, *N. meningitidis*, and *N. gonorrhoeae*, but not as close as that between *N. meningitidis* and *N. gonorrhoeae* (Siddiqui and Goldberg, 1975; Hoke and Vedros, 1982a; Garborg and Tønjum, personal communication).

11. **Neisseria macacae** Vedros, Hoke, and Chun 1983, 519[VP]
ma' ca.cae. Port. n. *macaco* female monkey; N.L. fem. gen. *macacae* of a monkey, referring to the source of the isolates.

Cocci occurring in pairs with adjacent sides flattened or singly; cells are nonmotile and 0.6–1.0 μm in diameter. Colonies on Mueller–Hinton agar or nutrient agar are slightly raised, yellowish green, and glistening, have entire edges, and are about 1–1.5 mm in diameter after 17 h of incubation at 37°C in a humid atmosphere. Aerobic. Optimal

growth at 35–37°C; less growth at 30°C. Growth enhanced by 5–8% CO_2 at 30°, 35°, or 37°C. Slight or no growth at 22° and 42°C. Moderate hemolysis of horse blood agar and rabbit blood agar. Oxidase positive. Catalase positive. Nitrate is not reduced, nitrite is reduced with the production of gas. Polysaccharides are produced from sucrose, DNA is hydrolyzed, tributyrin is not hydrolyzed. Isolated from the oropharynges of rhesus monkeys.

The mol% G + C of the DNA is: 50–51 (T_m).

Type strain: M-740, ATCC 33926.

GenBank accession number (16S rRNA): L06169.

12. **Neisseria meningitidis** (Albrecht and Gohn 1901) Murray 1929, 8[AL] (*Micrococcus meningitidis* Albrecht and Gohn 1901, 498.)
me.nin.gi′ ti.dis. Gr. n. *meninx, meningis* the membrane enclosing the brain; M.L. fem. n. *meningitis, meningitidis* inflammation of the meninges.

Common name: meningococcus.

Cocci arranged in pairs. Cellular division occurs in two planes with the second division at a right angle to the first. Transient tetrads can therefore be observed in wet mounts of young, growing cultures (less than 8-h-old). Primary isolation is made on blood agar, chocolate agar, or Mueller–Hinton agar. An atmosphere containing 3–10% CO_2 and high relative humidity enhances growth. Optimal temperatures 36–37°C. Colonies vary in size depending on the medium, extent of crowding, and length of incubation; in 18–24 h they are approximately 1.0 mm in diameter. Colonies are small, round, smooth, glistening, sometimes mucoid and translucent on Mueller–Hinton agar, and are often iridescent. Due to autolysis with age, colonies become more butyrous and rubbery to the touch of an inoculating needle. Other characteristics are listed in Table BXII.β.76. Some strains are erratic in producing acid from maltose and glucose (Jyssum and Jyssum, 1968; Bøvre, 1969). Found in cerebrospinal fluid as the causative agent of cerebrospinal meningitis and in blood as the cause of septicemia (including Waterhouse–Friderichsen syndrome), lower genital tract infections (rare), and pneumonia (rare). Can be cultivated from petechiae, joints, nasopharynx, and conjunctiva, occasionally found in venereal discharges. Frequently found in a commensal state in the oro- or nasopharynx of asymptomatic carriers.

The mol% G + C of the DNA is: 50–52 (T_m, chromatography).

Type strain: M1027, ATCC 13077, CCUG 3269, CIP 73.10, DSM 10036, NCTC 10025.

N. meningitidis shows a very high genetic relatedness to *N. gonorrhoeae* by DNA–DNA hybridization (>80%) (Kingsbury et al., 1969) and by subtractive hybridization (96% similarity) (Tinsley and Nassif, 1996).

13. **Neisseria mucosa** (von Lingelsheim 1906) Véron, Thibault and Second 1959, 508[AL] (*Diplococcus mucosus* von Lingelsheim 1906, 395.)
mu.co′ sa. L. fem. adj. *mucosa* slimy.

The characteristics are as described for the genus and as listed in Table BXII.β.76. Cocci arranged in pairs. Colonies are large, mucoid, and often adherent. Most strains are nonpigmented (Berger and Miersch, 1970) or grayish to buff yellow colonies, but one strain has been described as slightly yellow (Véron et al., 1959). Found in the nasopharynx of humans and, in one report, as part of the normal flora of the respiratory tissues in dolphins (Vedros et al., 1973). Occasionally pathogenic for humans, causing pneumonia in children (rare). Pathogenic for mice.

The mol% G + C of the DNA is: 50.5–52.0 (T_m, Bd).

Type strain: ATCC 19696, CCUG 26877, CIP 59.51, DSM 4631, NCTC 12978.

An organism called "*N. mucosa* biovar heidelbergensis" was described by Berger (1971). It differed from "*N. mucosa* biovar mucosa" in that some strains were pigmented, possessed deoxyribonuclease, and produced more gas from nitrite. "*N. mucosa* mucosa" has white and larger colonies of more dry consistence than "*N. mucosa* biovar heidelbergensis". Growth in broth results in pellet forming. "*Neisseria mucosa* biovar heidelbergensis" has smaller colonies of more butyrous consistence than "*N. mucosa* biovar mucosa". Yellow pigment on blood agar. Diffuse growth in broth. 16S rDNA sequence analysis shows significant differences between "*N. mucosa* biovar mucosa" and "*N. mucosa* biovar heidelbergensis". By 16S rDNA sequence analysis *N. mucosa* strains are most closely related to *N. sicca* and *N. subflava* biovar flava.

14. **Neisseria polysaccharea** Riou and Guibourdenche 1987, 163[VP]
pol.y.sac.cha.re.a. Gr. adj. *poly* many; Gr. n. *Saccharum* sugar; M.L. fem. adj. *polysaccharea* with many saccharides.

Unencapsulated cocci arranged in pairs or tetrads. Oxidative respiratory metabolism. Oxidase and catalase produced. All strains grow on selective medium producing small, grayish yellow colonies that are translucent and raised of about 2 mm in diameter after 24 h at 37°C. No growth occurs at 22°C. Large amounts of polysaccharide are produced on solid or in liquid medium containing 1% or 5% sucrose. Requires cystine–cysteine for growth on *Neisseria* defined medium (Catlin, 1973); in addition, some strains require arginine. Acid is produced from glucose and maltose, rarely from sucrose, but never from fructose, D-mannitol, or lactose. Tributyrin and *o*-nitrophenyl-β-D-galactopyranoside are not hydrolyzed. Nitrites are reduced, nitrates are not. Deoxyribonuclease, gelatinase, and γ-glutamyltransferase are not produced. No hemolysis is observed on horse blood agar. Produces extracellular polysaccharide and exhibits γ-glutamyltransferase activity. It is found in the nasopharynx of infants and children. No strain of this species has been recognized as a cause of human disease.

The mol% G + C of the DNA is: 52.5–54. (T_m, Bd).

Type strain: ATCC 43678, CCUG 18030, CIP 100113, NCTC 11858.

GenBank accession number (16S rRNA): L06167, AJ239289.

15. **Neisseria sicca** (von Lingelsheim 1908) Bergey, Harrison, Breed, Hammer and Huntoon 1923a, 43[AL] (*Diplococcus siccus* von Lingelsheim 1908, 476.)
sic′ ca. L. fem. adj. *sicca* dry.

The characteristics are as described for the genus and as listed in Table BXII.β.76. Cocci arranged in pairs and tetrads. Colonies are usually large (up to 3 mm), grayish white, opaque, dry, wrinkled, and adherent. Forms opaque, dry, wrinkled, adherent, colonies but this may vary with some strains. Some strains may produce a xanthophyll pig-

ment (Berger, 1961b); when extracted, this pigment shows absorption peaks similar to the pattern exhibited by the pigments of *N. perflava*, *N. flava*, and *N. mucosa* (Hoke and Vedros, 1982c). Spontaneous agglutination occurs in saline. The strain used in the report on envelope proteins is questionable (Russell et al., 1975). *N. sicca* may be serologically distinct from *N. subflava* (*N. flava*, *N. perflava*) and *N. flavescens* (Berger and Brunhoeber, 1961; Berger and Wulff, 1961). The species is serologically related to *N. mucosa* (Véron et al., 1959). Found in the nasopharynx, saliva, and sputum of humans (very common); opportunistic pathogen.

The mol% G + C of the DNA is: 49.0–51.5 (T_m, Bd, chromatography).

Type strain: ATCC 29256, CCUG 23929, CCUG 24959, CIP 103345, LMG 5290, NRL 30,016.

Genetic transformation and DNA–DNA hybridization indicate that *N. sicca* should be considered for inclusion with *N. perflava* and *N. flava* into the single species *N. subflava* (Catlin and Cunningham, 1961; Hoke and Vedros, 1982a). However, 16S rDNA sequence analysis shows closer relationship to *N. mucosa* and *N. macacae* (Pettersson and Tønjum)

16. **Neisseria subflava** (Flügge 1886) Trevisan 1889, 32[AL] (*Micrococcus subflavus* Flügge 1886, 159; *Neisseria flava* Bergey, Harrison, Breed, Hammer and Huntoon 1923a, 43.)
sub.fla′ va. L. pref. *sub* less than; L. adj. *flavus* yellow; L. fem. adj. *subflava* yellowish.

The characteristics are as described for the genus and as listed in Table BXII.β.76. Cocci arranged in pairs and tetrads. Colonies are smooth, transparent or opaque, often adherent. Grows on blood agar at 22°C. Some strains produce a yellowish pigment. Often agglutinates spontaneously in saline (Reyn, 1974). Found in secretions from the human nasopharynx and rarely in cerebrospinal fluid in cases of meningitis (Noguchi et al., 1963; Baraldes et al., 2000).

The mol% G + C of the DNA is: 48.0–51.0 (T_m, Bd, chromatography).

Type strain: ATCC 49275, CCUG 23930, CCUG 33675, CIP 103343, LMG 5313, NRL 30,017.

Neisseria subflava contains the previous species *Neisseria flava*, *Neisseria perflava*, and *Neisseria subflava*. *N. subflava* biovar flava and *N. subflava* biovar perflava produce acid from fructose, whereas *N. subflava* biovar subflava does not. *N. subflava* biovar perflava produces acid and polysaccharide from sucrose which *N. subflava* biovar flava and *N. subflava* biovar subflava do not. 16S rDNA sequence analysis shows that *N. subflava* biovar subflava and biovar perflava are considerably more closely related to each other than they are to *N. subflava* biovar flava. Inclusion of *N. sicca* into this species could be considered based on its relatedness to *N. subflava* biovar flava.

17. **Neisseria weaveri** Holmes, Costas, On, Vandamme, Falsen and Kersters 1993, 691[VP]
wea′ ver.i. M.L. gen. n. *weaveri* was named in honor of Robert E. Weaver.

The cells are broad, plump, medium-to-large, straight rods of varying length when grown on slants and plates, with a tendency to grow in chains or longer rods in broth cultures. They are nonmotile, aerobic, and non-salt requiring. Grow well between 25° and 35°C; most strains grow at 42°C. Colonies are gray-white with an entire border, flat, somewhat glistening, and smooth and variable in size. They are 1–2 mm in diameter after 24 h of incubation at 35°C and 2–4 mm after 48 h of incubation. A zone of α-hemolysis is produced on sheep blood agar plates in areas of heavy growth. The oxidase and catalase reactions are strongly positive. The bacterium does not utilize carbohydrates; it uses nitrite but not nitrate and has a weakly positive phenylalanine deaminase reaction from culture grown on sheep blood agar plates. It is found as normal oral flora in dogs and is associated with human wound infections resulting from dog bites.

The mol% G + C of the DNA is: 50.8–52.0 (T_m).

Type strain: ATCC 51410, CCUG 4007, CCUG 33675, CIP 103940, ISL775/91, LMG 5135, NCTC 12742.

Genus II. **Alysiella** *Langeron 1923, 116*[AL]

TONE TØNJUM

A.ly.si.el′ la. Gr. fem. n. *alysion* small chain; M.L. *-ella* dim. ending; M.L. fem. n. *Alysiella* small chain.

Organisms that exist in characteristic **flat, ribbon-like multicellular filaments**. The **long axis of the individual cells is perpendicular to the long axis of the filament**. The **cells within the filament are paired**, and in axenic culture the filament often breaks up into groups of two or four cells. The width of an individual cell (the width of a filament) is about 2.0–3.0 µm, and the length of a cell is about 0.6 µm. The length of the filament is quite variable. The filament does not show either a dorsal-ventral differentiation or a convex-concave curvature in transverse cross-section. The **ends of the individual filaments are square**. Gram negative. **Motile by gliding** of the entire filament in the direction of the long axis. Aerobic. Chemoorganotrophic. Some may produce acid aerobically from carbohydrates. Optimal temperature: 37°C. Found in the oral cavity of warm-blooded vertebrates

The mol% G + C of the DNA is: 44–48.

Type species: **Alysiella filiformis** (Schmid *in* Simons 1922) Langeron 1923, 118, *Simonsiella filiformis* Schmid *in* Simons 1922, 509.)

FURTHER DESCRIPTIVE INFORMATION

The filaments of *Alysiella* are distinctive, and members of this genus can be recognized by their morphology alone (Fig. BXII.β.64). The filament is flat and ribbon-shaped rather than cylindrical and consists of continuous pairs of cells (Figs. BXII.β.65 and BXII.β.66). The individual cells are oblong, disk-shaped, and several times greater in width than in length. Fibrils are produced from only one side of the filament (Fig. BXII.β.66), and the fibrils appear to be involved in anchoring the filament to epithelial cells of the oral cavity (Kaiser and Starzyk, 1973; McCowan et al., 1979). Cells anchored in this way give rise to a typical palisade arrangement (Fig. BXII.β.64).

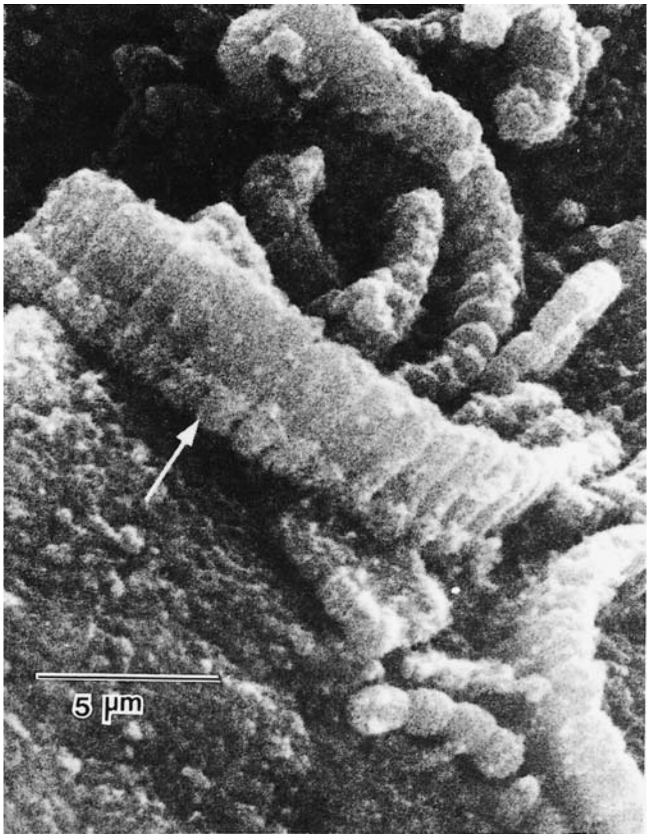

FIGURE BXII.β.64. Scanning electron micrograph of an *Alysiella* filament attached to the epithelium of the bovine tongue. The arrow indicates the fringe of fibers that attach the bacterial filament by its side to the substrate. The palisade organization of the filament is characteristic of *Alysiella*. (Reproduced with permission from R.P. McCowen et al., Applied and Environmental Microbiology *37:* 1224–1229, 1979, ©American Society for Microbiology.)

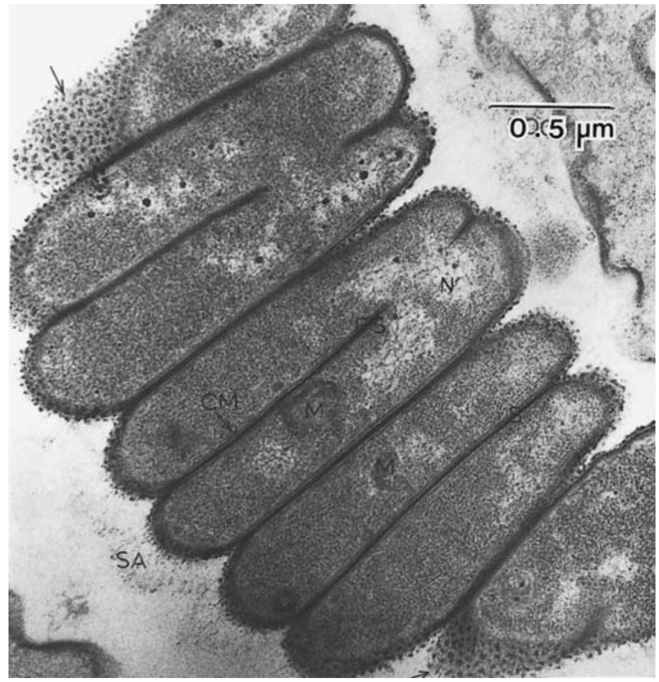

FIGURE BXII.β.65. Longitudinal electron micrograph of *Alysiella* from the oral cavity of a rabbit. The paired nature of the cells within the filament is typical of the genus. (Reproduced with permission from G.E. Kaiser and M.J. Starzyk, Canadian Journal of Microbiology *19:* 325–327, 1973, ©National Research Council of Canada.)

Gliding motility occurs when the flat surface of the filament is in contact with an agar surface. No organs of locomotion have been detected. Colonies on Oxoid nutrient agar containing 10% horse or ox serum are nonpigmented and about 1.0–1.5 mm in diameter (Steed, 1962). On BSTSY agar (see *Simonsiella* for ingredients), the colonies are about 1.0–2.0 mm in diameter and exhibit a pale yellow pigmentation (Kuhn, 1981). No resting stage has been detected. Generally, the cellular carbohydrate pattern exhibits some similarities with that of *S. muelleri* (Heiske and Mutters, 1994). However, although *A. filiformis* has a cellular carbohydrate pattern different from all other taxa described, the results have to be regarded as preliminary because only the type strain has so far been analyzed.

All reports of *Alysiella* indicate that it is restricted to the oral cavity of warm-blooded vertebrates, where it apparently is nonpathogenic.

Enrichment and Isolation Procedures

At the present time there is no enrichment procedure for *Alysiella*. Direct isolation from the oral cavity can be achieved; however, Steed (1962) isolated *Alysiella* from sheep and rabbits with oral swabs that were plated directly onto Oxoid nutrient agar containing 10% horse or ox serum. After 6 h the microcolonies were transferred to new media using a micromanipulator.

McCowan et al. (1979) isolated *Alysiella* from cows by pressing a portion of tongue on the agar surface and then spreading the organisms or by washing a portion of tongue in phosphate-buffered saline, homogenizing the tongue with a Waring blender, and plating the resulting suspension on agar. They used both Tryptose-blood agar (Difco Laboratories) with 10% sheep blood or an agar consisting of the following ingredients: nutrient agar (Difco), 2.5%; sodium acetate, 0.01%; and yeast extract (Difco), 0.5%.

Kuhn (1981) suggested that *Alysiella* can be isolated on BSTSY agar by using the procedures that she used for isolating *Simonsiella* (see the description of the genus *Simonsiella*).

Maintenance Procedures

Alysiella should be grown at 37°C, and freshly isolated cultures should be transferred at intervals of 2–3 days. Older cultures must be transferred at weekly intervals.

Refrigeration is not recommended for preservation of cultures, but they can be preserved by freezing in liquid nitrogen using glycerol as a cryoprotectant or by lyophilization.

Procedures for Testing Special Characters

The procedures that should be used for characterizing isolates of *Alysiella* are identical to those used for *Simonsiella*, and they are presented in the description of that genus.

Differentiation of the genus *Alysiella* from other genera

The unusual morphology of the *Alysiella* filaments serves to differentiate the genus from all other procaryotic organisms. *Alysiella* filaments differ from *Simonsiella* in consisting of continuous pairs of cells instead of being segmented into units of eight cells,

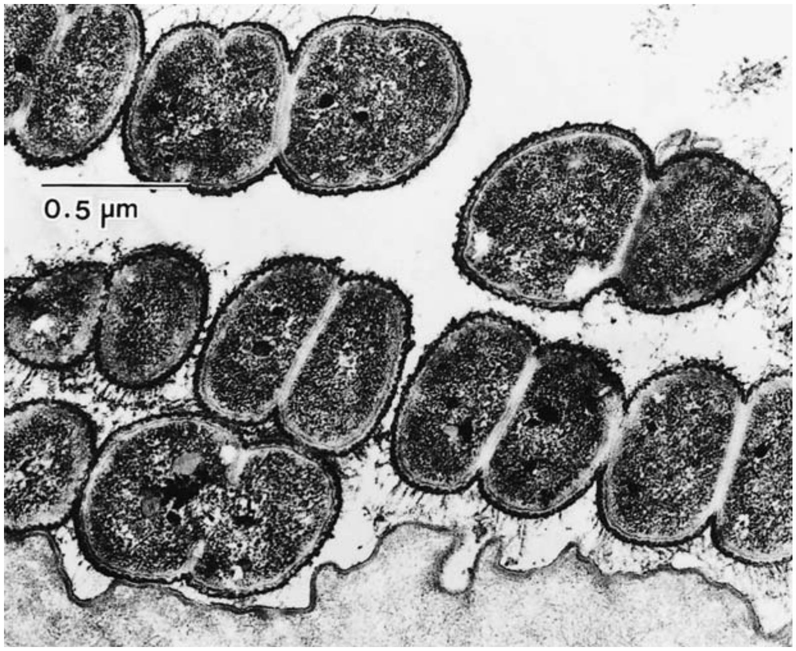

FIGURE BXII.β.66. Section of *Alysiella* from the bovine tongue, showing ruthenium red-stained fibrils emanating from one side of the filament only. (Photo courtesy of J.W. Costerton.)

and the terminal cells are not rounded, but square. In addition, *Alysiella* has a fringe of fibers on the side of the filament rather than on the bottom as in *Simonsiella*. Furthermore, *Alysiella* does not show the dorsal–ventral, convex–concave curvature of *Simonsiella*.

Taxonomic Comments

Alysiella has been reported from the oral cavity of many animals including chickens, sheep, horses, cows, goats, pigs, rabbits, and guinea pigs. Isolates have only been obtained from guinea pigs (Berger, 1963), sheep (Steed, 1962), and cows (McCowan et al., 1979); only a few strains from sheep have been described in detail. Strains from other animals have resisted isolation. It is probable that as strains from other animals are isolated, there will prove to be additional species, just as with *Simonsiella*. The analysis of misnamed *Alysiella* strains has confused the taxonomic work on this entity (Rossau et al., 1989). However, the combined and repeated findings on *Alysiella* morphology (Kaiser and Starzyk, 1973), cellular carbohydrate pattern (Heiske and Mutters, 1994), ribosomal RNA hybridization (Rossau et al., 1989), and 16S rDNA sequence analysis on the verified type strain clearly show that *Alysiella* belongs to the family *Neisseriaceae*. The complete data also indicate that *Alysiella* is a separate genus within this family, closely affiliated with the genus *Simonsiella* (see Fig. BXII.β.76 under chapter on the genus *Simonsiella* and Fig. BXII.β.61 under chapter on the order *Neisseriales*).

Acknowledgments

The information provided in the first version of *Bergey's Manual of Systematic Bacteriology* (1984) by J.M. Larkin is greatly acknowledged.

Differentiation of the species of the genus *Alysiella*

Only a single species of *Alysiella* is currently recognized. The multicellular spore formers found in the rumen of domestic animals and in the cecum of guinea pigs that Grassè (1924) termed *Alysiella filiformis* are probably members of the genus *Arthromitus* (Kuhn, 1981). Some strains in the literature have been misnamed as *A. filiformis* (Rossau et al., 1989).

List of species of the genus Alysiella

1. **Alysiella filiformis** (Schmid *in* Simons 1922) Langeron 1923, 118[AL] *Simonsiella filiformis* Schmid *in* Simons 1922, 509.)

fi.li.for′ mis. L. n. *filum* thread; L. n. *forma* shape; M.L. adj. *filiformis* filiform.

See the generic description for additional features. *Alysiella* is aerobic, possesses cytochrome oxidase, and produces catalase. Good growth occurs between 33° and 40°C, with an optimal temperature at 37°C. Growth also occurs at 43°C but not at 27°C. This organism grows in the presence of 1% but not 1.5% NaCl. Grows at pH 7.3 and 9.0 but not 6.0. Acid is produced from D-fructose, α-D-glucose, maltose, sucrose, and trehalose. No acid is produced from the following: L-arabinose, cellobiose, dulcitol, erythritol, D-galactose, glycerol, inositol, α-lactose, mannose, melibiose, melizitose, raffinose, rhamnose, salicin, sorbitol, sorbose, or xylose. Variable results occur on inulin and ribose. A rich medium containing 10% serum is best for growth. A slight hydrolysis of gelatin may occur, but agar, casein, starch, esculin, and hippurate are not hydrolyzed. No change occurs in litmus milk. Indole, MR, VP, and reduction of nitrates are negative. Urease is not produced. H_2S production is variable and inconsistent. Hemolytic on rabbit or horse blood agar. The type strain was isolated from sheep saliva.

The mol% G + C of the DNA is: 44–48 (T_m, Bd).

Type strain: ATCC 15532, ATCC 29469, CIP 103342, ICPB 3653, HIM 928-7,NCTC 10282.

GenBank accession number (16S rRNA): AF487710.

Genus III. **Aquaspirillum** *Hylemon, Wells, Krieg and Jannasch 1973b, 36l*[AL]*

Bruno Pot and Monique Gillis

Aq.ua.spi.ril' lum. L. *aqua* water; Gr. n. *spira* a spiral; N.L. dim. neut. n. *spirillum* a small spiral; *Aquaspirillum* a small water spiral.

Rigid, helical cells, 0.2–1.4 μm in diameter; however, one species is vibrioid and one species contains straight-to-curved rods. A polar membrane underlies the cytoplasmic membrane at the cell poles in all species so far examined for this characteristic by electron microscopy. **Intracellular poly-β-hydroxybutyrate** is formed, except in two species. Some species form thin-walled coccoid bodies, which predominate in cultures of three to four weeks. **Gram negative**. **Motile by polar flagella, generally bipolar tufts**; one species is monotrichous, others have a single flagellum at one or at each pole. **Aerobic to microaerophilic**, having a respiratory type of metabolism with **oxygen as the terminal electron acceptor**; a few species can grow anaerobically with nitrate. The optimal growth temperature for most species is 30–32°C. **Chemoorganotrophic**; however, one species is a facultative hydrogen autotroph. **Oxidase positive. Usually catalase and phosphatase positive. Indole and sulfatase negative**. Casein, starch, and hippurate are not hydrolyzed. No growth occurs in the presence of 3% NaCl. A few species can denitrify. Nitrogenase activity occurs in some species, but only under microaerobic conditions. Carbohydrates are not usually metabolized, but a few species can attack a limited variety. Amino acids or the salts of organic acids serve as carbon sources. Vitamins are not usually required. Usually occur in stagnant, freshwater environments.

The mol% G + C of the DNA is: 49–66.

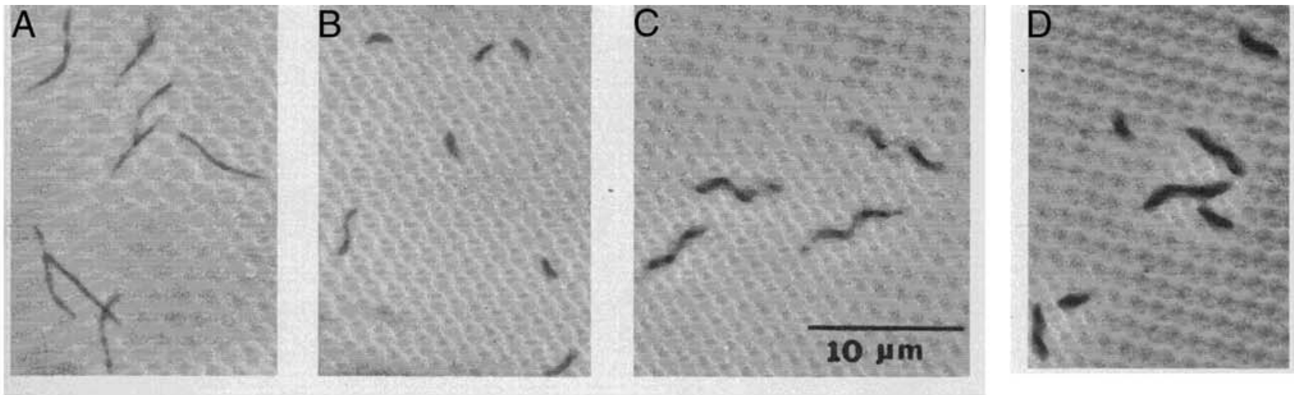
Type species: **Aquaspirillum serpens** (Müller 1786) Hylemon, Wells, Krieg and Jannasch 1973b, 366 (*"Vibrio serpens"* Müller 1786, 48.)

Further descriptive information

Cellular morphology Most species of *Aquaspirillum* have helical cells; however, *A. delicatum* is vibrioid (has less than one complete turn or twist). Variants that are nearly straight rods have been obtained from helical species after prolonged transfer (Terasaki, 1972). For helical aquaspirillae, the cells within a given species have a constant type of helix clockwise (right-handed) or counter-clockwise (left-handed) (Terasaki, 1972). The effect of the beta-lactam antibiotic cephalexin on the spiral conformation has been examined by scanning electron microscopy (Konishi and Yoshii, 1986). *A. itersonii* and *A. peregrinum*, which have a left-handed spiral shape, maintained this shape in elongated cells in medium containing cephalexin. The spiral conformation of the elongated cells is therefore considered to represent the natural condition (Konishi and Yoshii, 1986). Photographs showing the comparative size and shape of various aquaspirillae are presented in Fig. BXII.β.67.

Although aquaspirillae are more rigid than spirochetes, they do have a certain degree of flexibility. For example, during rapid swimming the helical cells tend to become straighter. Also, cells embedded in glycerol gelatin can be stretched to three times their original length (Isaac and Ware, 1974).

As unusual elaboration of the plasma membrane, the "polar membrane," occurs in all of the species examined so far (I.J. Beveridge and R.G.E. Murray, unpublished results). It is attached to the inside of the plasma membrane by bar-like links and is most commonly located in the region surrounding the polar flagella (Murray and Birch-Andersen, 1963; Fig. BXII.β.68). Such a membrane has been found mainly in genera of helical bacteria, such as *Spirillum*, *Oceanospirillum*, *Campylobacter*, *Ectothiorhodospira*, and *Rhodospirillum*.



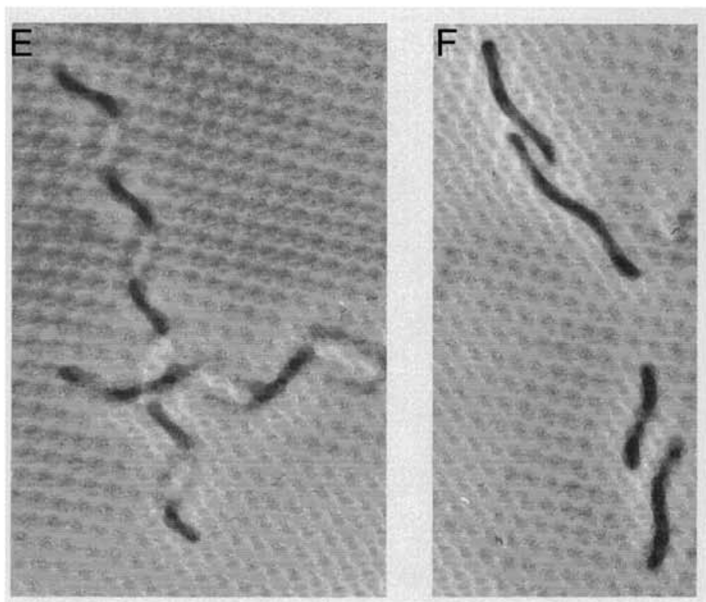
Intracellular poly-β-hydroxybutyrate occurs in all species except *A. gracile* and *A. psychrophilum*. The granules of this polymer stain with metachromatic dyes such as toluidine blue (Martinez, 1963), as well as with lipid-soluble dyes such as Sudan black.

In certain species, the cells develop into thin-walled coccoid bodies (sometimes termed "microcysts") within several days to several weeks. All species may show a few such forms in old cultures, but in *A. itersonii*, *A. peregrinum* subsp. *peregrinum*, and *A. polymorphum* they predominate. Such coccoid bodies are also formed by members of the genus *Oceanospirillum* and the genus *Campylobacter*. In *A. itersonii*, the development of the helical cells into coccoid bodies can be greatly accelerated by treatment with mitomycin or ultraviolet light; this effect has been correlated with the induction of a defective bacteriophage (Clark-Walker, 1969). Whether the coccoid bodies of aquaspirillae are resistant to desiccation, or whether they are viable, is not known.

Most species of *Aquaspirillum* are motile by means of bipolar tufts or fascicles of flagella; however, *A. delicatum* usually has 1–2 flagella at a single pole, and *A. polymorphum* has bipolar single flagellum. Aquaspirillae generally have flagella that are crescent shaped or that have a long wavelength (over 3 μm), with less than one complete wave. Such flagella are especially likely to occur with the larger aquaspirillae such as *A. serpens*, *A. metamorphum*, and *A. putridiconchylium*, and the motility of such spirilla is similar to that described for *Spirillum volutans* (i.e., the flagellar fascicles form cones of revolution). However, some aquaspirillae, especially those that are small or medium in cell diameter such as *A. dispar* or *A. delicatum*, have more conventional, helical flagella (see Hylemon et al., 1973b).

A. serpens has been studied extensively with regard to its flagella cell-wall association (Coulton and Murray, 1978), cell-wall ultrastructure, and cell-wall chemical composition (Murray et al.

**Editorial Note:* Phylogenetically, the genus *Aquaspirillum* is heterogeneous; however, it is difficult to definitively delineate new genera for potentially misclassified species. Therefore these organisms are retained in the genus *Aquaspirillum*. The following species are not true aquaspirillae (i.e., not phylogenetically related to the type species, *Aquaspirillum serpens*, at the genus level) but have not been transferred to other genera: *A. anulus*, *A. autotrophicum*, *A. delicatum*, *A. dispar*, *A. giesbergeri*, *A. gracile*, *A. metamorphum*, *A. polymorphum*, *A. psychrophilum*, *A. putridiconchylium*, and *A. sinuosum*. Aquaspirillae that have been generically renamed since the first edition of the *Bergey's Manual of Systematic Bacteriology* (Krieg, 1984a), or for which a new genus name is proposed here, include: *Aquaspirillum aquaticum*, *A. bengal*, *A. fasciculus*, *A. itersonii*, *A. magnetotacticum*, and *A. peregrinum*.



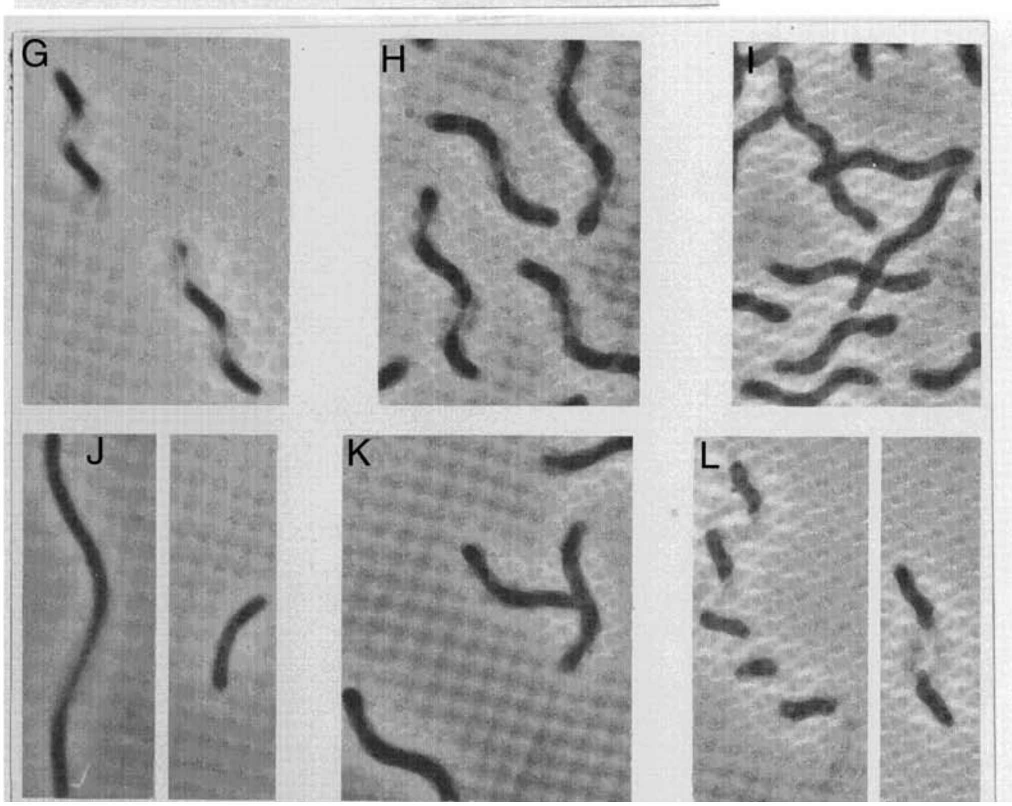


FIGURE BXII.β.67. Phase-contrast photomicrographs of several species of the genus *Aquaspirillum*. The spirillae were cultured in MPSS broth for 24–48 h at 30°C; however, *A. serpens* subsp. *bengal* was incubated at 37°C and *A. delicatum* was cultured in nutrient broth, since its morphology and mobility are more characteristic in this medium. All photographs were taken at the same magnification. *A*, *A. gracile* ATCC 19624. *B*, *A. delicatum* ATCC 14667. *C*, *A. polymorphum* NCIB 9072. *D*, *A. dispar* ATCC 27510. *E*, *A. sinuosum* ATCC 9786. *F*, *A. putridiconchylium* ATCC 15279. *G*, *A. serpens* subsp. *serpens* strain VH. *H*, *A. serpens* subsp. *serpens* ATCC 12638. *I*, *A. serpens* subsp. *bengal* ATCC 27641. *J*, *A. metamorphum* ATCC 15280. *K*, *A. anulus* NCIB 9012. *L*, *A. giesbergeri* NCIB 8320. (Reproduced with permission from N.R. Krieg, Bacteriological Reviews *40:* 55–115, 1976, ©American Society for Microbiology.)

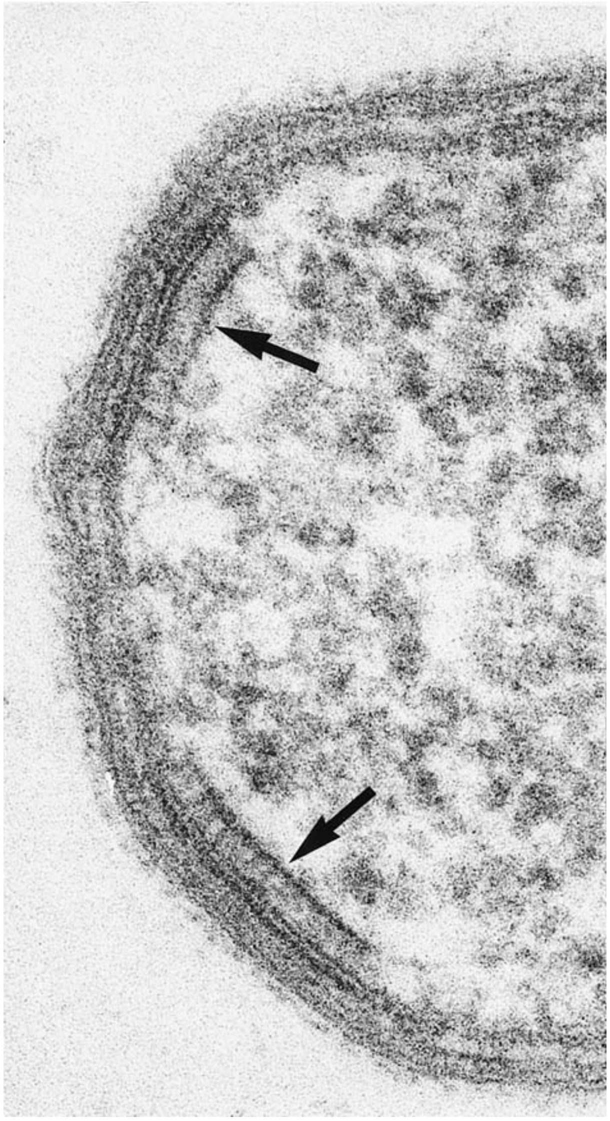

FIGURE BXII.β.68. Thin-section through the polar region of a cell of *Aquaspirillum serpens* strain VHA, showing the polar membrane (*arrows*). A protein layer can also been seen external to the outer wall membrane. × 262,000. (Reproduced with permission from R.G.E. Murray, University of Western Ontario, London, Canada.)

1965; Chester and Murray, 1975, 1978). A protein layer, consisting of a regular array or mosaic of subunits, surrounds the cell walls of certain species of aquaspirillae (Buckmire and Murray, 1970; Beveridge and Murray, 1976; Stewart et al., 1980). Such protein layers can be dissociated by agents such as sodium dodecyl sulfate or guanidine, and can subsequently be reassembled onto templates *in vitro* in the presence of Ca^{2+}. One function of the protein layer of *A. serpens* is to protect against attack by bdellovibrios (Buckmire, 1971). The cell wall lipopolysaccharide of *A. serpens* differs from that of the majority of other Gram-negative bacteria in that it lacks 2-keto-3-deoxyoctonic acid (Chester and Murray, 1975); this compound is also present in the lipopolysaccharide of *A. itersonii* and *A. peregrinum*. In *A. serpens*, lipid A of the lipopolysaccharide differs from that found in members of *Enterobacteriaceae* in that 3-hydroxydodecanoic acid, rather than 3-hydroxytetradecanoic acid, is the *N*-acylating acid.

Physiology All species of *Aquaspirillum* are aerobic. Although *A. itersonii* and *A. peregrinum* can acidify fructose-containing media sealed with a layer of oil or petrolatum, significant turbid growth does not occur, and these species should be considered to have an essentially oxidative type of metabolism. *A. itersonii*, *A. dispar*, and *A. psychrophilum* can grow anaerobically using nitrate and possess a dissimilatory nitrate reductase. *A. itersonii*, *A. dispar*, and *A. psychrophilum* can reduce nitrate beyond nitrite, but only *A. psychrophilum* appears to form visible amounts of gas from nitrate (Terasaki, 1972, 1979).

The respiratory chain of *A. itersonii* has been studied in detail and appears to be an unbranched, membrane-bound electron transport chain from NADH and succinate to oxygen (Dailey, 1976). Cytochromes of both the *b* and *c* type, but not of the *a* type, are present, and their biosynthesis and properties have been investigated (Clark-Walker et al., 1967; Clark-Walker and Lascelles, 1970; Ho and Lascelles, 1971; Dailey and Lascelles, 1974). *A. itersonii* synthesizes higher levels of cytochromes *b* and *c* under semi-anaerobic conditions with nitrate in the medium than it does anaerobically without nitrate (Clark-Walker et al., 1967), and much of the cytochrome *c* is present in a soluble form in the periplasmic space (Gauthier et al., 1970). This soluble cytochrome *c*, and other periplasmic proteins, can be selectively liberated from the cells by the use of a mixture of Tris buffer and EDTA (Garrard, 1971). Biosynthesis of the soluble cytochrome *c* has been investigated by Garrard (1972). The complete amino acid sequence of the cytochrome c_{550} from *A. itersonii* has been elucidated (Woolley, 1987). The sequence is a single polypeptide chain of 111 residues and shows a high degree of sequence homology with the cytochrome c_2 from the photosynthetic bacterium *Rhodospirillum rubrum*. This homology is in agreement with other phylogenetic data, as shown below.

Aquaspirillum species cannot grow in the presence of 3% NaCl, and many species cannot tolerate even 1% NaCl. This lack of salt tolerance distinguishes *Aquaspirillum* from *Oceanospirillum*, because the latter genus requires seawater or Na^+ for growth.

Commonly used culture media for aquaspirillae are PSS broth, MPSS broth, and nutrient broth[1]. Aquaspirillae generally produce moderate-to-abundant turbid growth in 2–3 d in PSS broth (Hylemon et al., 1973b). In nutrient broth, membranous masses are often formed at the surface and can be dispersed with shaking to yield turbid cultures (Terasaki, 1972).

Colonies of aquaspirillae generally develop within 2–3 d on PSS agar and are usually white, circular, and convex, ranging from pinpoint to 1.5 mm in diameter (Hylemon et al., 1973b). Colonies on nutrient agar are generally pinpoint in size at 48 h but become larger (up to 2.0 mm in diameter) at 7 d; they are usually convex or umbonate, glistening, opaque, pale yellow, and butyrous (Terasaki, 1972). S–R variation has been found in several species (Terasaki, 1972). Some species produce a water-soluble, yellow-green, fluorescent pigment on PSS agar.

Most species grow best at 30–32°C, except *A. psychrophilum*, which grows best at 20°C and cannot grow above 26°C, and *A. bengal*, which grows best at 41°C. The optimal pH for most species

1. PSS broth (g/l): Bacto Peptone (Difco), 10.0; succinic acid (free acid), 1.0; $(NH_4)_2SO_4$, 1.0; $MgSO_4 \cdot 7H_2O$, 1.0; $FeCl_3 \cdot 6H_2O$, 0.002; and $MnSO_4 \cdot H_2O$, 0.002. The pH is adjusted to 6.8 with KOH before autoclaving the medium. For PSS agar, 16.0 g of agar is added/l; for PSS semisolid medium, 1.5 g of agar is added/l. For MPSS media, use 5.0 g of peptone rather than 10.0 g. Nutrient broth (g/l): peptone, 5.0; meat extract, 3.0 g; the pH is adjusted to 7.0–7.2 with KOH before autoclaving. For nutrient agar, 15.0 g/l of agar is added.

is 6.5–7.5, but many species can grow at pH values as high as 8.5 or 9.0 (Terasaki, 1972).

The nutrition of aquaspirillae is generally simple. Most species grow in simple defined media with amino acids or the salts of organic acids as carbon sources and ammonium salts as the nitrogen source. Only *A. gracile* is known to require biotin. Few species can catabolize sugars, although a limited set of sugars can be used by *A. gracile*, *A. itersonii*, and *A. peregrinum*. Acidification of sugar media by these species occurs only when the peptone level is kept low (0.2% or less). A listing of the carbon sources for aquaspirillae is given in Table BXII.β.79. In this table, some contradictions exist between the results obtained in different laboratories, although the intralaboratory results are reproducible. These contradictions are likely due to the differences in methodology, to the definition of what constitutes a positive growth response, and, in some cases, to the use of different strains.

It is clear that the genus *Aquaspirillum* is quite heterogeneous (see below). Some of the phenotypic and nutritional differences confirm the genotypic differentiation. The subdivision of the species in the Tables BXII.β.79, BXII.β.80, BXII.β.81, BXII.β.82, and BXII.β.83 corresponds with the genotypic groupings obtained from 16S rRNA sequencing and rRNA–DNA hybridization data, as discussed below.

A. peregrinum exhibits nitrogenase activity, but only under microaerobic conditions (Strength et al., 1976). In this respect, it is similar to members of the genus *Azospirillum*. Atmospheric nitrogen fixation has also been reported in certain strains of *Aquaspirillum itersonii* (Ketkar, 1967; Ketkar and Dhala, 1978). Phylogenetic data also suggest that both species are phylogenetically more closely related to members of the genus *Azospirillum* than to other species of the genus *Aquaspirillum*.

The intermediary metabolism of sugars has been studied in *A. itersonii* and *A. gracile*. *A. itersonii* can acidify glucose media under semi-anaerobic conditions, but not under aerobic conditions (Terasaki, 1972, 1979); this observation has not yet been explained. Under aerobic conditions, *A. itersonii* is impermeable to glucose despite the occurrence of high levels of glucokinase activity (Hylemon et al., 1974). Fructose is transported and phosphorylated by means of a fructose-specific phosphoenolpyruvate phosphotransferase system (P.V. Phibbs, unpublished results). The Embden–Meyerhof–Parnas and Entner–Doudoroff pathways occur in *A. itersonii* and *A. gracile*, but the hexose monophosphate pathway is absent (Hylemon et al., 1974; Laughon and Krieg, 1974). *A. gracile* acidifies sugar media by formation of sugar acids, such as gluconic acid; other organic acids are not formed (Laughon and Krieg, 1974).

The tricarboxylic acid cycle has been demonstrated in *A. serpens* and *A. itersonii* (Cole and Rittenberg, 1971). Whether the glyoxylate shunt occurs is not known.

Serology McElroy and Krieg (1972) reported serological differentiation of most species of *Aquaspirillum*. Antisera are prepared against whole cells and adsorbed with heated cells, leaving only antibodies against thermolabile cell components. The use of such antisera in agglutination tests with a limited number of strains suggests that most species can be distinguished from one another and from organisms of other genera.

Genetics Electroporation methods and conjugal mating have been used to transfer several plasmid vectors (including the incompatibility P class plasmid RP4 by conjugation from *Escherichia coli* HB101) to *A. dispar* and *A. itersonii*. The transconjugants were able to donate the plasmid to plasmid-free *E. coli* and *A. dispar* strains by conjugal mating (Eden and Blakemore, 1991). *A. dispar* and *A. itersonii* were transformed at efficiencies as high as 3×10^4 transformants/μg plasmid DNA by high-voltage electrotransformation. RP4 DNA from *Spirillum* hosts, but not RP4 from *E. coli*, was successfully transferred to *A. dispar* and to *A. itersonii*, indicating the possible presence of a restriction/modification system in these *Aquaspirillum* species. The restriction endonuclease *Ase*I has been isolated from *A. serpens*. This enzyme recognizes the sequence 5′-AT–TAAT-3′ (Polisson and Morgan, 1988).

There has been only one report of bacteriophages for *Aquaspirillum*. An icosahedral, double-stranded DNA phage specific for a particular strain of *A. itersonii* was isolated from raw sewage in Australia by Clark-Walker and Primrose (1971). It produced plaques on plate cultures, but was unable to lyse broth cultures. Oddly, the host strain of *A. itersonii* was originally isolated from Lake Erie, U.S.A., rather than from Australia.

Ecology Aquaspirillae are considered to be nonpathogenic for humans and animals. An organism known as *"Spirillum minus"* (see *Species Incertae Sedis*) is the cause of one of the two forms of rat-bite fever in man, and another organism, *"Spirillum pulli"* (see *Species Incertae Sedis*), is apparently the cause of a diphtheritic stomatitis in chickens. Neither of these species belong to the genus *Spirillum* or to the genus *Aquaspirillum*, and their affiliation with other established genera is uncertain. A few cases of human infection have been reported to be caused by, or associated with, organisms resembling aquaspirillae (e.g., see Edwards and Kraus, 1960; Kowal, 1961). The identity of these strains is uncertain.

A total of seven strains were isolated from blood cultures of six patients and from the cerebrospinal fluid of one patient (five cases of pneumonia and two cases of pneumonia associated with meningitis). These unusual Gram-negative rods had highest protein profile similarity with *A. serpens* and *Chromobacterium violaceum* (Casalta et al., 1989), as measured by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). However, no serologic cross-reactions were observed (Western blot and immunofluorescence), and considerable differences in morphological and biochemical characteristics were seen. It was concluded that additional studies, including DNA–DNA hybridization, were required to classify this bacterium.

Spirillum-like organisms have also been detected in diseased mosquito larvae (Fulton et al., 1974), but whether they are aquaspirillae is uncertain. Giant spore-forming spirillae have been described in the intestinal contents of tadpoles by Delaporte (1964) (see *Genus Incertae Sedis "Sporospirillum"*); little is known of these organisms, but they do not appear to be *Aquaspirillum*. Tiunov et al. (1997) also reported that bacteria of the genera *Aquaspirillum* and *Cytophaga* invariably predominated in the saprotrophic bacterial community at 2 mm distance from the burrow wall of the earthworm *Lumbricus terrestris* (drilosphere). The earthworm burrow walls differed from the surrounding soil by the high density of bacteria (10 times more, or $15–20 \times 10^6$ CFU/g, at 7–10 cm depth) and by the composition. Spirillae predominated in the 2 mm zone around the burrow walls over the entire experimentation period. At distances of 5 and 10 mm from the burrow, the taxonomic structure of the bacterial community was highly diverse and varied significantly depending on the season. Identification, however, was based only on microscopic examination of isolated colonies; therefore possible con-

[a]As determined by the method of Hylemon et al. (1973b). A turbidimetrically standardized cell suspension in physiological saline was inoculated into a defined, vitamin-free medium containing the carbon sources (0.1%) and ammonium sulfate as the nitrogen source. Growth responses were measured turbidimetrically after one 72-h serial transfer from the initial cultures, using a Klett colorimeter with the blue (420 nm) filter and 16-mm cuvettes. Symbols: +, 10 or more Klett units of turbidity for all strains tested; −, less than 10 Klett units of turbidity; d, differs among strains; blank space, not determined.

[b]As determined by the method of Terasaki (1972, 1979). A cell suspension washed in basal, defined, vitamin-free medium (Williams and Rittenberg, 1957) lacking carbon sources was inoculated into similar media containing the test compounds (0.05%) and ammonium chloride as the nitrogen source. After 7 days, growth was estimated turbidimetrically. Symbols: +, a turbidity of 0.025 absorbance units or greater for all strains tested; w, a turbidity of less than 0.025; −, no growth (turbidity equals the same as the appearance of controls without a carbon source); d, differs among strains; blank space, not determined.

[c]As determined by Kumar et al. (1974), using a modification of the method of Hylemon et al. (1973b). Symbols: +, a turbidity of 0.03 absorbance units or more, using a green filter and 16-mm cuvettes; −, turbidity less than 0.03; blank space, not determined.

[d]The utilization of compounds as sole carbon sources was tested on agar plates as described by Stanier et al. (1966) using a velvet-disk replicator. The medium was the basal mineral agar described under Procedures for Testing Special Characters, supplemented with 0.2% carbohydrates or 0.1% of other compounds. Symbols: +. growth greater than on control plate with no carbon source; −, growth no greater than on control plate; blank space, not determined.

[e]As determined by the method of Canale-Parola et al. (1966). A complex growth-limiting medium containing the carbon sources at 0.5% was used. Growth in the presence of the test compounds was compared turbidimetrically or by microscopic count to that occurring in the absence of the compounds. Symbols: +, >10% increase in the growth of all strains in the presence of the test compound; −, 10% or less increase in growth; blank space, not determined.

[f]The nutritional requirements of *A. psychrophilum* have not yet been determined.

[g]Strains of subsp. *nipponicum* were not tested.

[h]Strains of subsp. *integrum* were not tested.

[i]As determined by the method of Kropinski (1975). Samples (0.1 ml) of a washed cell suspension were spread on plates of a minimal agar medium containing ammonium sulfate and niacin. Approximately 8 mg of the test compounds were placed in small areas on the plates. After incubation for 48 h, the growth response was estimated. Symbols: + growth in the area around the test compound; −, no growth; blank space, not determined.

[j]As determined by the method of Strength et al. (1976). A washed, turbidimetrically standardized suspension was inoculated into a defined, vitamin-free, semisolid medium containing the test compounds (on an equal carbon basis relative to 0.2% fumaric acid) and ammonium sulfate as the nitrogen source. Growth responses were measured turbidimetrically at 36 h after gently inverting the semisolid cultures several times to obtain an even distribution of cells. A Klett colorimeter was used (blue filter, 420 nm) with 16 mm cuvettes. Symbols: +, production of at least 10 Klett units of turbidity; −, less than 10 Klett units; blank space, not determined.

[a]Data from Sakane and Yokota (1994).

[b]Numbers refer to the percentage of a quinone system relative to total cellular quinone systems.

[c]Strain ATCC 33333^{T} has been shown to be different from strain IFO 13615^{T} (Pot, 1996).

fusion with azospirillae cannot be excluded. These "spirillae" are common in soil communities. A similar remark can probably be made regarding the description of some nitrogen-fixing *Aquaspirillum* spp. from the endorhizosphere of rice (Garcia et al., 1983; Mishustin, et al., 1984), sorghum, winter rye, annual rye grass, meadow fescue, timothy grass, meadow soft grass, hogweed cow parsnip, and common colewort growing on different soils (Berestetsky et al., 1985). Genotypic identification is needed to confirm the identity of the *Aquaspirillum* species reported.

Aquaspirillae have been isolated from a wide variety of freshwater sources, especially stagnant ones or those containing organic matter: ditch water, canal water, stagnant ponds, primary oxidation ponds, and eutrophic lakes. They have also been isolated from storage tanks of distilled water in laboratories, where the organisms and the nutrients to support their growth or survival apparently come from the surrounding air. Aquaspirillae have also been isolated from hay infusions made with pond water (the water is probably the source of the organisms) and from putrid infusions of freshwater mussels (where the mud adherent to the shellfish is probably the source).

Aquaspirillae, including strains of *A. itersonii*, have been isolated from soils polluted with chloroanilines (Surovtseva et al., 1996). Under aerobic conditions, these strains were able to grow and degrade 3- and 4-chloroaniline and 3,4-dichloroaniline as sole sources of carbon and nitrogen. Enzymes with different substrate specificity were synthesized during cultivation on different substrates, indicating a potential use for these organisms as bioremediators in soil polluted with chloroanilines (Vasilyeva et al., 1996). Identification of these microorganisms, however, has so far been based only on morphological and physiological characteristics.

Although widely distributed in nature, aquaspirillae comprise only a very small proportion of the total flora of natural habitats. Helical bacteria in general represent only 0.1–0.6% of the flora of pond mud, surface water, slime on stones, or trickling filter effluents, and less than 0.01% in most other habitats (Scully and Dondero, 1973). Consequently, an enrichment procedure is usually necessary before spirillae can be isolated from these habitats.

Chemotaxonomic characteristics In a comparison of the chemotaxonomic characteristics of 34 spirillae, Sakane and Yokota (1994) found two groups with different nonpolar fatty acid profiles. The first group consisted of aquaspirillae (and oceanospirillae) with the Q-8 quinone system and containing hexadecanoic acid ($C_{16:0}$) and hexadecenoic acid ($C_{16:1}$) as major fatty acids. This group consisted of all the aquaspirillae and oceanospirillae that belonged to the *Betaproteobacteria* and *Gammaproteobacteria*, respectively. A second group, consisting of aquaspirillae, oceanospirillae, and some magnetospirillae, had Q-9 and Q-10 quinones and contained octadecenoic acid ($C_{18:1}$) as a major fatty acid. Phylogenetically all these spirillae belong to the *Alphaproteobacteria*. With regard to the 3-hydroxy fatty acids, more than eight different profiles were found among the 34 spirillae in-

[a]Data from Sakane and Yokota (1994).

[b]The numbers refer to the percentage of an acid relative to the total nonpolar acids.

[c]The numbers refer to the percentage of an acid relative to the total 3-hydroxy acids.

[d]All strain numbers are from the IFO (NBRC) culture collection.

[e]–, absent; +, present

[f]Strain ATCC 33333[T] has been shown to be different from strain IFO 13615[T] (Pot, 1996).

TABLE BXII.β.82. Cellular concentrations of polyamines in *Aquaspirillum*, former *Aquaspirillum* species, *Magnetospirillum*, and *Spirillum*[a,b]

[a]Data from Hamana et al. (1994).

[b]Abbreviations: Dap, diaminopropane; H-Put, 2-hydroxyputrescine; Put, putrescine; Cad, cadaverine; Spd, spermidine; HSpd, homospermidine; IFO, Institute for Fermentation, Osaka, Japan; IAM, Institute of Applied Microbiology, The University of Tokyo, Tokyo, Japan; ATCC, American Type Culture Collection, Rockville, Maryland, U.S.A.; DSM, German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany; T, type strain; –, not detectable (<0.005).; ATY, growth medium containing 0.1% sodium acetate, 0.05% sodium thioglycolate, 0.01% yeast extract, 0.01% NH_4Cl, 0.01% $MgSO_4 \cdot 7H_2O$, 0.05% K_2HPO_4, 20 µM ferric citrate, pH 6.9; PY, growth medium containing 1% peptone, 0.2% yeast extract, 0.1% $MgSO_4$, pH 7.0; 199, polyamine-free growth medium from Flow Lab., Irvine, U.K., pH 7.0.

[c]Harvested at logarithmic growth phase (others were harvested at stationary growth phase).

[d]Strain ATCC 3333^{T} has been shown to be different from strain IFO 13615^{T} (Pot, 1996).

vestigated. In regard to the 2-hydroxy fatty acids, all group 2 strains contained 2-hydroxy-octadecenoic acid ($C_{18:1\ 2OH}$) and/or 2-hydroxy-*iso*-nanodecenoic acid ($C_{19:0\ iso\ 2OH}$). Only one group 1 species with Q-8, namely *A. autotrophicum*, contained a single 2-hydroxy-fatty acid, namely undecanoic acid ($C_{11:0\ 2OH}$). *A. autotrophicum* is the only member of the genus known to be a facultative hydrogen autotroph, i.e., capable of growing with CO_2 as a sole carbon source under an atmosphere containing $H_2/O_2/CO_2$ (Aragno and Schlegel, 1978). Although hydrogen autotrophy may not have been tested in other species, the separate genotypic characteristics of this species (Gillis et al., unpublished results) support these aberrant chemotaxonomic and phenotypic characteristics and its separate taxonomic position among the aquaspirillae (see below sub taxonomic comments). Chemotaxonomic data on polyamines separated the *Aquaspirillum* species into six groups (Hamana et al., 1994). The species *A. metamorphum*, *A. giesbergeri*, *A. anulus*, *A. delicatum*, *A. gracile*, *A. sinuosum*, *A. autotrophicum*, *A. putridiconchylium*, and *A. serpens* belong to the 2-hydroxyputrescine–putrescine type. *A. aquaticum* and *A. psychrophilum* belong to the 2-hydroxyputrescine–putrescine–spermidine type and differ from the above seven species by the presence of spermidine in addition to putrescine and 2-hydroxyputrescine, suggesting a corresponding phylogenetic difference. *A. dispar* belongs to the diaminopropane–2-hydroxyputrescine–putrescine–spermidine–cadaverine type. *A. peregrinum* belongs to the putrescine–spermidine type, *A. itersonii* to the putrescine–spermidine–homospermidine type, and *A. polymorphum* to the 2-hydroxyputrescine–putrescine–spermidine-homospermidine type. These last three species differ from the species mentioned above in their dominant polyamines; it has been shown (see below) that these species occupy a separate phylogenetic position.

TABLE BXII.β.83. Differential characteristics for species of the genus *Aquaspirillum* and comparison to related and former species of the genus[a]

[a]Symbols: +, positive for all strains; −, negative for all strains; W, weak reaction; blank space, not determined; H, helical (one or more complete turns or twists); V, vibrioid (less than one complete turn or twist); SR, straight rod; C, clockwise helix; CC, counterclockwise helix; BT, bipolar tufts; U (1–2), 1 or 2 flagella at only one pole; BS, single flagellum at each pole; US, single flagellum at one pole; L, lophotrichous flagellation; d, differs among strains.

[b]The phylogenetic position of *A. arcticum* has not been investigated.

[c]By phase-contrast microscopy of 24- to 48-h-old broth cultures.

[d]Determined by focusing on the bottom of the cells. The pattern //// indicates a clockwise (right-handed) helix, whereas the pattern \\\\ indicates a counterclockwise (left-handed) helix.

[e]*Prolinoborus fasciculus* is a straight rod, the length of the helix refers to the length of the rod; *A. delicatum* is vibrioid rather than helical; length of helix can not be determined; helix diameter refers to the width of the vibrio; length of helix refers to the length of the vibrio.

[f]For *A. gracile*, acid from D-glucose, D-galactose, and L-arabinose (aerobically). For *Levispirillum itersonii*, acid from glycerol (aerobically), fructose (aerobically and anaerobically), and glucose (anaerobically only). For *Levispirillum peregrinum*, acid from fructose (aerobically and anaerobically). Peptone concentrations must be kept low (0.2% or less) in order to detect changes in pH indicator. Although *Levispirillum itersonii* and *Levispirillum peregrinum* acidify sugar media anaerobically, turbid growth does not occur and the organisms should be considered to have mainly a respiratory rather than fermentative type of metabolism. *A. arcticum* uses fructose, glucose, and ribose, although the use of fructose is listed positive as well as negative in the original publication.

[g]See Procedures for Testing Special Characters.

[h]*A. gracile* requires biotin and *Comamonas terrigena* biovar aquaticum requires niacin.

[i]Acid formation from D-glucose and D-fructose belong to the differentiating features for the discrimination of *Azospirillum* species.

[j]Positive at 37°C but not at 41°C.

(*continued*)

[a]Symbols: +, positive for all strains; −, negative for all strains; W, weak reaction; blank space, not determined; H, helical (one or more complete turns or twists); V, vibrioid (less than one complete turn or twist); SR, straight rod; C, clockwise helix; CC, counterclockwise helix; BT, bipolar tufts; U (1–2), 1 or 2 flagella at only one pole; BS, single flagellum at each pole; US, single flagellum at one pole; L, lophotrichous flagellation; d, differs among strains.

[b]The phylogenetic position of *A. arcticum* has not been investigated.

[c]By phase-contrast microscopy of 24- to 48-h-old broth cultures.

[d]Determined by focusing on the bottom of the cells. The pattern //// indicates a clockwise (right-handed) helix, whereas the pattern \\\\ indicates a counterclockwise (left-handed) helix.

[e]*Prolinoborus fasciculus* is a straight rod, the length of the helix refers to the length of the rod; *A. delicatum* is vibrioid rather than helical; length of helix can not be determined; helix diameter refers to the width of the vibrio; length of helix refers to the length of the vibrio.

[f]For *A. gracile*, acid from D-glucose, D-galactose, and L-arabinose (aerobically). For *Levispirillum itersonii*, acid from glycerol (aerobically), fructose (aerobically and anaerobically), and glucose (anaerobically only). For *Levispirillum peregrinum*, acid from fructose (aerobically and anaerobically). Peptone concentrations must be kept low (0.2% or less) in order to detect changes in pH indicator. Although *Levispirillum itersonii* and *Levispirillum peregrinum* acidify sugar media anaerobically, turbid growth does not occur and the organisms should be considered to have mainly a respiratory rather than fermentative type of metabolism. *A. arcticum* uses fructose, glucose, and ribose, although the use of fructose is listed positive as well as negative in the original publication.

[g]See Procedures for Testing Special Characters.

[h]*A. gracile* requires biotin and *Comamonas terrigena* biovar aquaticum requires niacin.

[i]Acid formation from D-glucose and D-fructose belong to the differentiating features for the discrimination of *Azospirillum* species.

[j]Positive at 37°C but not at 41°C.

Enrichment and Isolation Procedures

A number of enrichment methods have been used, usually taking advantage of the ability of aquaspirillae to grow with levels of nutrients low enough to discourage active growth of many other organisms. Two methods employed by Williams and Rittenberg (1957) have yielded excellent results:

a. Peptone or yeast autolysate (1%) is added to a sample of the source water. The samples are incubated at room temperature for ~1 week or until the spirillae become numerous. A portion of this culture is then added to an equal quantity of the source water and the mixture is sterilized by autoclaving. It is then inoculated from the unsterilized portion of the initial culture. After 1–3 transfers through successively nutrient-exhausted medium, the spirillae predominate.
b. A second method is to enrich the initial sample of source water with 1% calcium malate or lactate and incubate for ~1 week. A serial transfer is then made into more source water similarly supplemented with malate or lactate. Spirillae predominate after 3 or 4 such transfers.

For isolation, the enrichments are diluted 1:100 to 1:100,000 with sterile tap water. The dilution bottles are shaken vigorously and allowed to stand at room temperature for 20 min to allow migration of spirillae to the surface of the diluent. Isolation is then accomplished by streaking the surface water onto a suitable medium such as PSS agar or nutrient agar.

For enrichment by the use of putrid infusions of mussels or mud and sand samples, see Terasaki (1963, 1970, 1980); Jannasch (1965) summarized other general methods. Special methods have been used for the following organisms: *A. gracile*, see Canale-Parola et al. (1966); *A. autotrophicum*, see Aragno and Schlegel (1978); *A. bengal*, see Kumar et al. (1974).

Maintenance Procedures

Aquaspirillae may be maintained in semisolid PSS medium at 30°C (except for *A. psychrophilum*, which is maintained at 15°C) with weekly transfer (Hylemon et al., 1973b). Cultures may also be maintained as nutrient agar stabs at room temperature (except for *A. psychrophilum* which is maintained in a refrigerator) with monthly transfer (Terasaki, 1972).

Preservation is most easily accomplished by adding a dense suspension of cells to nutrient broth containing 10% (v/v) dimethylsulfoxide, with subsequent freezing in liquid nitrogen. Terasaki (1975) reported a method for freeze-drying spirillae.

Procedures for Testing Special Characters

Characterization methods for aquaspirillae have been described in detail by Terasaki (1972, 1979) and by Hylemon et al. (1973b). The following comments refer to certain aspects of these procedures. Cell dimensions are best measured in wet mounts of broth cultures by phase-contrast microscopy, rather than by dark-field microscopy or by light microscopy of stained smears. To determine whether the cells have a clockwise or counter-clockwise type of helix, see footnote d of Table BXII.β.83. The presence of intracellular poly-β-hydroxybutyrate is best determined by chemical analysis; for example, *A. delicatum* has no visible granules but does make the polymer. The type and number of flagella is best determined by electron microscopy rather than by flagella staining (Williams, 1960). With regard to coccoid bodies, all strains have a few such forms in old cultures; however, it is only in certain species that coccoid bodies become predominant in old cultures and have taxonomic significance. For testing the acidification of sugar media it is important to use a low concentration of peptone (0.2% or less). For the urease test, cells should be cultured in PSS broth for 24 h and centrifuged and suspended in sterile water to a dense concentration. An aliquot of 0.5 ml of this suspension is then added to 2.0 ml of a medium consisting of 0.1% BES buffer (*N,N*-bis (2-hydroxyethyl)-2-aminoethane sulfonic acid), 2% urea, and 0.001% phenol red; pH 7.0. This medium must be sterilized by filtration because of the thermolability of the urea. A red or magenta color after incubation at 30°C for 24 h indicates a positive reaction, provided that controls in similar media lacking urea remain colorless. For detection of a water-soluble fluorescent pigment, cultures are streaked in a line across plates of PSS agar and incubated for 48–72 h; the covers of the plates are removed and the plates examined with an ultraviolet lamp of the type used for mineralogical specimens (254-nm wavelength). The occurrence of a distinct, yellow-green, fluorescent zone in the agar medium surrounding the growth constitutes a positive test. Cultures to be tested for nitrogenase activity should be cultured in nitrogen-deficient semisolid malate medium (see the genus *Azospirillum*) supplemented with 0.005% yeast extract. Cultures are incubated for 3 d at 30°C and then sealed with rubber vaccine bottle stoppers. Acetylene is injected to a final concentration of 10% (v/v) and the cultures are tested for ethylene production by gas chromatography after 1 h of further incubation. Controls using liquid rather than semisolid medium, and semisolid medium containing 0.1% $(NH_4)_2SO_4$, should be negative for ethylene production. For testing hydrogen autotrophy, the mineral medium of Aragno and Schlegel (1978) is used[2]. Cultures are incubated under an atmosphere of $O_2/CO_2/H_2$ (5:10:85). A requirement for both H_2 and CO_2 should be demonstrated. For testing sole carbon sources, the procedures of Terasaki (1972, 1979) or Hylemon et al. (1973b) should be followed for most species (see Tables BXII.β.79 and BXII.β.83 for additional methods). It is recommended that the type strain of the suspected species be subjected to the same battery of characterization tests as used for the new isolate in order to confirm an identification. Chemotaxonomic characteristics of the aquaspirillae and *Magnetospirillum* can be tested as described by Sakane and Yokota (1994) and Hamana et al. (1994).

Differentiation of the genus *Aquaspirillum* from other genera

Table BXII.β.84 indicates the characteristics of *Aquaspirillum* that distinguish it from other genera with similar morphological or physiological features. The phylogenetic diversity observed is used to delineate the different subgroups considered within the genus *Aquaspirillum*. The renamed *Aquaspirillum* species (see below) have been represented by their new generic names.

Taxonomic Comments

In the eighth edition of *Bergey's Manual of Determinative Bacteriology* (Krieg, 1974), a single genus, *Spirillum*, contained all of the

---

2. Mineral medium (g/l): $Na_2HPO_4 \cdot 12H_2O$, 9.0; KH_2PO_4, 1.5; $MgSO_4 \cdot 7H_2O$, 0.2; NH_4Cl, 1.0; ferric ammonium citrate, 0.005; $CaCl_2 \cdot 2H_2O$, 0.01; R trace element solution (see below), 3.0 ml; pH 7.1. For a solid medium, 17.0 g of agar is added. For both liquid and solid media, 0.05% $NaHCO_3$ should be incorporated aseptically into the sterilized medium to buffer against changes in pH caused by the CO_2 of the gas atmosphere. Trace element solution (mg/l): $ZnSO_4 \cdot 7H_2O$, 10.0; $MnCl_2 \cdot 4H_2O$, 3.0; H_3BO_3, 30.0; $CoCl_2 \cdot 6H_2O$, 20.0; $CuCl_2 \cdot 6H_2O$, 0.79; $NiCl_2 \cdot 6H_2O$, 2.0; $Na_2MoO_4 \cdot 2H_20$, 3.0.

TABLE BXII.β.84. Differential characteristics of the genus *Aquaspirillum* and other genera of oxidase-positive, motile, curved, vibrioid, or helical Gram-negative rods[a]

[a]Symbols: +, all species positive except where noted; –, all species negative except where noted; d, differs among species.

[b]*A. delicatum* is mainly vibrioid.

[c]Cells in chains resemble spirilla.

[d]In pure cultures, a proportion of the cells may be straight rods.

[e]The genus *Pseudomonas* contains straight rods and rods that are curved in one plane, but not helically curved rods.

[f]*A. delicatum* mainly has a single flagellum at one pole; *A. polymorphum* mainly has a single flagellum at each pole.

[g]*Oceanospirillum pusillum* mainly has a single flagellum at each pole.

[h]Most species of *Vibrio* have a single polar flagellum, but two species (*V. fischeri* and *V. logei*) have a tuft of polar flagella.

[i]*A. gracile* and *A. psychrophilum* lack this polymer.

[j]Growth of all species is stimulated by NaCl, and most species have an absolute requirement for Na^+.

[k]*A. gracile, Levispirillum itersonii*, and *Levispirillum peregrinum* can catabolize a very restricted number of sugars. All other species are incapable of catabolizing any carbohydrates.

[l]Only a few carbohydrates are used.

[m]Some species fix nitrogen in microaerophilic conditions, but with a source of fixed nitrogen they grow as aerobes.

[n]Only known for *M. minutulum*.

[o]*M. megaterium* has been isolated from kusaya gravy (used to produce traditional dried fish).

various aerobic and microaerophilic spirillae. However, the DNA base composition for this genus ranged from 38 to 65 mol% G + C, a range much greater than expected for a well-defined bacterial genus. Within the genus, three groups became evident: (a) the aerobic freshwater spirillae that could not tolerate 3% NaCl (mol% G + C is 49–66); (b) the aerobic marine spirillae that required seawater for growth (mol% G + C is 42–51); and (c) the large microaerophilic spirillae that belonged to the species *Spirillum volutans* (mol% G + C is 38). Accordingly, Hylemon et al. (1973a, b) divided the genus into three genera *Aquaspirillum*, *Oceanospirillum*, and *Spirillum*, respectively.

In the first edition of the *Bergey's Manual of Systematic Bacteriology* (Krieg, 1984a), for practical purposes, the single genus *Aquaspirillum* was maintained for a considerably heterogeneous group of microorganisms, as indicated by the wide range of mol% G + C (49–66). Phenotypically, however, the genus *Aquaspirillum* was based largely on a pattern of core properties considered typical for the genus. These included, besides the lack of tolerance to 3% NaCl: a helical shape; bipolar tufts of flagella; poly-β-hydroxybutyrate formation; a strictly respiratory type of metabolism; positive oxidase, catalase, and phosphatase reactions; an inability to attack sugars; hydrolysis of starch and casein; a negative indole test; an optimal growth temperature of 30°C; and a simple chemoheterotrophic nutrition with amino acids or the salts of organic acids serving as carbon sources. Species were assigned to the genus based on a similarity between their characteristics and this pattern of core features, with the recognition that exceptional characteristics may occur. Such exceptional characteristics are: a vibrioid shape or a straight rod shape, nitrogen-fixing ability, hydrogen autotrophy, lack of poly-β-hydroxybutyrate, high or low temperature optima for growth, a single flagellum at one or both poles, catabolism of a limited variety of sugars, and vitamin requirements.

Other than the wide mol% G + C range of the DNA, genotypic evidence to support the lack of phylogenetic relationship at the genus level of the various species of *Aquaspirillum* was scarce, and mainly based on 16S rRNA oligonucleotide catalogs of three *Aquaspirillum* species (Woese et al., 1982). *A. serpens* was shown to belong to group II of the phototrophic bacteria as defined by Gibson et al. (1979), or to the β-subdivision of the purple bacteria (*Proteobacteria*) (Woese et al., 1984c; Vandenberghe et al., 1985). It was found to be related to *Rhodospirillum tenue* and, to a lesser extent, to *Spirillum volutans. A. gracile* was also shown to be a member of group II, but was more closely related to *Rhodopseudomonas gelatinosa* than to *A. serpens*, *S. volutans*, or *R. tenue.* Importantly, *A. itersonii* was found to be a member of group I or the α-subdivision of the purple bacteria (*Proteobacteria*) (Woese et al., 1984b) and to be related to *Rhodospirillum rubrum* and *Azospirillum brasilense.* The relationship of *A. itersonii* and *A. polymorphum* to the genus *Azospirillum* was also demonstrated by rRNA–DNA hybridization studies (De Smedt et al., 1980).

Subsequent rRNA–DNA hybridizations (Willems et al., 1991a, c; Pot et al., 1992b; Pot, 1996), DNA–DNA hybridizations (Boivin et al., 1985; Pot, 1996), and 16S rRNA sequencing results (Kawasaki et al., 1997; Wen et al., 1999) confirmed this extensive genotypic heterogeneity and revealed some unexpected relationships. It is striking that most of these genotypic variations could not be linked to clear phenotypic descriptions of well-defined separate taxa. Still, some formal taxonomic changes have recently been introduced.

As suggested by Krieg (1984a), DNA–DNA hybridization showed that indeed some species did not deserve separate species status; e.g., it was shown that *A. serpens* and *A. bengal* belonged to a single species (Boivin et al., 1985; Pot, 1996), with DNA–DNA hybridization values between 59 and 73%. Consequently, *A. bengal* was included in *A. serpens* as *A. serpens* biovar bengal. *A. serpens* biovar bengal showed an average of 58% DNA–DNA relatedness to three reference strains of *A. serpens*, while the average DNA–DNA relatedness between these *A. serpens* strains (ATCC 12638^{T}, 15278, and 27050) was 72%. Considering these values and the clear phenotypic differences (Tables BXII.β.79 and BXII.β.83), *A. serpens* biovar bengal could be regarded as a subspecies of *A. serpens* or even as a separate species. The description of the two subspecies, *A. serpens* subsp. *bengal* and *A. serpens* subsp. *serpens*, was first mentioned by Pot (1996) and will be proposed here.

The position of *A. serpens* biovar azotum is, at present, not very clear. Pot (1996) showed by SDS-PAGE of whole-cell proteins that strain ATCC 11335 belonged to *A. serpens* (comparison with strains Murray VHA, Murray St. Rhodes, Murray VHL, Murray VH, ATCC 27050, and ATCC 12638^{T}), confirming some of the serological relationships observed by McElroy and Krieg (1972) and the phenotypic similarity found by Hylemon et al. (1973b) and Carney et al. (1975). However, strain ATCC 11335 was shown by SDS-PAGE of whole-cell proteins to be different from its supposed homologous subculture NCIB 9011 (Pot, 1996). The latter strain was found to be as far removed from *A. serpens* as the genera *Neisseria* and *Chromobacterium* and had no significant DNA–DNA relatedness with the other *A. serpens* strains (Pot, 1996). Possibly this subculture of NCIB 9011 can be regarded as a contaminant.

A polyphasic study resulted in the inclusion of *A. aquaticum* and 13 clinical isolates previously designated EF group 10 (Falsen, 1996) in *Comamonas terrigena* (Willems et al., 1991c; and the chapter on *Comamonas* in this *Manual*). Consequently *A. aquaticum* should be considered as a junior synonym of *Comamonas terrigena.* The synonymy between *C. terrigena* and *A. aquaticum* was previously suggested by 16S rRNA cataloging data (Woese et al., 1984c).

Seven other *Aquaspirillum* species were classified in the *Comamonadaceae* based on rRNA–DNA hybridizations and 16S rDNA sequencing (Willems et al., 1991c; Wen et al., 1999; the chapter on the *Comamonadaceae* in this *Manual*): *A. anulus*, *A. delicatum*, *A. giesbergeri*, *A. gracile*, *A. metamorphum*, *A. sinuosum*, and *A. psychrophilum.* These species are phylogenetically too distantly removed from the type species, *A. serpens*, to be considered members of the genus *Aquaspirillum. A. anulus*, *A. giesbergeri*, and *A. sinuosum* share a relatively low mol% G + C content (57–58). SDS-PAGE analysis of whole-cell proteins showed that the type strains of *A. giesbergeri* and *A. sinuosum* are very similar (a Pearson correlation of 0.9), with only small differences in the zone with molecular weights between 40,000 and 70,000, and therefore possibly belong to a single species. Further DNA–DNA hybridization studies are necessary to confirm this similarity. *A. giesbergeri* and *A. sinuosum* together constitute a separate rRNA branch in the *Comamonadaceae.* The position of *A. anulus* as a separate rRNA branch has been solely determined by rRNA–DNA hybridizations (Pot et al., 1992b).

A. delicatum, *A. gracile*, *A. metamorphum*, and *A. psychrophilum* have mol% G + C values of 62–66. *A. psychrophilum* and *A. metamorphum* have 97.2% 16S rDNA sequence similarity and con-

stitute a separate rRNA branch in the *Comamonadaceae*. *A. delicatum* belongs to the same rRNA branch as *Rhodoferax* (96.8% 16S rDNA sequence similarity). More data are needed to determine whether *A. delicatum* should be considered as a third species in *Rhodoferax* (Hiraishi et al., 1991a; Hiraishi, 1994; Madigan et al., 2000b), which currently contains two species of curved rods to spirillae, able to grow phototrophically and having a mean mol% G + C of ~61. A possible relationship between *A. delicatum* and *Comamonas* had already been suggested (Krieg, 1984a) because *A. delicatum* is vibrioid rather than helical, and has one or two flagella at only one pole rather than bipolar flagellar tufts. Although Leifson (1962) placed the organism in the genus *Spirillum* (*Aquaspirillum*), he recognized that it differed morphologically from typical spirillae and suggested the possibility of creating a new genus for such non-carbohydrate-utilizing vibrios.

A. gracile belongs to a separate group deeply branching within the *Comamonadaceae*. The detailed chemotaxonomic data on polyamines, quinones, 2- and 3-hydroxy fatty acids, and main nonpolar fatty acids (Hamana et al., 1994; Sakane and Yokota, 1994) are displayed in Tables BXII.β.80, BXII.β.81, and BXII.β.82, but do not completely support the division on the basis of 16S rDNA sequence analysis. For example, *A. psychrophilum* differs considerably from *A. metamorphum* in its polyamine content and in its 3-hydroxy fatty acid content.

The considerable phenotypic inertness of the aquaspirillae, the lack of uniform phenotypic testing procedures, and the large phenotypic differences observed with the other genera of the *Comamonadaceae* make it difficult to phenotypically describe *Aquaspirillum* species within the family *Comamonadaceae*. Until more phenotypic characters are available, or until genotypic parameters can be used exclusively for the description of taxonomic entities, the species will be maintained in the genus *Aquaspirillum*.

Aquaspirillum fasciculus received special attention in the first edition of *Bergey's Manual of Systematic Bacteriology* (Krieg, 1984a). This species showed many characteristics atypical for the aquaspirillae (straight-rod shape, forming of viscous flocs, failing to swim except in a viscous medium, and nitrogenase activity). However, *A. fasciculus* did possess bipolar tufts of flagella, formed poly-β-hydroxybutyrate, had a strictly respiratory type of metabolism, did not attack sugars, could not grow with 3% NaCl (or even 1% NaCl), had a simple nutrition, grew best at 30°C, was indole-negative, did not hydrolyze starch or casein, possessed oxidase, catalase, and phosphatase activity, and had a mol% G + C content of the DNA of 62–65. Moreover, *A. fasciculus* formed coccoid bodies in abundance, which is a characteristic of certain aquaspirillae and other helical or vibrioid bacteria (*Oceanospirillum*, *Campylobacter*, *Desulfovibrio*, and *Vibrio*; see Williams and Rittenberg, 1957; Ogg, 1962; Levin and Vaughn, 1968; Felter et al., 1969; Baker and Park, 1975). Furthermore, the presence of a polar membrane is also a characteristic mainly associated with helical bacteria (Murray and Birch-Andersen, 1963; Hickman and Frenkel, 1965a, b; Keeler et al., 1966; Ritchie et al., 1966), although it has also been found in the rod-shaped organism *Chromatium* (Murray and Birch-Andersen, 1963). Nitrogenase activity, typical for *A. fasciculus*, but unusual for aquaspirillae, did occur in two helical species. The morphology of some aquaspirillae is variable: Strength et al. (1976) reported the isolation of a strain with rods very similar to *A. fasciculus*, but after prolonged transfer many cells were found to be curved or even S-shaped. Moreover, some typical helical species develop variants that are nearly straight rods upon prolonged transfer (Williams, 1959a, b; Terasaki, 1973). Genotypic comparison of *A. fasciculus* to other *Aquaspirillum* species by rRNA–DNA hybridization showed that the species has to be regarded as belonging to a separate genus, for which the name *Prolinoborus* has been proposed (see the genus *Prolinoborus* in this family).

Another species with a separate phylogenetic position is *A. autotrophicum*, which can grow autotrophically under an atmosphere of oxygen, carbon dioxide, and hydrogen. Other members of *Aquaspirillum* are not facultative hydrogen autotrophs or have not been tested for this character. The other characteristics of *A. autotrophicum* are completely consistent with the description of the genus *Aquaspirillum*. However, rRNA–DNA hybridization data showed that this species is phylogenetically more closely related to *Janthinobacterium lividum* and *Herbaspirillum* than to *A. serpens*, the type species of the genus *Aquaspirillum* (Pot, 1996). 16S rDNA sequence analysis confirmed the relationship between *Herbaspirillum* and *Janthinobacterium* (Kirchhof et al., 2001). Whether *A. autotrophicum* can be considered as a separate species of *Herbaspirillum*, or deserves a separate genus status, requires further study.

The taxonomic position of *A. dispar* has been partially clarified. The two available strains of *A. dispar* (ATCC 27510^T and ATCC 27650) showed 88–100% DNA–DNA binding, and have nearly identical electrophoretic protein profiles (Aragno and Schlegel, 1978; Pot, 1996). Both strains shared the highest rRNA cistron similarity with *Chromobacterium violaceum* NCTC 9757^T, although according to 16S rRNA cataloging, *A. dispar* appeared to be more closely related to *A. serpens* than to *Chromobacterium violaceum*. Because of a $T_{m(e)}$ difference of 6°C (Pot, 1996) or more, and some considerable phenotypic differences, *A. dispar* cannot be assigned to the genus *Chromobacterium*. More data are required to determine its exact relationship to a new genus, *Vogesella* (see the genus *Vogesella* in this family), which is phylogenetically the closest neighbor of *Chromobacterium*.

A. putridiconchylium also belongs in the *Betaproteobacteria*, where it constitutes a separate branch (Pot, 1996); a close taxonomic relationship with *A. dispar* is excluded. Because neither of these species can be discriminated phenotypically from the *Aquaspirillum* species, we continue to consider them as separate species of the genus *Aquaspirillum*.

Three species of the genus *Aquaspirillum* belong to the *Alphaproteobacteria* based on rRNA–DNA hybridization and 16S rRNA gene sequencing. *A. itersonii* and *A. peregrinum* were more closely related to *Rhodospirillum rubrum* and *Rhodospirillum photometricum* (Kawasaki et al., 1997), and formed a separate branch in the *Alphaproteobacteria*. *A. polymorphum* was shown to be most closely related to *Magnetospirillum gryphiswaldense*. Schleifer et al. (1991) proposed this generic name for the former species *Aquaspirillum magnetotacticum* (Blakemore et al., 1979, 1989) and the new isolate *M. gryphiswaldense*. Also, it was shown by rRNA–DNA hybridization that *A. itersonii* and *A. peregrinum* form a separate rRNA branch at the node of the *Azospirillum* and *Rhodospirillum rubrum* branch (Pot, 1996). The different subspecies of *A. peregrinum* and *A. itersonii* were shown by 16S rRNA gene sequence comparison to be very highly related within each species (Kawasaki et al., 1997). *A. peregrinum* subsp. *peregrinum* and *A. peregrinum* subsp. *integrum* showed 91% DNA–DNA relatedness and clearly belong to a single species (Pot, 1996). In our hands, however, the two subspecies of *A. itersonii* were not closely related. *A. itersonii* subsp.

itersonii was situated on the *A. peregrinum* rRNA branch, but *A. itersonii* subsp. *nipponicum* was found to belong to the *Betaproteobacteria* (A. Willems unpublished results). In these studies, different subcultures of the type strain were used (*Aquaspirillum itersonii* subsp. *nipponicum* ATCC 33333^T by Pot (1996) and *Aquaspirillum itersonii* subsp. *nipponicum* IFO 13615^T by Kawasaki et al., 1997).

In contrast to the aquaspirillae of the *Betaproteobacteria*, the aquaspirillae of the *Alphaproteobacteria* all contain a counter-clockwise type of helix and can hydrolyze esculin. Using these characteristics, they can easily be discriminated from the authentic aquaspirillae and from *Prolinoborus*. Given these genotypic and phenotypic differences, it is possible to allocate two of these species to a new genus. The name *Levispirillum*, with *L. itersonii* and *L. peregrinum*, has been proposed (Pot, 1996) and has been effectively published but not yet validly published. The position of *A. polymorphum* is not clear: phenotypically it could belong to *Levispirillum*, but genotypically it definitely belongs to the genus *Magnetospirillum* (Kawasaki et al., 1997). It certainly does not belong phylogenetically to *Aquaspirillum*. A formal transfer, however, has not been proposed, probably because of the extensive phenotypic differences between *A. polymorphum* and *Magnetospirillum*.

Although the genus *Oceanospirillum* belongs to the *Gammaproteobacteria*, *O. pusillum* has been shown to belong to the *Alphaproteobacteria* (Woese et al., 1985; Kawasaki et al., 1997) by 16S rDNA sequence analysis. This position was confirmed by rRNA–DNA hybridization results (Pot, 1996). Using either method, the type strain occupies a separate branch in the *Alphaproteobacteria*. Although this species also has a counter-clockwise type of helix, is not capable of esculin hydrolysis, requires 3% NaCl for growth, and occupies a phylogenetically distinct position, its inclusion in the genus *Levispirillum* is questionable. Kawasaki et al. (1997) suggested creation of a new genus for this species.

Butler et al. (1989) isolated and described a new psychrophilic, straight-to-curved rod-shaped bacterium, with an optimal growth temperature of 5°C, from an Arctic sediment. It was assigned to the genus *Aquaspirillum* as *Aquaspirillum arcticum* based on its morphological and physiological characteristics. It was distinguished from *A. psychrophilum* (Terasaki, 1973, 1979) by a different optimal temperature for growth (5°C rather than 20°C), and by its ability to grow at 0°C. Unlike *A. psychrophilum*, *A. arcticum* will also grow in vitamin-free, defined, basal salts–glucose medium. Other biochemical characteristics are listed in Table BXII.β.83. *A. arcticum* was found to acquire thermotolerance when heat shocked or treated with nalidixic acid, two conditions responsible for the introduction of heat shock- or stress proteins (McCallum and Inniss, 1990; Gounot, 1991). This indicates that growth temperature is not necessarily a reliable parameter for delineation of species. Genotypic or phylogenetic information is not presently available for *A. arcticum*.

Taxonomic conclusions In the past, species descriptions have been based mainly on differences in morphology, nutrition, and DNA base composition. In some cases, such species are obviously different; for example, a small spirillum such as *A. polymorphum* would not belong to the same species as a large spirillum (such as *A. serpens*), and a spirillum having a mol% G + C of 50 would not be placed in the same species as one with a mol% G + C of 60. However, species distinctions within a particular morphological group of strains having a similar DNA base composition are less firm. Another difficulty is that many species are represented by only one or two strains, and the limits of variation within such a species may be broader than is presently assumed. Therefore, it was suggested by Krieg (1984a) that some species may not deserve separate species status while other species may represent more than a single species. Genotypic analysis of most aquaspirillae confirmed these observations. The true aquaspirillae should be restricted to the type species *Aquaspirillum serpens*, including the former species *Aquaspirillum bengal*. All other species are phylogenetically too distantly related to be regarded as "true" or authentic aquaspirillae. However, with the exception of a few species, the majority cannot be described reliably from the phenotypic point of view. Therefore they are presently retained in the genus *Aquaspirillum*. The genus definition needed only minor adaptations so as to compensate for the formal removal of *Aquaspirillum fasciculus*, *Aquaspirillum aquaticum*, *Aquaspirillum peregrinum*, and *Aquaspirillum itersonii*.

The two *species incertae sedis*, *"Spirillum minus"* and *"Spirillum pulli"*, do not belong to the genera *Aquaspirillum*, *Oceanospirillum*, or *Spirillum*, and their placement is uncertain. Studies of these species have been hampered by the lack of reproducible *in vitro* cultivation methods. They do not appear on the Approved Lists of Bacterial Names because no type or reference strains are available and the organisms are not well characterized. The disease syndromes caused by these species are distinct and recognizable, however. If possible, neotype strains should be designated and either maintained by animal passage or preserved in a recognized culture collection.

Acknowledgments

We acknowledge Dr. N.R. Krieg for the template text, figures, and tables on which this chapter has been based.

List of species of the genus Aquaspirillum

1. **Aquaspirillum serpens** (Müller 1786) Hylemon, Wells, Krieg and Jannasch 1973b, 366^{AL} (*"Vibrio serpens"* Müller 1786, 48.)

   ser′pens. L. v. *serpo* to crawl or creep; L. part. adj. *serpens* creeping.

   The morphological characters are depicted in Fig. BXII.β.67 and described in Table BXII.β.83. Optimal growth temperature 35°C. Chemotaxonomic and physiological characters are described in Tables BXII.β.80, BXII.β.81, BXII.β.82, and BXII.β.83. Sole carbon sources

are listed in Table BXII.β.79; the best growth occurs with glutamate. Nitrate is not used as a sole nitrogen source; results with ammonium salts have been conflicting (Terasaki, 1972; Hylemon et al., 1973b). A defined medium suitable for batch and continuous cultures has been described by Whitby and Murray (1980).

Habitat: pond waters.

Aquaspirillum serpens belongs phylogenetically to the *Betaproteobacteria* (Pot, 1996). The former species *Aquaspirillum bengal* (Kumar et al., 1974, 457) has been assigned to *A. serpens* as *A. serpens* biovar bengal (Boivin et al., 1985). Based on sufficient phenotypic differences and a low level of DNA relatedness, *A. serpens* biovar bengal could be regarded as a subspecies of *A. serpens* or even as a separate species.

The mol% G + C of the DNA is: 49–51 (T_m).

Type strain: ATCC 12638, DSM 68.

a. **Aquaspirillum serpens** *subsp.* **serpens** *subsp. nov.* (*Aquaspirillum serpens* (Müller 1786) Hylemon, Wells, Krieg and Jannasch 1973b, 366; *"Vibrio serpens"* Müller 1786, 48.)

Cell diameter 0.6–1.1 μm. Description as for the species. No brown pigments in media with aromatic components; some strains do produce water-soluble fluorescent pigments. Growth at temperatures from 12 to 44°C with 35°C as optimum. Can grow at pH values up to 9. Some strains produce gelatinase and ribonuclease. Can grow on EMB agar. KNO_3 can sometimes be reduced to KNO_2 (*Aquaspirillum serpens* subsp. *serpens* var. azotum ATCC 11335).

The mol% G + C of the DNA is: 49–51 (T_m).

Type strain: ATCC 12368, DSM 68.

b. **Aquaspirillum serpens** *subsp.* **bengal** *subsp. nov.* (*Aquaspirillum bengal* Kumar, Banerjee, Bowdre, McElroy and Krieg 1974, 457.)

ben' gal. M.L. n. *bengal* Bengal.

The description is as for the species, but the cells are usually shorter. They have a diameter of 0.9–2.2 μm, the wavelength of the helix is 4.6–8.1 μm, and the helix length ranges from 5.2 to 22 μm. Brown pigments can be formed on media containing 0.1% tyrosine or tryptophan. Water-soluble fluorescent pigments are not produced. Can grow at temperatures from 12 to 42°C; 41°C is the optimal growth temperature. Can grow at pH values up to 8.4. No growth on EMB agar, no gelatinase and ribonuclease activity. Prefer to grow in microaerophilic conditions. KNO_3 can not be reduced to KNO_2.

The mol% G + C of the DNA is: 52 (T_m).

Type strain: ATCC 27641.

2. **Aquaspirillum anulus** (Williams and Rittenberg 1957) Hylemon, Wells, Krieg and Jannasch 1973b, 368[AL] (*Spirillum anulus* Williams and Rittenberg 1957, 86.)

a' nu.lus. L. masc. n. *anulus* a ring.

The morphological characters are shown in Fig. BXII.β.67 and described in Table BXII.β.83. Optimal growth temperature 27–30°C. Chemotaxonomic and physiological characters are described in Tables BXII.β.80, BXII.β.81, BXII.β.82, and BXII.β.83. Sole carbon sources are listed in Table BXII.β.79. Ammonium salts can be used as sole nitrogen sources; nitrate is not used.

Isolated from pond water and from putrid infusions of fresh water mussels.

Aquaspirillum anulus belongs phylogenetically to the *Comamonadaceae* (Willems et al., 1991c; Wen et al. 1999; Willems and Gillis, The *Comamonadaceae*, this volume) in which it constitutes a separate branch.

The mol% G + C of the DNA is: 58–59 (T_m).

Type strain: ATCC 35958, NCIB 9012.

3. **Aquaspirillum arcticum** Butler, McCallum, Inniss 1990, 320[VP] (Effective publication: Butler, McCallum, Inniss 1989, 265.)

arc' ti.cum. L. adj. *arcticum* of the Arctic, where the species was first isolated.

The morphological characters are described in Table BXII.β.83. The species is atypical in that it possesses only a single polar flagellum rather than bipolar tufts. The species is considered psychrophilic (defined as organisms having an optimal temperature for growth of ~15°C or lower, a maximum temperature for growth of ~20°C, and a minimum growth temperature of 0°C or below; (Morita, 1975). Optimal growth temperature is 5°C. Differential characteristics are described in Table BXII.β.83. The species is atypical in that it produces acid from carbohydrates (fructose, glucose, and ribose).

Isolated from Arctic sediment; other habitats unknown.

There are no phylogenetic data available for *Aquaspirillum arcticum.*

The mol% G + C of the DNA is: not reported.

Type strain: Res-10, ATCC 49402, DSM 6444.

4. **Aquaspirillum autotrophicum** Aragno and Schlegel 1978, 116[AL]

au.to.tro' phi.cum. Gr. n. *autos* self; Gr. adj. *trophikos* nursing, tending or feeding; M.L. neut. adj. *autotrophicum* self-nursing or self-feeding.

The morphological characters are described in Table BXII.β.83. Optimal growth temperature 28°C. Chemotaxonomic and physiological characters are described in Tables BXII.β.80, BXII.β.81, BXII.β.82, and BXII.β.83. Sole carbon sources are listed in Table BXII.β.79. Ammonium salts and nitrate can be used as sole nitrogen sources.

Aquaspirillum autotrophicum is phylogenetically not closely related to the type species of *Aquaspirillum* (Pot, 1996), but belongs to the *Herbaspirillum–Janthinobacterium* rDNA branch (Gillis et al., 1991; Baldani et al., 1996; Willems et al., unpublished results). Further studies are required to determine whether it belongs in *Herbaspirillum* and/or if it deserves a separate genus status.

Isolated from an eutrophic lake in Switzerland.

The mol% G + C of the DNA is: 60–62 (T_m).

Type strain: SA 32, ATCC 29984, DSM 732.

5. **Aquaspirillum delicatum** (Leifson 1962) Hylemon, Wells, Krieg and Jannasch 1973b, 371[AL] (*Spirillum delicatum* Leifson 1962, 164.)

de.li.ca' tum. L. neut. adj. *delicatum* delicate.

Vibrioid. Chains of cells may resemble spirillae. The morphological characters are shown in Fig. BXII.β.67 and described in Table BXII.β.83, and are most characteristic for

cultures grown in nutrient broth rather than PSS broth. Intracellular poly-β-hydroxybutyrate granules are not evident, but chemical tests indicate the presence of this polymer. Optimal growth temperature 30–32°C. Chemotaxonomic and physiological characters are described in Tables BXII.β.80, BXII.β.81, BXII.β.82, and BXII.β.83. Sole carbon sources are listed in Table BXII.β.79. Growth is poor in defined media; the best growth occurs with malate as the carbon source and glutamine as the nitrogen source. Ammonium salts or potassium nitrate are used poorly as nitrogen sources.

Aquaspirillum delicatum belongs phylogenetically to the *Comamonadaceae* (Willems et al., 1991c; Wen et al. 1999; Willems and Gillis, The *Comamonadaceae*, this volume).

Isolated from stored distilled water.

The mol% G + C of the DNA is: 63 (T_m).

Type strain: 146, ATCC 14667, CCUG 15846, DSM 11558, LMG 4328, NCIB 9419.

GenBank accession number (16S rRNA): AF078756.

6. **Aquaspirillum dispar** Hylemon, Wells, Krieg and Jannasch 1973b, 372[AL]
dis' par. L. neut. adj. *dispar* unlike.

The morphological characters are shown in Fig. BXII.β.67 and described in Table BXII.β.83. Optimal growth temperature 30°C. Moderate growth at 25 and 37°C; no growth at 10 or 45°C. Chemotaxonomic and physiological characters are described in Tables BXII.β.80, BXII.β.81, BXII.β.82, and BXII.β.83. Although originally described as being unable to grow anaerobically with nitrate (Hylemon et al., 1973b), the species does grow well under these conditions (Aragno and Schlegel, 1978). Sole carbon sources are listed in Table BXII.β.79. Ammonium salts are used well as sole nitrogen sources; nitrate is not used.

Isolated from fresh water.

Aquaspirillum dispar is phylogenetically not closely related to the type species of *Aquaspirillum* (Pot, 1996); because more than 84% DNA–DNA hybridization was found with the type strain of *Microvirgula aerodenitrificans* (Cleenwerck et al., 2003), both names can be considered as subjective synonyms.

The mol% G + C of the DNA is: 63–65 (T_m).

Type strain: ATCC 27510, DSM 736.

7. **Aquaspirillum giesbergeri** (Williams and Rittenberg 1957) Hylemon, Wells, Krieg and Jannasch 1973b, 368[AL] (*Spirillum giesbergeri* Williams and Rittenberg 1957, 88.)
gies' ber.ger.i. M.L. n. *giesbergeri* of Giesberger, the first investigator to study certain physiological characteristics of spirillae.

The morphological characters are depicted in Fig. BXII.β.67 and described in Table BXII.β.83. Optimal growth temperature 30°C. Chemotaxonomic and physiological characters are as described in Tables BXII.β.80, BXII.β.81, BXII.β.82, and BXII.β.83. Sole carbon sources are listed in Table BXII.β.79. Ammonium salts can be used as sole nitrogen sources; nitrate is not used.

This species includes organisms previously assigned to the two species *"Spirillum giesbergeri"* and *"Spirillum graniferum"* by Williams and Rittenberg (1957). The two species were combined into a single species by Hylemon et al. (1973b) based on a high degree of similarity in phenotypic characters and in DNA base composition. *Aquaspirillum giesbergeri* belongs phylogenetically to the *Comamonadaceae* (Willems et al., 1991c; Wen et al., 1999; Willems and Gillis, The *Comamonadaceae*, this volume) where it constitutes a separate rRNA branch together with *A. sinuosum*. By SDS-PAGE of whole-cell proteins, it was shown that the type strains of *A. giesbergeri* and *A. sinuosum* are very similar (a correlation of 0.9) and therefore possibly belong to a single species. Further DNA–DNA hybridization data are necessary to confirm this homology.

Isolated from pond water.

The mol% G + C of the DNA is: 57–58 (T_m).

Type strain: ATCC 11334, DSM 9157, NCIB 9073, NRRL B-2060.

8. **Aquaspirillum gracile** (Canale-Parola, Rosenthal and Kupfer 1966) Hylemon, Wells, Krieg and Jannasch 1973b, 369[AL] (*Spirillum gracile* Canale-Parola, Rosenthal and Kupfer 1966, 124.)
gra.ci' le. L. neut. adj. *gracile* slender or thin.

The smallest of the aquaspirillae. The morphological characters are shown in Fig. BXII.β.67 and described in Table BXII.β.83. When originally isolated, all strains formed subsurface, spreading, semitransparent colonies on a medium containing 1.0% agar, the spreading occurring within the medium (Canale-Parola et al., 1966). After prolonged subculturing, some of the spirillae in each strain lost the ability to diffuse through 1.0% agar and formed small, nonspreading colonies. *A. gracile* was originally described as being microaerophilic, based on the growth of the organisms a few millimeters below the surface of semisolid media (Canale-Parola et al., 1966). However, later analysis of the type strain indicated that in liquid media a maximum growth response occurred under an air atmosphere (Laughon, 1973). Optimal growth temperature 30°C. Scanty growth in PSS broth at 25°C; no growth at 10 or 42°C. Chemotaxonomic and physiological characters are described in Tables BXII.β.80, BXII.β.81, BXII.β.82, and BXII.β.83. Carbon sources are listed in Table BXII.β.79. Ammonium chloride can be used as a nitrogen source but potassium nitrate cannot (Canale-Parola et al., 1966). A chemically defined medium has been devised by Laughon (1973; see also Krieg, 1976). Biotin is required for growth. Isolation is accomplished by allowing the spirilla to pass through a membrane filter disk (0.45 μm pore size) to an underlying agar medium (Canale-Parola et al., 1966).

Aquaspirillum gracile phylogenetically belongs to the *Comamonadaceae* (Willems et al., 1991c; Wen et al., 1999; see also Willems and Gillis in the chapter in this book on *Comamonas*).

Isolated from pond or stream water.

The mol% G + C of the DNA is: 64–65 (T_m).

Type strain: D4, ATCC 19624, DSM 9158.

GenBank accession number (16S rRNA): AF078753.

Additional Remarks: Reference strains are ATCC 19625 and 19626.

9. **Aquaspirillum metamorphum** (Terasaki 1961b) Hylemon, Wells, Krieg and Jannasch 1973b, 366[AL] (*Spirillum metamorphum* Terasaki 1961b, 220.)

me.ta.mor′ phum. Gr. neut. adj. *metamorphum* changing.

The morphological characters are shown in Fig. BXII.β.67 and described in Table BXII.β.83. Optimal growth temperature 30°C. Chemotaxonomic and physiological characters are described in Tables BXII.β.80, BXII.β.81, BXII.β.82, and BXII.β.83. Sole carbon sources are listed in Table BXII.β.79. Ammonium salts can be used as a sole nitrogen source; nitrate is not used.

Isolated from the putrid infusion of a freshwater mussel.

Aquaspirillum metamorphum belongs phylogenetically to the *Comamonadaceae* (Willems et al., 1991c; Wen et al., 1999; Willems and Gillis, The *Comamonadaceae*). With *A. psychrophilum*, it constitutes a separate rRNA branch within this family.

The mol% G + C of the DNA is: 63 (T_m).

Type strain: ATCC 15280, CCUG 13794, DSM 1837, IFO 12012, LMG 4339, NCIB 9509.

GenBank accession number (16S rRNA): AF078757.

10. **Aquaspirillum polymorphum** (Williams and Rittenberg 1957) Hylemon, Wells, Krieg and Jannasch 1973b, 371[AL] (*Spirillum polymorphum* Williams and Rittenberg 1957, 85.)
po.ly.mor′ phum. Gr. adj. *poly* many; Gr. n. *morphus* form, shape; M.L. neut. adj. *polymorphum* of many shapes.

Although originally reported to have bipolar tufts of flagella (Williams and Rittenberg, 1957), this species appears to have only a single flagellum at each pole (Terasaki, 1972; Hylemon et al., 1973b). The morphological characters are shown in Fig. BXII.β.67 and described in Table BXII.β.83. Optimal growth temperature 30°C. Chemotaxonomic and physiological characters are described in Tables BXII.β.80, BXII.β.81, BXII.β.82, and BXII.β.83. Although originally reported to grow anaerobically with nitrate (Williams and Rittenberg, 1957), more recent studies have not confirmed this result (Terasaki, 1972; Hylemon et al., 1973b). Sole carbon sources are listed in Table BXII.β.79. The best sole carbon sources are glutamate and aspartate; they are also the best sole nitrogen sources. Ammonium salts can serve as nitrogen sources; there are conflicting results concerning the utilization of nitrate as a sole nitrogen source (Terasaki, 1972; Hylemon et al., 1973b). Growth in PSS broth abundant, cloudy. Colonies on PSS agar are circular, convex, translucent, pinpoint.

Aquaspirillum polymorphum is a member of the *Alphaproteobacteria*; it is possibly most closely related to the genus *Magnetospirillum* (Pot, 1996; Kawasaki et al., 1997).

Isolated from pond water.

The mol% G + C of the DNA is: 61–62 (T_m).

Type strain: ATCC 11332, DSM 9160, IAM 14441, IFO 13961, NCIB 9072, NRRL B-2066.

11. **Aquaspirillum psychrophilum** (Terasaki 1973) Terasaki 1979, 138[AL] (*Spirillum psychrophilum* Terasaki 1973, 57.)
psy.chro′ phi.lum. Gr. adj. *psychros* cold; Gr. adj. *philus* liking, preferring; M.L. neut. adj. *psychrophilum* preferring cold.

The morphological characters are described in Table BXII.β.83. Grows in nutrient broth or PSS broth. Optimal growth temperature 20°C. No growth above 26°C. The organism may be best described as psychrotolerant or psychrotrophic rather than psychrophilic (Morita, 1975). Chemotaxonomic and physiological characters are described in Tables BXII.β.80, BXII.β.81, BXII.β.82, and BXII.β.83. This species has not been cultured in vitamin-free defined media and most likely has a growth factor requirement.

Isolated from Antarctic mosses.

Aquaspirillum psychrophilum belongs phylogenetically to the *Comamonadaceae* (Willems et al., 1991c, Wen et al., 1999; Willems and Gillis, The *Comamonadaceae*, this volume). With *A. metamorphum*, it constitutes a separate rRNA branch within this family.

The mol% G + C of the DNA is: 65 (T_m).

Type strain: CA 1, ATCC 33335, DSM 11588, IFO 13611, LMG 5408.

GenBank accession number (16S rRNA): AF078755.

12. **Aquaspirillum putridiconchylium** (Terasaki 1961a) Hylemon, Wells, Krieg and Jannasch 1973b, 367[AL] (*Spirillum putridiconchylium* Terasaki 1961a, 80.)
pu′ tri.di.con.chy.li.um. L. adj. *putridus* putrid, decayed; L. n. *conchylium* a shellfish; L. n. *putridiconchylium* decayed shellfish.

The morphological characters are shown in Fig. BXII.β.67 and described in Table BXII.β.83. Optimal growth temperature 32°C. Chemotaxonomic and physiological characters are described in Tables BXII.β.80, BXII.β.81, BXII.β.82, and BXII.β.83. Sole carbon sources are listed in Table BXII.β.79. Ammonium salts can be used as a sole nitrogen source; nitrate is not used.

Isolated from the putrid infusion of a freshwater mussel.

Phylogenetically, *Aquaspirillum putridiconchylium* is not closely related to the type species of *Aquaspirillum* (Pot, 1996). It constitutes a separate branch in the *Betaproteobacteria*.

The mol% G + C of the DNA is: 52 (T_m).

Type strain: ATCC 15279, IFO 12013, NCIB 9508.

13. **Aquaspirillum sinuosum** (Williams and Rittenberg 1957) Hylemon, Wells, Krieg and Jannasch 1973b, 368[AL] (*Spirillum sinuosum* Williams and Rittenberg 1957, 94.)
si.nu.o′ sum. L. neut adj. *sinuosum* full of curves.

The morphological characters are shown in Fig. BXII.β.67 and described in Table BXII.β.83. Optimal growth temperature 30°C. Chemotaxonomic and physiological characters are described in Tables BXII.β.80, BXII.β.81, BXII.β.82, and BXII.β.83. Sole carbon sources are listed in Table BXII.β.79. Ammonium salts can be used as a sole nitrogen source; nitrate is not used.

Aquaspirillum sinuosum phylogenetically belongs to the *Comamonadaceae* (Willems et al., 1991c; Wen et al., 1999; Willems and Gillis, The *Comamonadaceae*, this volume); it constitutes a separate rRNA branch together with *A. giesbergeri*. By SDS-PAGE of whole-cell proteins, it was shown that the type strains of *A. sinuosum* and *A. giesbergeri* are very similar (a correlation of 0.9) and therefore possibly belong to a single species. Further DNA–DNA hybridization studies are necessary for confirmation.

Isolated from freshwater.

The mol% G + C of the DNA is: 57–59 (T_m).

Type strain: ATCC 9786, CCUG 13728, LMG 4393, NCIB 9010, NCMB 59, NRRL B-2065, VPI 18.

GenBank accession number (16S rRNA): AF078754.

Other Organisms

1. *"Aquaspirillum bipunctata"* Dubinina, Grabovich, Lysenko, Chernykh and Churikova 1993.

bi.punc.ta′ ta. L. *bis* twice; L. part. adj. *punctatus* punctate, dotted; M.L. fem. adj. *bipunctata* twice punctate.

Dubinina et al. (1993) discussed the diagnostic criteria of the genus *Thiospira* and the taxonomic validity of this genus. Six strains of gigantic sulfur spirillae, whose characteristics corresponded to the species diagnosis of *Thiospira winogradski* and *"Thiospira bipunctata"*, were shown to belong to the genera *Spirillum* and *Aquaspirillum* according to phenotypic properties, nucleotide composition, and DNA relatedness studies. Strains D-405, D-409, D-410, D-411, and D-423, which were morphologically similar to *"Thiospira bipunctata"* formed a tight cluster phenotypically and genotypically and were assigned to a new species within the genus *Aquaspirillum* as *"Aquaspirillum bipunctata"* comb. nov. They are isolated from sediments of sewage from aerotanks and a water pond containing up to 7 mg/l H_2S. Strain D-427, which corresponded to the description of *Thiospira winogradski*, was proposed as a species of the genus *Spirillum*. The species name has not been validly published.

The mol% G + C of the DNA is: 48–51 (T_m).

Deposited strain: D-411.

2. *"Aquaspirillum denitrificans"* Dubinina, Churikova, Grabovich, Chernykh, Raichenstein and Petukhova 1989.

de.ni.tri′ fi.cans. M.L. adj. *denitrificans* pertaining to the property of denitrification.

Spiral-shaped cells, from 1 to 1.4 µm wide, 2–4.1 to 25–30 µm long. Motile with bipolar flagella. Gram negative. Poly-β-hydroxybutyrate, volutin, and elemental sulfur (in the presence of sulfides) are accumulated in the cells. Colonies are flat, nonpigmented, 2–4 mm in diameter. Facultatively anaerobic growth with nitrates, fumarate, or molecular oxygen as electron acceptors. Under anaerobic conditions, nitrates are reduced to molecular nitrogen. Growth within a pH range of 6.0–8.5; optimal pH is 7.0–8.2. Optimal temperature for growth is 28°C. Chemoorganotrophs, using a wide variety of organic acids for growth: acetate, succinate, malate, fumarate, benzoate, α-ketoglutarate, oxaloacetate, pyruvate, lactate, and glyoxylate. Use several amino acids as carbon source: tyrosine, proline, asparagine, and cysteine. Growth on yeast extract and casein hydrolysate; vitamin solution is essential for growth. Does not use carbohydrates and alcohols. Nitrates, ammonium salts, casein hydrolysate, yeast extract, peptones, cysteine, and serine are used as nitrogen source. Catalase, oxidase, and urease positive. Casein and starch not hydrolyzed. Nongelatinolytic. Does not produce indole. Nitrate reduced to nitrites. Hydrogen sulfide produced from cysteine. Does not grow with 3% NaCl. Forms brown products on benzoate medium. Cannot fix nitrogen and does not contain proteolytic enzymes. Two very similar strains have been isolated from the sewage sludge of a putrefying aero tank. A limited phenotypic comparison with *A. metamorphum*, *A. giesbergeri*, *A. itersonii*, and *A. anulus* has been published. The species name has not been validly published.

The mol% G + C of the DNA is: 60 (T_m).

Deposited strain: D-415.

3. *"Aquaspirillum elegans"* Grabovich, Churikova, Chernykh, Leshcheva, Pushkina, Shipilova and Panteleyeva 1990.

e′ le.gans. L. adj. *elegans* elegant.

Helical cells with pointed ends. Cell diameter varies from 0.6 to 1.0 µm. The length of the helix is 6.5–11 µm. Motile with bipolar flagella. Poly-β-hydroxybutyrate, volutin, and elemental sulfur (in the presence of sulfides) are stored in the cells. Colonies are flat, nonpigmented, 2–4 mm in diameter. Facultatively anaerobic growth with a strictly respiratory type of metabolism. Under anaerobic conditions, nitrates are reduced to nitrites. Grows in pH range 6.5–8.5; optimal pH is 7.5. Optimal temperature for growth is 28°C. Chemoorganotrophs, using a wide variety of organic compounds for growth: organic acids (acetate, succinate, malate, fumarate, citrate, isocitrate, oxaloacetate, aconitate, α-ketoglutarate, pyruvate, lactate), amino acids (lysine, tyrosine, proline, histidine, alanine, aspartate, and ornithine), alcohols (ethanol, glycerol, mannitol), and carbohydrates (fructose and sorbose), as well as yeast extract and casein hydrolysate. Vitamins and trace elements are essential for growth. Of the nitrogen sources investigated, growth occurred on nitrates, nitrites, ammonium salts, casein hydrolysate, yeast extract, peptone, aspartate, glutamate, cysteine, and serine. Nitrate reduced to nitrite. Casein, gelatin, and starch not hydrolyzed. Catalase, oxidase, and urease positive. Does not produce indole. Hydrogen sulfide produced, from cysteine. Does not grow with 3% NaCl. Isolated from sewage of purification installations. A limited phenotypic comparison with *A. peregrinum*, *A. dispar*, *A. itersonii*, *A. autotrophicum*, *A. sinuosum*, and *A. putridiconchylium* has been published. The species name has not been validly published.

The mol% G + C of the DNA is: 61.6 (T_m).

Deposited strain: D-425.

4. *"Spirillum pleomorphum"* Inoue and Komagata 1976, 170.

ple.o.mor′ phum. L. adj. *pleomorphum* pleomorphic.

Helical cells, curved rods, crescent-shaped cells, U-form cells, and nearly ring-like forms occur on peptone–yeast extract–glucose (PYG) agar. Cell size: 0.7–1.0 × 2.0–4.5 µm. Motile by a single polar flagellum. Growth in PYG broth is turbid with sediment. Colonies on PYG agar are circular, smooth, convex, entire, opaque, and pale brown. Optimal growth temperature, 9°C; maximum, 20°C; minimum below 0°C. Aerobic. Oxidase and catalase positive. Indole, Voges–Proskauer, and methyl red tests are negative. No growth with 5% NaCl. Acid but no gas from xylose (aerobically). No acid or gas from glucose, lactose, sucrose, maltose, arabinose, or glycerol aerobically or anaerobically. No change in litmus milk. H_2S is not produced. Starch and cellulose are not degraded. Nitrate is reduced to nitrite. No growth occurs anaerobically with nitrate. Succinate, formate, acetate, fumarate, and propionate are assimilated. Citrate, lactate, protocatechuate, *p*-hydroxybenzoate, and hippurate are not assimilated. Isolated from Antarctic soil. Differences from *A. arcticum* include its high number of pleomorphic cells, its ability to reduce nitrate, its production of acid from xylose but not from glucose, its assimilation of formate but not lactate, and its higher temperature optimal for growth (9 versus 5°C).

The mol% G + C of the DNA is: 63 (T_m).
Deposited strain: 22-o-d, IAM 12028.

5. *"Aquaspirillum voronezhense"* Grabovich, Churikova, Chernykh, Kononykhina and Popravko 1987.
vo.ro.ne.zhen.se. M.L. adj. *voronezhense* pertaining to the city of Voronezh, former USSR.

Spiral-shaped cells, from 1.5–2.1 to 3 μm wide, with 1–3 turns of the spiral, 2.9–6.8 μm in diameter. Motile with bipolar flagella, in tufts of up to 50. Poly-β-hydroxybutyrate, volutin, and elemental sulfur (in the presence of sulfides) are stored in the cells. Colonies are flat, nonpigmented, 1–4 mm in diameter. Aerobic growth within a pH range of 6.0–9.0; optimal pH is 7.2–8.5. Optimal temperature for growth is 28°C. Chemoorganotrophs, using a wide variety of organic acids for growth including acetate, succinate, malate, fumarate, isocitrate, formate, α-ketoglutarate, oxaloacetate, pyruvate, salicylate, lactate, and glyoxylate. Strain D-420 differs from D-419 by its ability to use oxalate and aconitate and by the inability to grow on isocitrate and formate. Strain D-419 uses the amino acids proline, glycine, aspartate, glutamate, and valine; strain D-420 can use aspartate and tyrosine as carbon sources. A vitamin solution supplement is essential for growth. Ammonium salts, casein hydrolysate, yeast extract, peptone, aspartate, glutamate, cysteine, and serine (strain D-419) are used as nitrogen sources. Nitrate not reduced to nitrites. Casein and starch not hydrolyzed. Nitrates, sulfate, thiosulfate, and fumarate not used as electron acceptor. Catalase, oxidase, and urease positive. Hydrogen sulfide produced from cysteine. Do not produce indole. Form colored products on benzoate medium. The strains cannot fix nitrogen and do not contain proteolytic enzymes. Two very similar strains have been isolated from the sewage sludge of a putrifying aero tank. A limited number of DNA–DNA hybridization experiments showed that *"A. voronezhense"* is not related to *A. metamorphum*, *Levispirillum peregrinum*, and *"A. winogradskyi"* . The species name has not been validly published. Isolated from sewage sludge.
The mol% G + C of the DNA is: 58.5–60 (T_m).
Deposited strain: D-419.

Species Incertae Sedis

1. **"Spirillum minus"** Carter 1888, 47 (*Spirillum minor* (sic) Carter 1888, 47)*
mi′ nus. L. neut. adj. *minus* less, smaller and refers to the small cell size.

Rigid cells; usually described as spiral with two or three turns, although the waves have been reported to be planar (McDermott, 1928). The ends of the cell may be blunt or pointed. Cell diameter, ~0.2 μm; cell length, 3–5 μm; wavelength, 0.8–1.0 μm. Actively motile by one or more flagella at each pole.

Causes one of the two forms of rat-bite fever in man. The disease caused by *"S. minus"* is often termed "Sodoku", it occurs worldwide but has its greatest frequency in the Far East. The organisms are usually transmitted to humans through the bite of an infected rat, although mice, squirrels, and rodent-ingesting animals such as cats, dogs, ferrets, and weasels have also been implicated. *"S. minus"* appears to be a natural parasite of rats, which act as carriers; the infection is usually not lethal in rats. The natural infection frequency for rats varies from country to country but may be as high as 25% (see Babudieri, 1973, for pertinent literature).

The clinical aspects of rat-bite fever and the distinctions between the form caused by *"S. minus"* and that caused by *Streptobacillus moniliformis* have been summarized by Joklik et al. (1980) and by Rogosa (1980). Experimental infections of humans and animals by *"S. minus"* have been described by Babudieri (1973).

"S. minus" is best observed in blood or exudates from patients by dark-field or phase-contrast microscopy of wet mounts; staining with Giemsa or Wright's stain or by silver impregnation is also useful.

"S. minus" is cultured *in vivo* by intraperitoneal inoculation of patients' blood or exudates from lesions, or blood from naturally infected rats injected into spirillum-free mice or guinea pigs (Rogosa, 1980); mice are the animals most susceptible to *"S. minus"* infection (Babudieri, 1973). It is questionable whether the organism has ever been cultured successfully in artificial media. Numerous attempts have failed, and various claims of successful cultivation have not been confirmed. One report that may indicate successful cultivation is that of Hitzig and Liebesman (1944), who inoculated blood from a patient into 2% dextrose–veal infusion broth and into 10% tomato extract–veal infusion broth. The addition of citrated human or rabbit blood was required for successful subculturing; also, the organisms initially required incubation in a candle jar but eventually were able to grow aerobically after five months of serial transfer. Confirmation of this report is needed. Considering the morphology, pathogenicity, and sources of *"S. minus"*, serious attention should be given to the possibility that the organism might belong to, or be related to, the genus *Campylobacter*, and the microaerophilic techniques employed for campylobacters might also prove useful for *"S. minus"*.

The species name has not been validly published. There are no type or reference strains.
The mol% G + C of the DNA is: not determined.

2. **"Spirillum pulli"** Mathey 1956, 745.
pul′ li. L. gen. n. *pulli* of a young chicken.

Rigid spiral cells. By dark-field microscopy, the cell diameter is ~1 μm and the cell length is from 5 to 12 μm. Actively motile by means of a single flagellum at each end of the cell. Believed to be the cause of a diphtheroid stomatitis in the mouths of adult chickens. The lesions are yellowish white, rather firm, and adherent to the underlying tissue; often they are symmetrically ovoid, one at each side of the lower jaw. Lesions also occur on the palate, the lower surface of the tongue, the floor of the mouth, between the larynx and the transverse row of papillae on the tongue, around the larynx, and on the walls of the pharynx. The lesions vary in size from ~2 to 20 mm.

Attempts to culture *"S. pulli"* in artificial media have been unsuccessful. Experimental passage of the disease in chickens has been accomplished by contact and by experimental inoculation.

There are no type or reference strains. The species name has not been validly published.
The mol% G + C of the DNA is: not determined.

Editorial Note: The specific epithet *minor* is grammatically incorrect as noted by Robertson (1924) and the correct form is *minus*.

Genus IV. **Chromobacterium** *Bergonzini 1881, 153*[AL]

MONIQUE GILLIS AND NIALL A. LOGAN

Chro.mo.bac.te' ri.um. Gr. n. *chroma* color; Gr. n. *bakterion* a small rod; M.L. neut. n. *Chromobacterium* a small, colored rod.

Cells straight, round-ended, often coccoid, but usually occuring as rods, 0.6–0.9 × 1.5–3.0 μm, occurring singly, sometimes in pairs or short chains. No definite capsules are evident. No resting stages known. Gram negative. Usually contain poly-β-hydroxybutyrate crystals (80% of strains positive), but rarely contain metachromatic granules. **Motile by means of both a single polar flagellum and, usually, one or more subpolar or lateral flagella. Facultative anaerobes. Minimum temperature for growth 10–15°C; maximum about 40°C; optimal growth at 30–35°C.** Optimal pH 7–8; no growth occurs below pH 5. Grow on ordinary peptone media; no distinctive organic growth factor requirements. Colonies are smooth, but rough variants may occur; colonies are of butyrous consistency and are easily emulsified in water. **Most strains produce the violet pigment violacein**, but strains producing nonpigmented colonies are sometimes encountered, and subcultures of pigmented strains often contain partially or completely unpigmented colonies. Growth in nutrient broth produces a violet ring at the surface with a fragile pellicle. Chemoorganotrophs; **most strains (80%) attack carbohydrates fermentatively, some (20%) oxidatively, producing small amounts of acid** but usually no gas. Lactate is oxidized to CO_2. Usually oxidase positive by the method of Sivendra and Lo (1975). No growth in media containing 6% or more NaCl. Catalase positive, but very sensitive to hydrogen peroxide. Indole negative, Voges–Proskauer negative. Nitrate and nitrite reduced. Ammonia produced from peptone. Arginine hydrolyzed. **Hydrogen cyanide produced. Resistant to benzylpenicillin**, 10 mg/ml. **Sensitive to tetracycline**, 30 mg/ml. **Resistant to O/129 (2,4-diamino-6,7-diisopropyl pteridine)** by disc diffusion method, 50 mg/disc. Soil and water organisms, occasionally causing infections of humans and other mammals. 16S rRNA gene sequence data place *Chromobacterium* in the class *Betaproteobacteria*.

The mol% G + C of the DNA is: 65–68 (T_m).

Type species: **Chromobacterium violaceum** Bergonzini 1881, 153.

FURTHER DESCRIPTIVE INFORMATION

The pigment violacein is produced on or in media containing tryptophan. It is soluble in ethanol, but not in water or chloroform, and is readily identified by spectrophotometry and by testing with routine reagents (see Procedures for Testing for Special Characters). Subcultures of pigmented strains may contain partially or completely unpigmented colonies. An unpigmented strain is most readily recognized by having a colony morphology similar to that of a pigmented strain isolated at the same time under the same conditions. Once it has been confirmed as an oxidase- and catalase-positive, Gram-negative rod, such an isolate should be flagella-stained. If it possesses the characteristic polar and lateral flagella, it should then be subjected to the differential tests for the three genera *Chromobacterium*, *Iodobacter*, and *Janthinobacterium*. Although young cultures of *Aeromonas*, *Pseudomonas*, and *Vibrio* spp. grown on solid media sometimes produce lateral flagella in addition to their usual polar flagella, they give patterns of results different from those of the violet-pigmented organisms in the differential tests.

The characteristic flagellar arrangement is best seen in young cultures on solid media. The single polar flagellum is inserted at the tip of the cell, shows long, shallow waves, and often stains faintly. The lateral flagella are usually long. Usually 1–4 such flagella are produced, although up to eight may occur. They may be inserted subpolarly or laterally, usually show deep, short waves, and stain readily (see *Iodobacter fluviatilis* Fig. BXII.β.71).

Chromobacterium violaceum occurs in soil and water and is common in tropical climates. It occasionally causes serious pyogenic or septicemic infections of mammals, including humans (reviewed by Sneath, 1960; Gillis and De Ley,1992; with subsequent reports by Hassan et al., 1993; Ti et al., 1993; Roberts et al., 1997; Midani and Rathore, 1998; Desjardins et al., 1999). The disease can be cured by tetracyclines if treated at an early stage (Moss and Ryall, 1981) as well as by ciprofloxacin, norfloxacin, perfloxacin (Aldridge et al., 1988), gentamicin, imipenem, and trimethoprim–sulfamethazole (Midani and Rathore, 1998). In some cases, a sepsis mimicking melioidosis has been described (Chong and Lam, 1997), and potentially misidentification as *Burkholderia pseudomallei* might occur (Inglis et al., 1998). Pathogenic bacteria of carp have been characterized as closely resembling *Chromobacterium violaceum* (Rahmatullah and Beveridge, 1993; Kozinska and Antychowicz, 1996).

ENRICHMENT AND ISOLATION PROCEDURES

Selective and enrichment media have not been developed for *C. violaceum*, but colonies on routine growth media are readily recognized by their violet pigmentation, and isolates may be screened for the ability to grow at 37°C and for other characters that distinguish this organism from the species of *Iodobacter* and *Janthinobacterium* (Table BXII.β.85; see Procedures for Testing for Special Characters).

MAINTENANCE PROCEDURES

The organisms may survive for several years in dilute peptone water (0.1% peptone) at room temperature. They can also be preserved indefinitely by lyophilization or by freezing in nutrient broth containing 15% glycerol.

PROCEDURES FOR TESTING SPECIAL CHARACTERS

To identify the pigment violacein, pigmented growth is shaken from a plate culture into a small volume of 96% (v/v) ethanol, and cells are then removed by centrifugation, followed by filtration through a 0.22 μm membrane; the solution shows an absorption maximum of 579 nm and a minimum of 431 nm if violacein is present. In 10% (v/v) H_2SO_4 in ethanol (96% v/v), the pigment gives a green solution with an absorption maximum at 699 nm and a minimum at 502 nm. Color reactions may be observed by mixing loopfuls of pigmented growth in a few drops of 96% (v/v) ethanol on a white tile; stirring in a drop of 25% (v/v) H_2SO_4 gives a green color, and stirring a drop of 10% (w/v) NaOH into a fresh growth/ethanol mixture gives first a green, then a reddish brown color. The biosynthesis of violacein has been studied intensively, and different metabolites have been characterized e.g., pseudodeoxyviolacein (Hoshino et al., 1994), deoxyviolacein, and chromopyrrolic acid (Hoshino et al., 1993a).

TABLE BXII.β.85. Patterns of results in tests useful for distinguishing *Chromobacterium* from *Iodobacter*, *Janthinobacterium*, and *Vogesella*

[a]From Logan (1989) with later amendments. Number of strains studied for each species: *C. violaceum*, 9; *Iodobacter fluviatilis*, 53; *J. lividum* (typical), 68; *J. lividum* (atypical), 14; *Vogesella*, 17.

[b]Fluorescence on chalk agar (Starr et al., 1960) with short wavelength illumination. All *Vogesella* strains exhibited very weak fluorescence.

[c]Only tested for the type strain; − (T), type strain negative; + (T), type strain positive.

[d]Occasional strains are oxidative.

[e]Some strains give no reaction in this test.

[f]Similar patterns of results are obtained with D-cellobiose and D-galactose.

[g]Similar patterns of results are obtained with D-sorbitol.

[h]Grimes et al. (1997) found that the type strain was negative under conditions different from those used by the authors.

L-Tryptophan is the carbon source for violacein, and isatin and indole 3-acetic acid are important metabolic intermediates in violacein production and can also serve as substrates. Violacein has trypanocide activity (Duran et al., 1994).

Because the production of violacein by *Chromobacterium violaceum* is dependent on *N*-acetylhomoserine lactones (AHLs), it provides a simple assay for the detection of these molecules, which are signal molecules in quorum sensing that interact with a transcriptional activator protein to couple gene expression to cell population density (McClean et al., 1997; Bachofen and Schenk, 1998).

The procedure of Mayfield and Inniss (1977) is recommended for studies of flagellar arrangement, and the even simpler technique of Heimbrook et al. (1989) appears, on limited experience, to be equally dependable. For the latter method, cultures are grown overnight on slopes of nutrient agar prepared at a quarter of the usual nutrient strength (1/4 NA), which have drops of condensate at their bases. A drop of the condensate is removed with a small loop and touched to a small drop of water on a clean slide.

The oxidase reactions of pigmented strains are commonly obscured by the pigment, but may be revealed by the method of Sivendra and Lo (1975). Smears of pigmented growth and control organisms are placed along the edge of a strip of filter paper that has been soaked in the reagent (1% [w/v] tetramethyl-*p*-phenylenediamine HCl) and supported on a glass slide. When the positive control has oxidized the reagent to a violet color, further drops of reagent are placed above the smears and the slide tilted so as to flush reacted reagent onto a white background.

Unless indicated otherwise, all media are autoclaved at 121°C for 15 min. Media are inoculated with one drop or loopful of quarter strength nutrient broth (1/4 NB) culture grown overnight at 25°C and, with the exception of those used for growth temperature tests, incubated at 25°C. This temperature permits strains of *Chromobacterium*, *Iodobacter*, and *Janthinobacterium* to grow and be compared in the differential tests. For assessment of growth temperatures, tubes of 1/4 NB are incubated in waterbaths at 37°C and 4°C and examined for growth at 2 and 7 d, respectively. To assess anaerobic growth, plates of nutrient agar (full strength) are streak-inoculated and incubated in an anaerobic jar (GasPak, BBL) for 7 d at 25°C.

To investigate oxidative and fermentative attack of glucose, the medium of Ward et al. (1986) is used without its H_2S indicator system. This modified medium contains (g/l): glucose, 10; casitone, 2; yeast extract, 1; phenol red, 0.04; bromothymol blue, 0.02; agar, 15. After heating to dissolve components and adjustment to pH 7.1, the medium is dispensed into tubes in 10-ml amounts, autoclaved, and left to set as deep-butted slopes, which are then inoculated by streaking the slope and stabbing the butt and incubated for up to 7 d. Fermentative organisms readily produce a yellow color throughout the medium, whereas a yellow or light green color restricted to the slope indicates oxidative attack. *Chromobacterium violaceum* usually attacks carbohydrates fermentatively without gas production, but aerogenic isolates have been reported (Sivendra, 1976), and as many as 20% of strains may show oxidative attack (Sneath, 1984a). *Iodobacter fluviatilis* is always fermentative and anaerogenic. Typical strains of *J. lividum* are oxidative, but atypical strains may give no reaction in this test.

Acid production from carbohydrates may be determined using a medium containing (g/l): $(NH_4)_2HPO_4$, 1; KCl, 0.2; $MgSO_4 \cdot 7H_2O$, 0.2; yeast extract, 0.2; phenol red, 0.06; and agar, 12. After adjustment to pH 7.4 (orange), autoclaving, and addition of a filter-sterilized solution of L-arabinose, *myo*-inositol, D-maltose, D-mannitol, or trehalose to give a final concentration of 0.5%, the medium is dispensed into tubes and left to set as deep-butted slopes. Tubes are examined at 2, 4, and 7 d for acid (yellow) reactions in the slopes, butts, or both.

Utilization of lactate is assessed using a medium containing (g/l): lactic acid (sodium salt), 2; NaCl, 1; $(NH_4)_2HPO_4$, 1; KH_2PO_4, 0.5; $MgSO_4 \cdot 7H_2O$, 0.2; phenol red, 0.06; agar, 12. After adjustment to pH 6.8 and autoclaving (115°C for 20 min), the medium is distributed into tubes and left to set as slopes. The medium is streak-inoculated and examined for alkaline (red) reactions at 2, 4, and 7 d.

For esculin hydrolysis, the medium of Sneath (1979) is used, which contains (g/l): peptone, 10; esculin, 1; sodium citrate, 1; ferric citrate, 0.05. After adjustment to pH 7.0, 5-ml quantities are dispensed in tubes and autoclaved. Tubes are examined at 3 and 4 d for browning.

Arginine-hydrolysis medium contains (g/l): L-arginine HCl, 10; NaCl, 5; peptone, 1; K_2HPO_4, 0.3; phenol red, 0.06; and agar, 3. It is adjusted to pH 7.2 (orange), dispensed in tubes to a depth of 2 cm, and autoclaved. Following stab-inoculation and sealing with sterile paraffin oil, tubes are incubated for 4 d and examined for alkaline (red) reactions.

Hydrogen cyanide indicator papers are prepared by dipping filter paper strips in saturated aqueous picric acid, drying (potentially explosive, care and doing under chemical hood recommended), and then dipping in 10% (w/v) aqueous sodium carbonate and drying again. A bottle of half-strength (semi-solid) nutrient agar is inoculated by stabbing and an indicator paper is trapped between the cap and rim; HCN production is indicated by the paper strip changing color from orange-yellow to brick-red within 3 d.

Differentiation of the genus *Chromobacterium* from other genera

Table BXII.β.85 presents characteristics differentiating the genus *Chromobacterium* from the genera *Janthinobacterium*, *Iodobacter*, and *Vogesella*. *Microvirgula aerodenitrificans* is not included because comparable test results are not available.

Taxonomic Comments

The present description of the genus *Chromobacterium* is based primarily on the description given by Sneath (1984a). The phylogenetic affiliation of *Chromobacterium* was studied first by DNA–rRNA hybridization (De Ley et al., 1978), and later by 16S rDNA sequence analysis. It is a member of the class *Betaproteobacteria*, in which it constitutes a separate lineage in the *Neisseriaceae*. Its closest neighbor is the recently proposed genus *Vogesella* (see the genus *Vogesella* in this family). *Vogesella* was created to contain the former *Pseudomonas indigofera* and new isolates of blue-pigmented bacteria isolated from fresh water bacterial communities. A single species, *Vogesella indigofera*, has been proposed because no DNA–DNA hybridizations between this species and the group of new isolates are available. *Vogesella* members do not contain violacein, but rather indigoidine. Also belonging to the *Neisseriaceae*, but more distantly related, is the genus *Iodobacter* (see Genus *Iodobacter*, this *Manual*). Earlier results from DNA–rRNA hybridization (Pot et al., 1992a) have shown that *Aquaspirillum dispar* and *Aquaspirillum putridiconchylium* also belong to this phylogenetic lineage. A new genus, *Microvirgula*, with the single species *Microvirgula aerodenitrificans* recently has been created for a denitrifying bacterium occupying a separate phylogenetic position between the *Vogesella*–*Chromobacterium violaceum* lineage and *Iodobacter fluviatilis* (Patureau et al., 1998). It is an aerobic as well as anoxenic heterotroph that has an atypical respiratory type of metabolism, in which oxygen and nitrogen oxides can be used simultaneously as terminal electron acceptors.

In addition to species of *Chromobacterium*, *Janthinobacterium*, and *Iodobacter*, which are found in soil and fresh water, violacein-producing organisms have been isolated from marine waters. Hamilton and Austin (1967) have named their strain *"C. marinum"*, but Gauthier (1976) has considered his isolates to be excluded from *Chromobacterium* by their low mol% G + C range, and he assigned them to the genus *Alteromonas* as the new species *A. luteoviolaceus* (now *A. luteoviolacea*).

Species producing pigments that are not violacein, or even violet-colored in some cases, have at various times been assigned to *Chromobacterium*, and still occasionally appear in the literature as such. Of these, *"C. iodinum"* is established as a species of *Brevibacterium* (Collins et al., 1980), and *"C. marismortui"* has been placed in the new genus *Chromohalobacter* (Ventosa et al., 1989). The production of lipases by *"Chromobacterium viscosum"* has been reported. This bacterium does not belong in *Chromobacterium*; it is a Gram-positive bacterium whose exact taxonomic affiliation is unknown and which has been cited as *Corynebacterium* sp., *Micrococcus* sp., or *Arthrobacter* sp., (De Ley et al., 1978). Two strains isolated from *Psychrotia nairobensis* and *Ardisia crispa* and formerly named *"C. lividum"* or *"C. folium"* have been reclassified as *Sphingomonas yanoikuyae* (Takeuchi and Hatano, 1998). *"Chromobacterium chocolatum"* has been reclassified as *Microbacterium chocolatum* (Takeuchi et al., 1995), and *"C. typhiflavum"* strains (Pedersen et al., 1970) have been reclassified as *Chryseomonas luteola* and *Flavimonas oryzihabitans* (Holmes et al., 1987).

The genus *Chromobacterium* is of interest because it produces substances of importance to agriculture, medicine, and industry. Several of these have been reported in Gillis and De Ley (1992). *Chromobacterium* spp. have been reported to produce chitinase and to reduce the hatch of the nematode *Globodera rostochiensis* (Cronin et al., 1997); the production of a set of chitinolytic enzymes is regulated by an endogenous AHL (Chernin et al., 1998).

Depsipeptide, a cyclic peptide produced by *Chromobacterium violaceum* WB968, has potent antitumor activity against human tumor cells (Ueda et al., 1994; Chan et al., 1997). *Chromobacterium violaceum* strain DSMZ 30191 accumulate a homopolyester of 3-hydroxyvaleric acid up to high percentages of the cellular dry matter when grown on valeric acid (Steinbüchel et al., 1993; Marchessault et al., 1995; Steinbüchel and Schmack, 1995). Several enzymes and metabolites from *Chromobacterium* members have been intensively studied, including phenylalanine hydroxylase (Carr and Benkovic, 1993; Carr et al., 1995), L-tryptophan 2′,3′-oxidase (Hoshino et al., 1993b; Genet et al., 1995; Hammadi et al., 1997), indoloxygenase (Cheah et al., 1998), cytosine deaminase (Kim and Yu, 1998), and serine hydroxylmethyltransferase (Shirazi-Beechey and Knowles, 1984).

List of species of the genus Chromobacterium

1. **Chromobacterium violaceum** Bergonzini 1881, 153[AL]
vi.o.la′ce.um. L. adj. *violaceum* violet colored.

The description is the same as that given for the genus. Other characters are as shown in Table BXII.β.86.

The mol% G + C of the DNA is: 65–68 (T_m).
Type strain: MK, ATCC 12472, NCIMB 9131, NCTC 9757.
GenBank accession number (16S rRNA): M22510.

TABLE BXII.β.86. Characteristics of *Chromobacterium violaceum*[a]

Characteristics	*Chromobacterium violaceum*
Colonies on 1/4 nutrient agar:	
Spreading	−
Gelatinous	−
Pigmented	[+] (87)
Zoning of pigment	[−] (25)
Growth on:	
Minimal medium	+
4X Strength nutrient agar	+
Growth at:	
4°C	−
30°C	+
37°C	+
Growth in:	
1% NaCl	+
2% NaCl	+
4% NaCl	−
Growth at:	
pH 4	+
pH 3	−
Formation of cell chains	[−] (12)
Formation of filaments	[−] (15)
Acid from:	
L-Arabinose	−
D-Cellobiose	−
D-Fructose	+
D-Galactose	−
Gluconate	+
D-Glucose	+
Glycerol	+
Glycogen	+
myo-Inositol	−
Inulin	[−] (12)
Lactose	−
D-Maltose	−
D-Mannitol	−
D-Mannose	+
Melezitose	−
N-acetylglucosamine	+
D-Raffinose	−
D-Sorbitol	−
Starch	[+] (87)
Sucrose	[−] (25)
Trehalose	+
D-Xylose	−
Catalase	+
Oxidase	+
Nitrate reduction	[+] (87)
Nitrite reduction	[−] (25)
Production of HCN	+
Egg yolk reaction	+
Hemolysis	+
Carbon sources:	
Acetate	[+] (87)
Citrate	+
Fumarate	+
Glycerate	−
Lactate	+
Malate	+
Propionate	[+] (87)

Antimicrobial agents (per disk):	
Ampicillin, 25 μg	R
Cephaloridine, 25 μg	R
Colistin sulfate, 10 μg	R
Chloramphenicol, 10 μg	s
Chlortetracycline, 10 μg	S
Furazolidone, 50 μg	S
Kanamycin, 30 μg	S
Neomycin, 10 μg	s
Nalidixic acid, 30 μg	S
Nitrofurantoin, 200 μg	S
Oxytetracycline, 10 μg	S
Penicillin G, 1.5 U	R
Streptomycin, 10 μg	s
Sulfafurazole, 100 μg	R
Sulfafurazole, 500 μg	s
Vibriostatic agent O/129, 50 μg	R

[a]Symbols: +, all strains positive; [+], positive for 80% or more strains; d, positive for 31–79% strains; [−], positive for 30% or fewer strains; −, negative for all strains; R, resistant; S, sensitive; s, slightly sensitive. Numbers in parentheses indicate the % of strains giving positive reactions.

Genus V. **Eikenella** *Jackson and Goodman 1972, 74*[AL]

Edward J. Bottone, Francis L. Jackson and Yvonne E. Goodman

Ei.ke.nel'la. M.L. dim. ending *-ella*; M.L. fem. n. *Eikenella* named after M. Eiken, who first named the type species of the genus.

Straight rods, 0.3–0.4 × 1.5–04.0 μm, unbranched, with rounded ends and a regular morphology. Short filaments are occasionally formed. Nonsporeforming. Gram negative. **Nonmotile**, possessing no flagella; however, a "twitching motility" may occur on agar surfaces. **Facultatively anaerobic.** Optimal growth temperature, 35–37°C. **Colonies may appear to corrode the surface of the agar**; noncorroding strains may also occur. Nonhemolytic; a slight greening of blood media around colonies may occur. **Oxidase positive** (Kovacs method). **Negative for catalase, urease, arginine dihydrolase, and indole. Lysine-decarboxylase positive.** Nitrates are reduced to nitrites. **No acid is formed from glucose or other carbohydrates. Hemin is usually required for growth under aerobic conditions.** Occur in the human mouth and intestine; can be opportunistic pathogens.

The mol% G + C of the DNA is: 56–58.

Type species: **Eikenella corrodens** (Eiken 1958) Jackson and Goodman 1972, 75 (*Bacteroides corrodens* Eiken 1958, 415.)

Further descriptive information

Electron micrographs of *E. corrodens*, the only species, negatively stained with phosphotungstate show a finely convoluted (cerebral) cell surface. Sections stained with ruthenium red-OsO_4 show a cytoplasmic membrane and outer membrane characteristic of Gram-negative bacteria. A slime layer, loosely organized and fibrous, was present on strains examined by Progulske and Holt (1980). The slime layer is associated with the outer surface of the outer membrane, and it is possible that the pilus-like structures demonstrable by negative staining represent components of this layer modified by preparation techniques (Jackson et al., 1971; Progulske and Holt, 1980). Scanning electron microscopy of 7-d-old cultures shows fibrillar material connecting cells (Progulske and Holt, 1980). Adherence of *E. corrodens* to cell surfaces of host tissues is mediated by a cell-associated *N*-acetyl-D-galactosamine-specific, lectin-like substance (Ebisu and Okada, 1983). The lectin is also involved in coaggregation with other bacteria, forming dental plaque and causing proliferation of B-cells in peridontal lesions (Ebisu et al., 1988). The gene encoding a component protein of the lectin-like adhesin complex has been cloned (Yumoto et al., 1996).

Lipopolysaccharide from the organism has been reported to have endotoxin activity, whereas the slime layer has little endotoxin activity, but may be immunosuppressive (Behling et al., 1979). A component with endotoxin activity and containing 0.5% ketodeoxyoctonate, probably a lipopolysaccharide, has been obtained from cells by phenol–water extraction followed by differential centrifugation and gel filtration. It may represent a group antigen, and is distinct from type-specific outer membrane protein antigens, which may also be present (Maliszewski et al., 1983). This major outer membrane protein has a molecular weight of 42,000 Da. *E. corrodens* lipopolysaccharide also demonstrates mitogenic activity different from that elicited by conventional lipopolysaccharide (Progulske et al., 1984).

The organisms appear to be nonmotile according to conventional tests. Corroding colonies (see below) may show spreading edges, and microscopic observation of corroding strains growing on agar surfaces has shown that a form of surface translocation termed "twitching motility" occurs (Henrichsen, 1975a; Henrichsen and Blom, 1975; Schröter, 1975). This motility is correlated with the presence of asymmetrically arranged pili, each with a molecular mass of about 14.8 kDa and an N-terminal amino acid sequence, suggestive of type IV pilins (Hood and Hirschberg, 1995). "Twitching motility" involves small, intermittent jerks leading to displacement over only short distances, not regularly related to the long axis of the cell, at speeds of 1–2 to 2–5 mm/min. The use of cover slips over growth on agar surfaces may prevent this movement, as organisms adhere to the glass, and the phenomenon is dependent on the presence of a thin film of water at the surface of the medium, as is found in cultures incubated in a humidified atmosphere.

Two types of colonies may occur on agar media. Typical "corroding" strains are so named because the colonies appear to corrode the surface of the agar. The organisms penetrate into the surface of the medium and, under humid conditions, tend to spread by twitching motility. The colonies appear as if they are in small depressions in the agar surface, probably because of a combination of spreading surface growth, localized physical alterations of the medium, and optical properties of the colony. The appearance of pitting is not produced on inspissated serum medium. Problems of interpretation of these features have been discussed by Jackson et al. (1971) and by Khairat (1967). Colonies of corroding strains growing on Columbia or trypticase soy agar with 5% sheep's blood at 36°C under 10% CO_2 are dry, flat, and radially-spreading, with irregular peripheries (Bottone et al., 1973). With more prolonged incubation, colonies display a characteristic morphology consisting of a clear, moist, glistening center devoid of growth, encircled by a highly refractile, speckled, pearl-like zone of growth that is in turn surrounded by an outer nonrefractile perimeter of spreading growth (Fig. BXII.β.69). Colonies are small (0.2–0.5 mm at 24 h; 0.5–1.0 mm at 48 h). The spreading edge may give colonies a final diameter of ~3.0 mm (Jackson et al., 1971). Colony sizes are similar on cystine–hemin agar. Noncorroding strains, forming colonies 0.5–1.0 mm in diameter that are translucent and dome-shaped, may be isolated by selection from corroding strains and may also be encountered upon primary isolation. These variants do not produce colonies with spreading edges, do not exhibit twitching motility and lack pilus-like surface appendages (Henrichsen, 1975a).

Plate cultures have an odor described as "bleach-like" or as resembling that of *Haemophilus* and *Pasteurella* species.

Growth in fluid media is usually described as poor, but may be improved by addition of cholesterol (10 g/ml; Henriksen, 1969b) or 3% blood serum. The addition of 0.2% agar improves growth (Jackson et al., 1971). In thioglycollate broth, granular growth develops after 3 days in a band 1 cm below the surface. In glucose broth, growth may produce uniform turbidity or small granules adherent to the sides of the tube (Bottone et al., 1973). Granule formation may be related to the presence of pili.

The optimal temperature for growth is 35–37°C. At 25°C, minute colonies are visible in 5–7 days. Growth is good at 40°C but poor at 42°C. No growth occurs at 44°C. The optimal pH for growth is 7.3.

Hemin (5–25 g/ml) is required for aerobic growth of freshly

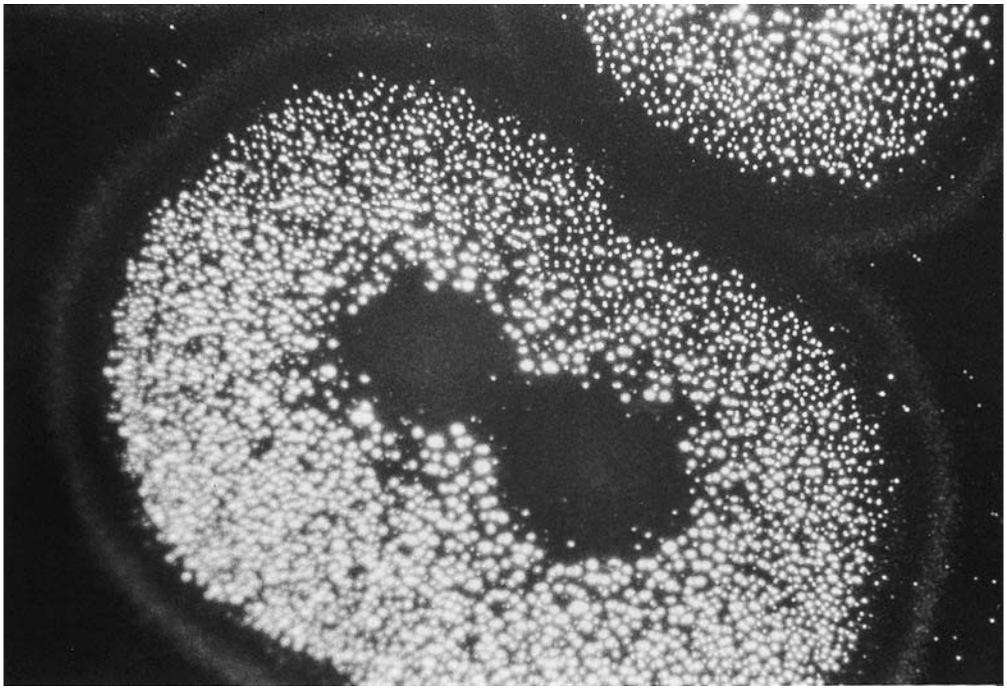

FIGURE BXII.β.69. Colony of *E. corrodens* viewed by oblique lighting, showing a clear, moist center circled by a highly refractive, speckled, pearl-like zone that is surrounded by a perimeter of spreading growth. (Reproduced with permission from E.J. Bottone et al., American Journal of Clinical Pathology *59:* 560–566, 1973 ©American Society of Clinical Pathologists.)

isolated strains, but not for anaerobic growth. The hemin requirement may be influenced by other constituents of the medium, as indicated by the demonstration that addition of cystine (0.005%) raises the minimum hemin requirement to 20–25 g/ml. Under these conditions, the colony size is increased. Cystine at 0.1% is strongly inhibitory to growth at all hemin concentrations that support growth in the absence of added cystine (Jackson et al., 1971).

Under aerobic or anaerobic conditions, growth of freshly isolated strains is enhanced by 5–10% CO_2. Repeated subculture in air leads to a loss of this response (Hill et al., 1970), but it is retained if strains are repeatedly transferred in a CO_2-enriched atmosphere (Jackson et al., 1971). Strains that have been tested for bile tolerance are inhibited under aerobic conditions by 5 or 10% bile; under anaerobic conditions, growth has been reported to occur in the presence of 10% bile, and there is evidence that this resistance may be higher under microaerobic conditions in the presence of nitrate (Jackson et al., 1971).

Organisms grown anaerobically or aerobically, with or without added CO_2, are strongly oxidase-positive by the method of Kovács (1956), using either dimethyl-*p*-phenylenediamine or the tetramethyl reagent. The standardized tube test (Jackson and Goodman, 1972) can also be used, and it shows that the reaction is azide-sensitive.

Spectroscopic examination has shown the presence of cytochromes of the *b* and *c* groups. Ubiquinone, but not demethylmenaquinone, is present (Holländer and Mannheim, 1975). Growth yields of oxygen-limited cultures are not increased by fumarate. Energy metabolism in *E. corrodens* proceeds via oxidative deamination of key amino acids (proline, glutamate, serine, and glutamine) linked to a respiratory chain, with nitrate, the ultimate electron acceptor, reduced to nitrite in the process (Gully and Rogers, 1996).

An examination of six strains of *E. corrodens* by gas–liquid chromatography/mass spectrophotometry has shown that the organisms contain hexadecanoic and octadecenoic acids as major fatty acid constituents (Prefontaine and Jackson, 1972). This is in contrast to *Bacteroides ureolyticus*, which has a high content of octadecenoic acid but a low content of hexadecanoic acid.

Antigenic differences between strains have been demonstrated by agglutination reaction and also by immunodiffusion studies, in which up to four antigens have been detected (although some strains lack one or two components) (Jackson et al., 1971). Badger and Tanner (1981) have divided 46 strains into four groups by microagglutination tests. Maliszewski and Badger (1980) have isolated a group antigen common to three serotypes. It appears to be a lipopolysaccharide containing 0.5% ketodeoxyoctonate and showing endotoxin activity by the Limulus amoebocyte lysate test. A type-specific antigen (protein, sensitive to trypsin and heat) has been prepared from one strain. According to Johnson et al. (1978), endotoxin prepared from a corroding strain of *E. corrodens*, in contrast to typical endotoxins, which tend to increase microviscosity of cell membranes, has the unusual effect of causing a decrease in microviscosity of cell membranes, a finding these authors attributed to unique characteristics of the *E. corrodens* endotoxin. Indeed, Progulske et al. (1984) have shown that *E. corrodens* endotoxin is nonclassical, as it contains little 2-keto-3-deoxyoctulosonic acid and heptose and no detectable 9-hydroxy fatty acids.

Some anaerobic Gram-negative rods may show a degree of cross-antigenicity with *E. corrodens* (Robinson and James, 1973), but as pointed out by Jackson and Goodman (1978) the differ-

ence in mol% G + C content of the DNA between *E. corrodens* and these anaerobes precludes a close genetic relationship, and the designation by Robinson and James of strain NCL-20 (now known to be a strain of *Bacteroides ureolyticus*) as a "link" strain between the facultative and anaerobic species is not justifiable.

For determination of antibiotic susceptibility, best results are obtained by standardized-inoculum plate-dilution methods, but other techniques have been used with variable results (Hill et al., 1970; Jackson et al., 1971; Zinner et al., 1973; Brooks et al., 1974; Robinson and James, 1974; Labbé et al., 1977; Goldstein et al., 1978; Slee and Tanzer, 1978). The reports presently available indicate that most strains are susceptible to penicillin G, ampicillin, and cefoxitin, but resistant to penicillinase-resistant penicillins and moderately susceptible or resistant to cephalothin, cephapirin, and cephaloridine. Resistance to aminoglycosides is variable, but usually sufficient to preclude clinical effectiveness. Strains are often susceptible to chloramphenicol, tetracycline, rifampicin, and colistin. Resistance to lincomycin, clindamycin and metronidazole is a constant feature. Two β-lactamase-producing strains of *E. corrodens* have been isolated from an intra-abdominal abscess and an abdominal wound abscess of a 10-year-old and a 2-year-old boy, respectively, hospitalized in San Sebastian, Spain (Trallero et al., 1986).

There is good evidence that *E. corrodens* alone may be pathogenic in humans. When isolated from lesions, it is usually present in mixed culture with other facultative bacteria or with anaerobic bacteria; however, in 10–15% of positive specimens, it is present in pure culture, and it may cause serious diseases. In some cases, it may be the sole survivor in antibiotic-treated mixed infections. Holm (1950) has noted the presence of "corroding bacilli" in actinomycotic lesions, and Reinhold (1966) has studied strains from human sources. Marsden and Hyde (1971) and Kaplan et al. (1973) have reported infections in children. Khairat (1967) has recovered corroding bacilli from 16% of blood cultures drawn 1 min after dental extraction, but the true identity of some of the strains remains uncertain. King (1964) included *E. corrodens* (termed "HB-I") in a discussion of unusual pathogenic Gram-negative bacteria. Brooks et al. (1974) have produced abscesses by injecting mixtures of *E. corrodens* and streptococci, with further potentiation by the addition of methylphenidate, thus simulating lesions found in drug addicts. Experimental endocarditis, rarely fatal and seldom bacteremic, has been produced in catheterized rabbits (Badger et al., 1979); the organism can be shown in vegetation by fluorescent-antibody staining. *E. corrodens* has been associated with endocarditis, osteomyelitis, and septicemia in intravenous drug abusers, and may be related to the practice of "licking needles or skin" prior to injection (Angus et al., 1994; Olopoenia et al., 1994; Swisher et al., 1994).

The possible role of *E. corrodens* in the production of periodontal disease with bone destruction has been discussed and investigated (Socransky, 1977; Johnson et al., 1978; Listgarten et al., 1978; Behling et al., 1979; Progulske and Holt, 1980). *E. corrodens* is frequently found in subgingival plaque in patients with advanced periodonitis (Müller et al., 1997b). Coaggregation with other bacterial species (*Capnocytophaga*, *Actinobacillus*, streptococci) in dental plaque and the ability to elaborate a toxin in gingival sulcus (Levine and Miller, 1996) that may damage surrounding cells both contribute to periodontal disease. Other potential virulence factors operative in periodontal disease include a thiol-dependent hemolysin and other hydrolytic enzymes (Allaker et al., 1994). Infection of the mouth, upper and lower respiratory tract, sinuses, lips, and face is sometimes reported (Schröter and Stawru, 1970; Jackson et al., 1971; Marsden and Hyde, 1971; Bottone et al., 1973; Carruthers and Sommers, 1973; Kaplan et al., 1973; Brooks et al., 1974; Rubenstein et al., 1976; Goodman, 1977; Piéron and Mafart, 1977; Dudley et al., 1978; DeMello and Leonard, 1979; Jones and Romig, 1979; Colloc et al., 1980; Mégraud et al., 1981; Knudsen and Simko, 1995). Serious infections, including brain abscesses, endocarditis, pneumonia, osteomyelitis, and septic arthritis (Johnson and Pankey, 1976), have been encountered. Transfer from the mouth through human bites and "clenched fist" injuries has resulted in more than 60 cases (Bilos et al., 1978; Goldstein et al., 1978).

The ability of *E. corrodens* to survive in the intestine leads to its presence in abdominal infections, including wound infection, abscesses, and peritonitis of the liver and other viscera (Quinlivan et al., 1996).

E. corrodens is regarded by several investigators as an opportunistic pathogen, particularly likely to produce infection in compromised hosts. Infection is often polymicrobic and is particularly associated with a *Streptococcus* species (Jackson et al., 1971; Bottone et al., 1973; Dorff et al., 1974; Shinhar et al., 1980; Flesher and Bottone, 1989; Quinlivan et al., 1996). Young et al. (1996) have shown that both coaggregation and growth stimulation occur between *E. corrodens* and viridans streptococci of the *"Streptococcus milleri"* group, which may enhance the establishment of mixed infections with these species.

Enrichment and Isolation Procedures

Specimens should be plated on blood agar medium (5% sheep or horse blood, Columbia, or Oxoid No. 2 base, or similar media) and incubated anaerobically and aerobically (in each case with 5–15% CO_2) at 35–37°C. About half of the strains isolated have been recovered from the anaerobic plates but will grow aerobically on first subculture. This may be partly accounted for by suppression of associated organisms and by faster initial growth anaerobically upon transfer from relatively anaerobic body sites to artificial media. In addition, the typical corroding appearance of colonies may develop better under the humid conditions that are usual in anaerobic cultures, leading to easier recognition of the organism. For further information on media and atmospheres of incubation, see Goldstein et al. (1981).

Isolation from mixed infections is facilitated by the use of the medium described by Slee and Tanzer (1978), which contains clindamycin (5 μg/ml), KNO_3 (2.0 mg/ml), and hemin (5.0 g/ml) in agar-solidified Todd–Hewitt medium.

Aerobic plates should be maintained in a humid atmosphere during incubation to encourage production of typical colonies, e.g., in properly humidified CO_2 incubators, or in plastic bags gassed with a CO_2/air mixture and containing wet absorbent paper. Plate cultures should be examined daily for up to 5 days.

Maintenance Procedures

Cultures on blood agar plates should be subcultured at weekly intervals to avoid loss of viability. They may be stored in plastic bags at 4°C after 3 d of incubation.

For preservation in liquid nitrogen, a portion of the growth from a plate is transferred to 1 ml of horse serum, placed in a sterile screw-capped plastic vial and stored in a liquid-nitrogen freezer. Survival for at least 2 years has been reported (Labbé et al., 1977).

For freeze-drying, growth from a single plate is washed off with a suspending medium (either bovine serum containing 7.5% glucose or double-strength reconstituted dried skim milk),

placed in 0.2-ml volumes in freeze-drying tubes, and lyophilized. Freeze-dried cultures in vacuum-sealed glass ampules should be stored in a refrigerator (4°C). Some strains may be serum-sensitive, and, for these, the milk medium may be preferable. The milk should be free from antibiotics. Samples of cultures preserved by any method should be tested for viability before storage of batches.

Differentiation of the genus *Eikenella* from other genera

Differentiation of *Eikenella* from morphologically similar microorganisms (Chadwick et al., 1995), especially *H. paraphrophilus*, is shown in Table BXII.β.87. Additional features that distinguish *E. corrodens* from *Bacteroides ureolyticus* are presented in Table BXII.β.88.

Taxonomic Comments

The genus has been defined to include facultative organisms formerly grouped under the name *"Bacteroides corrodens"* (Eiken, 1958). Examination of strains to which this name had been applied revealed that they are heterogeneous. Most are not strict anaerobes, but rather grow in the presence of oxygen on hemin-containing media (Henriksen, 1969a; Hill et al., 1970; Jackson et al., 1971). Certain less oxygen-tolerant strains that are urease-positive have been assigned to the species *Bacteroides ureolyticus* (Jackson and Goodman, 1978). It has been found that some other anaerobic "corroding bacteria" are poorly characterized flagellated organisms (Henrichsen, 1975a; Smibert and Holdeman, 1976; Jackson and Goodman, 1978; Tanner et al., 1981). The statement made by Smibert and Holdeman (1976) that the anaerobic, urease-positive strain VPI 7814 is flagellated is incorrect, as is the report by Brooks et al. (1974) that this strain has a mol% G + C DNA content of 55.0. The true value is 28.4%, and this strain is *B. ureolyticus* and not an atypical *Eikenella* (Jackson and Goodman, 1978).

The organisms termed HB-1 by King (1964) are the same as *E. corrodens* (Jackson and Goodman, 1972; Riley et al., 1973). Similar organisms were included among those referred to as "corroding bacilli" by Holm (1950). The Gram-negative anaerobes forming spreading colonies described by Henriksen (1948) were heterogeneous.

Coykendall and Kaczmarek (1980) have found that 22 *E. corrodens* strains examined have an overall mean mol% G + C DNA content of 56.3, and show at least 70% DNA–DNA relatedness. Variations in relatedness values (70–100%) do not correlate with antigenic differences. It has been concluded that *E. corrodens* can be regarded as a "molecularly homogeneous species," taking into account DNA relatedness, reported mol% G + C ratios, and fatty acid profiles.

[b]Møller's method (Møller, 1955).

[c]Frazier (1926) method preferred. 30% trichloroacetic acid may be substituted for mercuric chloride. If conventional 12% gelatin is used, formate–fumarate supplementation is necessary to ensure growth of *B. ureolyticus* (Smibert and Holdeman, 1976). The use of different methods for any test may affect the results. For suitable methods, see Lapage et al. (1968); Hill et al. (1970); Midgley et al. (1970); Jackson et al. (1971); Brooks et al. (1974); and Cowan (1974, appendix C).

List of species of the genus Eikenella

1. **Eikenella corrodens** (Eiken 1958) Jackson and Goodman 1972, 75[AL] (*"Bacteroides corrodens"* Eiken 1958, 415.)
cor.ro' dens. M.L. part. adj. *corrodens* gnawing.

The characteristics are as described for the genus and as listed in Tables BXII.β.87, BXII.β.88, and BXII.β.89. Probably normal inhabitants of the human mouth and intestine. Can be opportunistic.

The mol% G + C of the DNA is: 56–58 (T_m).

Type strain: 33/54-55, ATCC 23834, DSM 8340, NCTC 10596.

GenBank accession number (16S rRNA): M22512.

TABLE BXII.β.89. Other characteristics of *Eikenella corrodens*[a]

Test	Reaction/Result
Anaerobic growth can occur	+
Catalase	−
Oxidase test (di- or tetramethyl-*p*-phenylenediamine)	+
Cytochromes of *b* and *c* groups present	+
Nitrates reduced to nitrites[b]	+
Anaerobic growth enhanced by nitrate	+
Arginine dihydrolase[c]	−
Indole	−
Acid from glucose and other carbohydrates	−
Flagella present	−
Corroding and noncorroding colonies occur	+

[a]For symbols, see standard definitions.

[b]The method of Cook (1950) is convenient for this test (Jackson et al., 1971), but strains giving a negative reaction by this method have been encountered (Hill et al., 1970).

[c]Method of Møller (1955).

Genus VI. **Formivibrio** *Tanaka, Nakamura and Mikami 1991c, 580[VP] (Effective publication: Tanaka, Nakamura and Mikami 1991a, 494)*

The Editorial Board

For.mi.vib' ri.o. M.L. n. *acidum formicum* formic acid; M.L. masc. n. *Vibrio* that which vibrates, a generic name; M.L. masc. n. *Formivibrio* the formic acid forming vibrio.

Genus description is the same as for the description of *Formivibrio citricus.*

Type species: **Formivibrio citricus** Tanaka, Nakamura and Mikami 1991c, 580 (Effective publication: Tanaka, Nakamura and Mikami 1991a, 494.)

List of species of the genus Formivibrio

1. **Formivibrio citricus** Tanaka, Nakamura and Mikami 1991c, 580[VP] (Effective publication: Tanaka, Nakamura and Mikami 1991a, 494.)
ci' tri.cus. M.L. adj. *citricus* pertaining to citric acid.

Gram-negative, curved rods with tapered or rounded ends, 0.5–0.6 × 1.1–2.5 μm, occurring singly or in pairs. Motile in an active tumbling manner by means of a single polar flagellum. Colonies are colorless, translucent, circular, convex, with an entire margin, up to 0.2 mm in diameter. Anaerobic, having a fermentative type of metabolism. Cat-

alase negative. Do not reduce nitrate, sulfate, sulfite, thiosulfate, or S^0. Do not hydrolyze esculin, urea, or gelatin. Do not produce indole from tryptophan. *S*-Citramalate, citrate, mesaconate, and pyruvate are fermented to acetate and formate and serve as carbon and energy sources. Do not utilize acetoin, acrylate, citraconate, *R*-citramalate, crotonate, fumarate, L-glutamate, glycerol, H_2/CO_2/acetate, lactate, DL-threo-β-methylaspartate, L-malate, maleate, oxalate/acetate, peptones, yeast extract, or carbohydrates. Cells contain β-hydroxymyristic acid ($C_{14:0\ 3OH}$). Cells wall contains *meso*-diaminopimelic acid. Temperature range 30–35°C; no growth at 25°C or 40°C. Optimal pH 7.6 (range 7.1–7.9); no growth at pH 6.7 or 8.2. Specific growth rate on *S*-citramalate under optimal conditions is 0.12/h. Habitat: anoxic freshwater mud.

The mol% G + C of the DNA is: 59–61 (HPLC).

Type strain: CreCit1, ATCC 49791, DSM 6150.

GenBank accession number (16S rRNA): Y17602.

Genus VII. **Iodobacter** *Logan 1989, 455*[VP]

NIALL A. LOGAN

I.o.do.bac′ter. Gr. adj. *ioeides* violet-colored; M.L. masc. n. *bacter* the equivalent of Gr. neut. n. *bakterion* a small rod; M.L. masc. n. *Iodobacter* a violet-colored, small rod.

Straight, **round-ended rods, 0.7 × 3.0–3.5 μm, occurring singly, in pairs**, sometimes in chains, and occasionally as long filaments. Definite capsules are not evident. No resting stages known. Gram negative. **Motile by means of both a single polar flagellum and usually one or more subpolar or lateral flagella. Facultative anaerobes.** Grow on ordinary peptone media. **On low-nutrient media, such as nutrient agar containing a quarter of the normal concentration of nutrients, colonies are usually very thin, with rough surfaces and irregular edges, and may spread to 1 cm or more in diameter**; they are of butyrous consistency and are easily emulsified in water. Most strains produce the violet pigment violacein, and this shows most intensely in the centers of spreading colonies, but strains producing nonpigmented colonies (which are easily overlooked) are sometimes encountered. Occasional strains may spread only poorly and may even produce slightly gelatinous colonies, whose appearances are reminiscent of those produced by *Chromobacterium* and *Janthinobacterium* species. On full-strength nutrient agar and other routine, richer media, colonies may show less tendency to spread. Growth in quarter-strength nutrient broth is moderate after 24 h at 25°C, with uniform turbidity and a violet ring at the surface, but no pellicle; strains that produce long filaments may appear to gel in broths. Chemoorganotrophs; **attack carbohydrates fermentatively, producing small amounts of acid, but no gas. Grow at 4–30°C, with optimal growth at ~25°C.**

The mol% G + C of the DNA is: 50–52.

Type species: **Iodobacter fluviatilis** (Moss, Ryall and Logan 1978) Logan 1989, 455 (*Chromobacterium fluviatile* Moss, Ryall and Logan 1981, 216 (Effective publication: Moss, Ryall and Logan 1978, 18.))

FURTHER DESCRIPTIVE INFORMATION

The pigment violacein is produced on or in media containing tryptophan. It is soluble in ethanol but not in water or chloroform, and is readily identified by spectrophotometry and by testing with routine reagents (see section on *Chromobacterium violaceum*).

Colonies of *Iodobacter* on low-nutrient media are characteristically irregular, thin, spreading, and butyrous, with uneven surfaces like beaten copper. The centers show denser growth and thus more intense pigmentation than do the diffuse peripheries (Fig. BXII.β.70). Occasional strains produce slightly gelatinous, non-spreading colonies. Nonpigmented strains are, without doubt, frequently overlooked when isolated. Subcultures of pigmented strains may contain partially or completely unpigmented colonies. An unpigmented strain is most readily recognized by a colony morphology similar to that of a pigmented strain isolated at the same time under the same conditions. Once it has been confirmed as an oxidase- and catalase-positive, Gram-negative rod, such an isolate should be flagella-stained. If it possesses the characteristic polar and lateral flagella, it should then be subjected to the differential tests for the three genera *Chromobacterium*, *Iodobacter*, and *Janthinobacterium*. Although young cultures of *Aeromonas*, *Pseudomonas*, and *Vibrio* spp. grown on solid media sometimes produce lateral flagella in addition to their usual polar flagella, they give different patterns of results in the differential tests than do the violet-pigmented organisms.

The characteristic flagellar arrangement is best seen in young cultures on solid media. The single polar flagellum is inserted at the tip of the cell, exhibits long, shallow waves and often stains faintly. The lateral flagella are usually long, and 1–4 such flagella, but as many as 8, may occur. They may be inserted subpolarly or laterally, usually exhibit deep, short waves, and stain readily (Fig. BXII.β.71).

Iodobacter fluviatilis strains have been isolated from running fresh water in England and Scotland, and have also been reported from Antarctic lakes and their sediments (Wynn-Williams, 1983).

ENRICHMENT AND ISOLATION PROCEDURES

Iodobacter fluviatilis appears to be a minor member of fresh water floras, and competition with other organisms often results in poor growth and pigmentation and infrequent isolations. For general purposes, the selective medium developed by Ryall and Moss (1975) is recommended: nutrient broth (Oxoid No. 1) at one-quarter strength (¼× NB) is solidified with 1.2% agar (Oxoid No. 3) (to make ¼× Nutrient Agar; ¼× NA) and supplemented, immediately prior to pouring, with filter-sterilized solutions of colistin sulfate, cycloheximide, and sodium deoxycholate (final concentrations, 15, 30, and 300 μg/ml, respectively); the cycloheximide may be omitted if fungal contamination is negligible. Unsupplemented ¼× NA should also be prepared and used both alongside the supplemented medium for isolation and later for subcultures. Spread plates are prepared from undiluted water and from low dilutions and are incubated at 25°C for 5–7 d. Limited trials of the medium described by Keeble and Cross (1977) for isolating *Janthinobacterium* suggest that it is unsuitable for the isolation of *Iodobacter* (Logan, 1989).

MAINTENANCE PROCEDURES

The organisms survive for weeks to months in ¼× NB and for several years in dilute peptone water (0.1% peptone) at 4°C. They

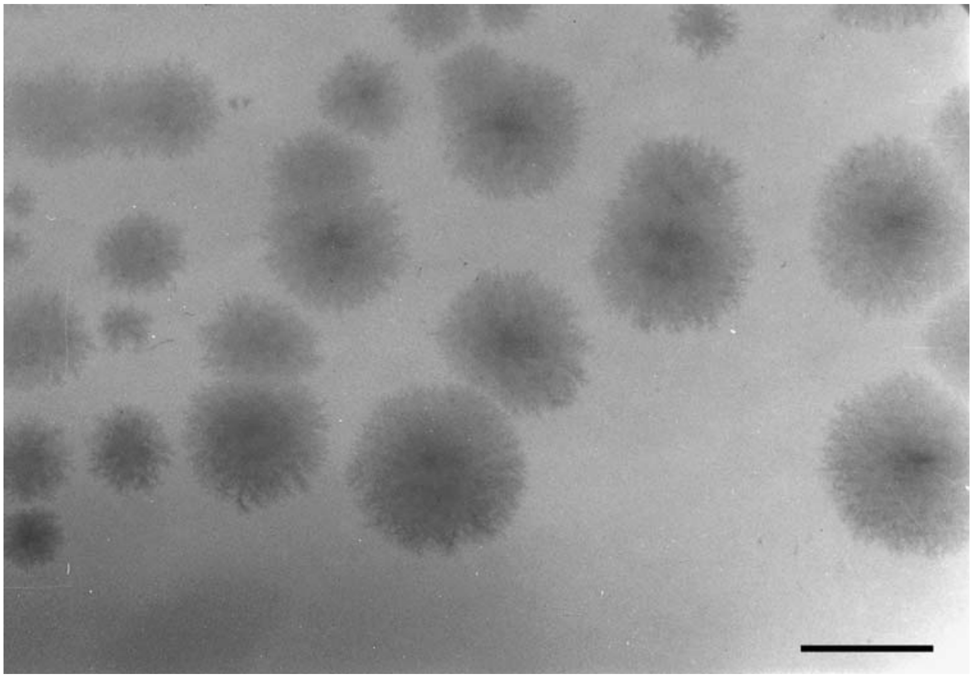

FIGURE BXII.β.70. Colonies of *Iodobacter fluviatilis* ATCC 33051 on quarter strength nutrient agar after 48–72 h at 25°C. Bar = 5 mm.

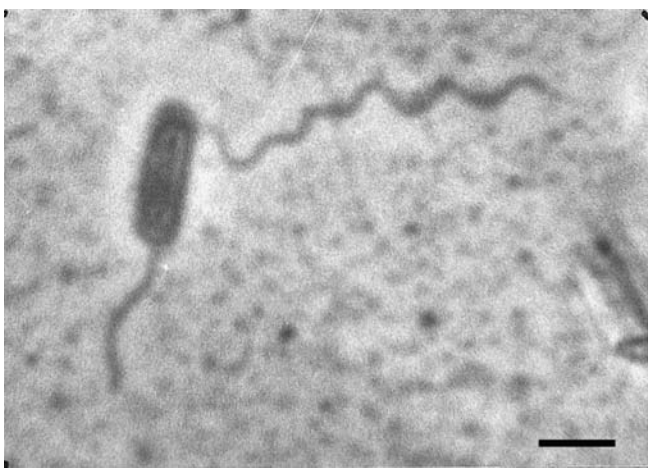

FIGURE BXII.β.71. *Iodobacter fluviatilis* ATCC 33051 stained for flagella by the method of Mayfield and Innis (1977) and showing a long, lateral flagellum with deep waves of short wavelength and a polar flagellum with shallow waves of long wavelength. Bar = 1 μm.

can also be preserved indefinitely by lyophilization or by freezing in nutrient broth containing 15% glycerol.

Procedures for Testing Special Characters

Methods for demonstrating the production of violacein, for the study of flagellar arrangement and growth temperature, and for demonstrating oxidase reaction, fermentative attack of glucose, anaerobic growth, and acid production from carbohydrates are described in the section on *Chromobacterium violaceum*.

Differentiation of the genus *Iodobacter* from other genera

Table BXII.β.90 presents characteristics differentiating the genus *Iodobacter* from the genera *Chromobacterium* and *Janthinobacterium*. Poorly growing and weakly reacting strains are not unusual (see Logan, 1989, for example), so an identification should be based upon a pattern of reactions rather than on the result of a single test.

Taxonomic Comments

Violacein production is a distinctive and important diagnostic feature of *Iodobacter*, but it cannot be emphasized as a taxonomic character, since unpigmented strains are not uncommon (Logan, 1989) and species producing the pigment are found in the genera *Alteromonas*, *Chromobacterium*, and *Janthinobacterium* (Logan and Moss, 1992). Although its mol% G + C range is much lower than that of the other two species in the genus, Moss et al. (1978) allocated their new species of violet chromogen to the genus *Chromobacterium* as *C. fluviatile*, as it is an oxidase- and catalase-positive Gram-negative rod producing violacein and showing the characteristic flagellar arrangement, and because its taxonomic affiliation was unknown. Similarly, *C. violaceum* and *"C. lividum"* were long retained in the same genus on account of these features, even though they show many differences in other respects. In the same year that *C. fluviatile* was described, De Ley et al. (1978) reclassified *"C. lividum"* in the new genus *Janthinobacterium.* Based on nucleic acid hybridization and phenotypic properties and following further nucleic acid hybridization studies (Moss and Bryant, 1982) and numerical analysis of phenotypic characters, *C. fluviatile* was transferred to the new genus *Iodobacter* (Logan, 1989). Phylogenetic relationships inferred from rRNA–DNA hybridization and 16S rRNA sequencing studies support the recognition of these three genera, which represent separate deeply branching lineages of the *Betaproteobacteria*, with *Chromobacterium* and *Iodobacter* being outlying members of the family *Neisseriaceae* (Dewhirst et al., 1989). The adjectival epithet of the only species of the genus, *Iodobacter fluviatile*, has been revised to *Iodobacter fluviatilis* in order to agree in gender with the masculine genus name (Euzéby, 1997).

TABLE BXII.β.90. Patterns of results in tests useful for distinguishing *Iodobacter* from *Chromobacterium* and *Janthinobacterium*[a, b]

[f]Similar patterns of results are obtained with *myo*-inositol and D-sorbitol.

List of species of the genus Iodobacter

1. **Iodobacter fluviatilis** (Moss, Ryall and Logan 1978) Logan 1989, 455[VP] (*Chromobacterium fluviatile* Moss, Ryall and Logan 1981, 216 (Effective publication: Moss, Ryall and Logan 1978, 18.))
flu.vi.a.ti' lis. L. masc. adj. *fluviatilis* of rivers.

Rods, 0.7 × 3.0–3.5 μm, occurring singly or in short chains, with occasional elongated forms.

Colonies on low-nutrient media are flat, very thin, irregular in outline, spreading and pale violet, with a copper-beaten, slightly rough surface, and they are not gelatinous. A uniform turbidity is produced in nutrient broth with a violet ring at the surface, but usually no pellicle.

Grows on ordinary peptone media. Grows on MacConkey agar, giving violet colonies.

Facultatively anaerobic. Optimal temperature, 25°C; minimum, 4°C; maximum, ~30°C.

Other characteristics are given in Tables BXII.β.90 and BXII.β.91.

Isolated from running fresh water in England and Scotland, and from Antarctic lakes and their sediments.

The mol% G + C of the DNA is: 50–52 (T_m).

Type strain: Moss 165/Sp7, ATCC 33051, DSM 3764, NCIMB 2053, NCTC 11159.

GenBank accession number (16S rRNA): M22511.

[a]Symbols: +, all strains positive; [+], positive for 80% or more strains; d, positive for 31–79% strains; [−], positive for 30% or fewer strains; −, negative for all strains; R, resistant; S, sensitive; s, slightly sensitive. Numbers in parentheses indicate the % of strains giving positive reactions.

Genus VIII. **Kingella** *Henriksen and Bøvre 1976, 449^AL emend. Dewhirst, Chen, Paster and Zambon 1993, 497*

ROBBIN S. WEYANT

King.el′la. M.L. *-ella* dim. ending; M.L. fem. n. *Kingella* named after Elizabeth O. King, an American bacteriologist.

Straight rods, 0.6–1.0 × 1.0 to 3.0 μm, with rounded or square ends. Occur in pairs and sometimes in short chains. Endospores are not formed. **Gram negative, but there is a tendency to resist Gram-decolorization.** Nonmotile by normal tests, but may be fimbriated (piliated) and show "twitching motility." **Aerobic or facultatively anaerobic**; grow best aerobically, but can grow weakly under anaerobic conditions on blood agar. Optimal growth temperature, 33–37°C. Two types of colonies occur on blood agar: (a) a spreading, corroding type associated with "twitching motility," fimbriation, and transformation competence, and (b) a smooth, convex type not showing "twitching motility", fimbriation, or competence. **Oxidase positive** (when tested with tetramethyl-*p*-phenylene diamine; the dimethyl reagent may give weak or negative reactions). **Catalase negative.** Coagulated serum is not liquefied. Urease- and indole-negative. Phenylalanine deaminase activity is negative or weak. Chemoorganotrophic. **D-Glucose and a limited number of other carbohydrates are fermented with production of acid, but no gas.** Occur as normal flora in human mucous membranes of the upper respiratory tract. *K. kingae* is an emerging human pathogen, and *K. denitrificans* has been isolated from human infections.

The mol% G + C of the DNA is: 47–58.

Type species: **Kingella kingae** (Henriksen and Bøvre 1968a) Henriksen and Bøvre 1976, 449 (*Moraxella kingae* (Henriksen and Bøvre 1968a) Bøvre, Henriksen and Jonsson 1974, 307; *Moraxella kingii* (sic) Henriksen and Bøvre 1968a, 383.)

FURTHER DESCRIPTIVE INFORMATION

Phylogenetic treatment The genus *Kingella* is in the family *Neisseriaceae*, class *Betaproteobacteria*, and contains three species, *K. kingae*, *K. denitrificans*, and *K. oralis* (Snell, 1984; Dewhirst, et al., 1993).

Cellular morphology and colonial characteristics Cells of *Kingella* strains are characteristically plump, Gram-negative rods or coccobacilli, occurring in pairs or chains. Films from 18-h-old cultures show a tendency to retain the crystal violet of the Gram stain. *Kingella* cells show some pleomorphism, with swollen, irregularly-stained variants. Cells of *Kingella* may show "twitching motility" (Henrichsen et al., 1972; Dewhirst et al., 1993). Twitching motility and competence in genetic transformation are associated with the presence of pili on the cell surface (Frøholm and Bøvre, 1972; Henrichsen, 1972; Weir et al., 1996). *K. kingae* and *K. denitrificans* express type 4 pili that are characteristically long and thin (5–6 nm in diameter) (Weir and Marrs, 1992). Colonies formed by piliated cells are spreading and corroding, in contrast to the smooth, entire, convex colonies formed by nonpiliated cells. Freshly isolated strains of *K. oralis* and *K. denitrificans* produce spreading, corroding colonies (Snell, 1984; Dewhirst et al., 1993). Colonies of *K. kingae* are easily recognized on blood agar in mixed culture by a distinct zone of β-hemolysis surrounding the colonies.

Nutritional and growth requirements All species in the genus are nutritionally fastidious; little or no growth occurs on unsupplemented peptone media. Growth on nutrient agar is only marginally improved by addition of blood or serum, and the colonies remain small, typically 0.5–1.0 mm in diameter after incubation for 48 h. There is no requirement for X or V factors. Although there is no strict requirement for a CO_2-enriched atmosphere, growth of some strains may be enhanced by incubation in 5% CO_2. Growth occurs at 30°C and 37°C but not at 5°C or 45°C. Strains differ in their ability to grow at 22°C. There is some disagreement about of *Kingella* species to grow anaerobically. Henriksen and Bøvre (1976) have described *K. kingae* as aerobic, but Snell and Lapage (1976) have found growth of *K. kingae* and *K. denitrificans* on blood agar in an atmosphere of H_2/CO_2, (95:5), and Dewhirst et al. (1993) have demonstrated growth of *K. oralis* in anaerobic conditions.

Cellular fatty acid composition Cells of *K. kingae* and *K. denitrificans* contain the following fatty acids: *n*-dodecanoic, 3-hydroxydodecanoic, *n*-tetradecanoic, 3-hydroxytetradecanoic, *cis*-9-hexadecenoic, *n*-hexadecanoic, *cis*-9,12-octadecadienoic, *cis*-9-octadecenoic, and *n*-octadecanoic (Weyant, et al. 1996). The cells do not contain *n*-pentadecanoic, 3-hydroxyhexadecanoic, or heptadecenoic acids (Jantzen et al., 1974). Waxes have not been found in *K. kingae* (Bryn et al., 1977).

Antibiotic sensitivity Although *Kingella* strains are normally sensitive to β-lactam antibiotics, sulfonamides, erythromycin, tetracycline, chloramphenicol, ciprofloxacin, and streptomycin, rare cases of antibiotic resistance have been reported. Sordillo et al. (1993) and Minamoto and Sordillo (1992) have reported human infections caused by β-lactamase-positive *K. kingae* and *K. denitrificans* strains. Knapp et al. (1988) have described *K. denitrificans* strains with plasmid-mediated, high-level tetracycline resistance, and Jensen et al. (1994) have identified trimethoprim-resistant *K. kingae* strains. *Kingella* strains are usually resistant to vancomycin.

Pathogenicity *Kingella* species have been associated with infections in humans. Since the 1990s, a significant increase of *K. kingae* septicemia, bone, and joint infections in children under the age of 3 years has been reported (Goutzmanis et al., 1991; Birgisson et al., 1997; Yagupsky and Dagan, 1997; La Scola et al., 1998b; Lundy and Kehl, 1998). *K. kingae* has also been isolated from human corneal ulcer specimens (Mollee et al., 1992). *K. denitrificans* and *K. kingae* have been isolated from blood cultures of individuals with endocarditis (Kerlikowske and Chambers, 1989; Hassan and Hayak, 1993). *K. oralis* has not been associated with invasive infections in humans, although Chen (1996) has reported a significantly higher concentration of this species in dental plaque of individuals with juvenile peridontitis. There have been no published reports of *Kingella* infections in animals or plants.

Natural habitat The natural habitat of *Kingella* is the upper respiratory tract and oral cavity of humans and possibly other primates, where the organisms are present on the mucous membranes as part of the normal flora. Although most *Kingella* isolates have been from human respiratory tract and oral sources, a few isolates of *K. denitrificans* have been obtained from chimpanzee throat and human urogenital specimens (Weyant et al., 1996).

Enrichment and Isolation Procedures

Recovery of *Kingella* from normally sterile clinical specimens, such as blood and synovial fluid, is greatly enhanced by inoculating the specimens into blood culture media (Yagupsky et al., 1992; Yagupsky and Press, 1997; Lejbkowicz et al., 1999). *Kingella denitrificans* has been isolated from specimens with mixed flora by culturing on Thayer–Martin agar (Hollis et al., 1972). *K. kingae* has been selectively isolated on sheep blood agar with 2 μg/ml vancomycin (BAV medium; Yagupsky et al., 1995), and a complex medium containing 5% sheep blood, 5 μg/ml hemin, 0.5 μg/ml menadione, and 1 μg/ml clindamycin has been described by Chen (1996) for the selective recovery of *K. oralis*. Incubation for 48 h may be required for development of colonies of reasonable size on any selective medium. Once isolated, *Kingella* strains may be subcultured on a general, enriched laboratory media, such as blood agar.

Maintenance Procedures

Kingella strains are difficult to maintain by serial transfer, because blood agar cultures become sterile after 6–12 d at room temperature. Preservation is best achieved by freeze drying. Horse serum containing 5% (w/v) *i*-inositol is a suitable suspending medium for freeze drying (Redway and Lapage, 1974). Alternatively, strains may be preserved by suspending fresh cultures in defibrinated rabbit blood and freezing in liquid nitrogen (Weyant et al., 1996).

Procedures for Testing Special Characters

The main difficulty in characterizing members of the genus is the poor growth obtained in nonenriched media. Growth is better on solid or semisolid media than in liquid media. Serum promotes a slight, although not a dramatic, improvement of growth, and addition of 5% horse or rabbit serum to test media is worthwhile. For testing the acidification of carbohydrates, rabbit serum is preferable because horse serum contains endogenous maltase activity (Hollis et al., 1983). Due to the slow growth of the organisms, longer than usual incubation periods (3–7 days) may be required to confirm negative results.

Methods suitable for characterization of the genus have been described by Snell et al. (1972), Snell and Lapage (1976), and Weyant et al. (1996).

Differentiation of the genus *Kingella* from other genera

Characteristics by which *Kingella* may be differentiated from phenotypically similar genera and species within the family *Neisseriaceae* are shown in Table BXII.β.92.

Taxonomic Comments

These bacteria were historically associated with the genus *Moraxella*. *K. kingae* was originally named *Moraxella kingii* by Henriksen and Bøvre (1968a). The masculine epithet *kingii* was later corrected to the feminine *kingae* by Bøvre et al. (1974). The species was transferred to a newly created genus *Kingella* by Henriksen and Bøvre (1976). In 1972, Hollis et al. described TM-1, a fastidious Gram-negative rod isolated on Thayer–Martin agar from human pharyngeal cultures (Hollis et al., 1972). TM-1 was later classified as *Kingella denitrificans* by Snell and Lapage, who also described *K. indologenes* in the same paper (Snell and LaPage, 1976). In 1990, Dewhirst et al., using 16S rRNA sequence-based methods, found that *K. indologenes* was sufficiently distant from the other *Kingella* species to justify its inclusion in the new genus *Suttonella* as *S. indologenes* (Dewhirst et al., 1990). With the description of *K. oralis* in 1993 (Dewhirst et al., 1993), the genus was again expanded to the 3 currently recognized species.

List of species of the genus Kingella

1. **Kingella kingae** (Henriksen and Bøvre 1968a) Henriksen and Bøvre 1976, 449[AL] (*Moraxella kingae* (Henriksen and Bøvre 1968a) Bøvre, Henriksen and Jonsson 1974, 307; *Moraxella kingii* (sic) Henriksen and Bøvre 1968a, 383.)
king' ae. M.L. gen. n. *kingae* of King, named after Elizabeth O. King, an American bacteriologist.

The characteristics are as described for the genus and as listed in Tables BXII.β.93 and BXII.β.94.

When grown on blood agar, *K. kingae* colonies produce a characteristic zone of β-hemolysis. This characteristic, along with the tendency of this species to resist Gram-stain decolorization and its failure to produce catalase, may cause some confusion between *K. kingae* and β-hemolytic streptococci in the analysis of specimens from the human throat and oral cavity. The oxidase test, which is generally positive for *K. kingae* and negative for *Streptococcus* species, is a simple and effective differential method.

In recent years, there has been an increased recognition of *Kingella kingae* as an etiologic agent of invasive infections of humans, especially children less than 2 years of age. Since 1985, numerous case reviews describing *Kingella kingae* septic arthritis, osteomyelitis, septicemia, or endocarditis in pediatric patients have been reported. These cases were from various geographic locations, including Sweden (9 cases)

[b]Data from Snell (1984), Dewhirst et al. (1993), and Weyant et al. (1996).

(Claesson et al., 1985), Iceland (5 cases) (Birgisson et al., 1997), Australia (10 cases) (Goutzmanis et al., 1991), France (5 cases) (La Scola et al., 1998b), Israel (42 cases) (Yagupsky and Dagan, 1997), and the United States (10 cases) (Lundy and Kehl, 1998). In many cases, *K. kingae* infections occur as sequelae to viral infections, with the viral agents presumably compromising mucosal immunity to allow the seeding of the bloodstream with *K. kingae* from the oral cavity (Waghorn and Cheetham, 1997; Amir and Yagupsky, 1998). Lundy and Kehl (1998) have observed that the apparent increase in *K. kingae* infections corresponds with the vaccine-mediated decrease in *Haemophilus influenzae* infections in young children, suggesting that *K. kingae* is replacing *H. influenzae* as a significant etiologic agent in this population.

The mol% G + C of the DNA is: 47.3–47.4 (T_m).

Type strain: ATCC 23330.

GenBank accession number (16S rRNA): M22517.

2. **Kingella denitrificans** Snell and Lapage 1976, 456[AL]
de.ni.tri′ fi.cans. L. prep. *de* away from; L. n. *nitrum* soda; M.L. n. *nitrum* nitrate; M.L. v. *denitrifico* to denitrify; M.L. part. adj. *denitrificans* denitrifying.

The characteristics are as described for the genus and as listed in Tables BXII.β.93 and BXII.β.94.

Kingella denitrificans was first described by Hollis et al. (1972), who encountered isolates of this species on Thayer–Martin selective agar while performing a study to determine pharyngeal carrier rates of *Neisseria meningitidis* and *N. lactamica* in healthy adults. The isolates were originally designated "TM-1" in recognition of their ability to grow on Thayer–Martin agar.

Kingella denitrificans is commonly found as part of the normal flora of the human pharynx and is generally considered to be of low pathogenicity. Of 60 strains studied at the U.S. Centers for Disease Control and Prevention, only 2 have been from sources, i.e., blood and mandibular abscess, suggestive of invasive infection (Weyant et al., 1996). Rare cases of endocarditis (Hassan and Hayek, 1993), and a case of granulomatous disease in an AIDS patient (Minamoto and Sordillo, 1992) have been reported.

The mol% G + C of the DNA is: 54.1–54.8 (T_m).

Type strain: ATCC 33394, DSM 10202, NCTC 10995.

GenBank accession number (16S rRNA): M22516.

3. **Kingella oralis** Dewhirst, Chen, Paster, and Zambon 1993, 498[VP] (*Kingella orale* (sic) Dewhirst, Chen, Paster, and Zambon 1993, 498.)
o.ra′ lis. L. adj. *oralis* oral, pertaining to the mouth.

The characteristics are as described for the genus and as listed in Tables BXII.β.93 and BXII.β.94.

Kingella oralis was originally described by Chen et al. (1990a) as *Eikenella corrodens*-like isolates obtained from human oral cavity specimens. In the original 1993 classification paper, this species was named *K. orale*, but the spelling of the species name was changed to "*oralis*" in 1994 (Dewhirst et al., 1993, 1994). *K. oralis* is found in the human oral cavity and produces corroding colonies similar to those of *E. corrodens*. Biochemical tests useful in differentiating *K. oralis* from *E. corrodens* include acidification of D-glucose and ornithine decarboxylase.

The mol% G + C of the DNA is: 56–58 (T_m).

Type strain: ATCC 51147, CCUG 30450.

GenBank accession number (16S rRNA): L06164.

Genus IX. **Microvirgula** *Patureau, Godon, Dabert, Bouchez, Bernet, Delgenes and Moletta 1998, 781[VP]*

DOMINIQUE PATUREAU

Mi.cro.vir′ gu.la. Gr. adj. *micros* small; L. fem. n. *virgula* twig or rod; M.L. n. *Microvirgula* small twig or rod.

Curved rods, occurring singly, in pairs, or in clusters. **Motile.** Gram negative. **Oxidase and catalase positive. Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor; however, anaerobic respiration occurs in the presence of nitrate, nitrite, and nitrous oxide, with the formation of N_2. **Denitrification is not repressed under aerobic conditions.** Chemoorganotrophic. **Growth occurs on a variety of carbon sources including acetate, succinate, propionate, ethanol, methanol, and glycerol, but not on sugars.** Belongs to the *Betaproteobacteria*. Isolated from an up-flow anoxic filter inoculated with activated sludges.

The mol% G + C of the DNA is: 65.

Type species: **Microvirgula aerodenitrificans** Patureau, Godon, Dabert, Bouchez, Bernet, Delgenes and Moletta 1998, 781.

DIFFERENTIATION OF THE GENUS *MICROVIRGULA* FROM OTHER GENERA

Phenotypically, the genus most closely resembles *Comamonas testosteroni*, *Alcaligenes faecalis*, and *Thauera mechernichensis*. Table BXII.β.95 lists characteristics that differentiate the genus from these species and from the phylogenetically related organisms *Chromobacterium violaceum* and *Vogesella indigofera*.

TAXONOMIC COMMENTS

In this edition of the *Manual*, the genus *Microvirgula* is placed in the class *Betaproteobacteria*, the order *Neisseriales*, and the family *Neisseriaceae*. Based on studies of the 16S rDNA sequence by Patureau et al. (1998), the genus is most closely related to *Vogesella indigofera* (87.3%) and *Chromobacterium violaceum* (87.9%) (Fig. BXII.β.72).

List of species of the genus Microvirgula

1. **Microvirgula aerodenitrificans** Patureau, Godon, Dabert, Bouchez, Bernet, Delgenes and Moletta 1998, 781[VP]
ae.ro.de.ni.tri′ fi.cans. Gr. n. *aer* air; M.L. v. *denitrificare* to denitrify; M.L. part. *aerodenitrificans* denitrifying with or in air.

The characteristics are as described for the genus, with the following additional information. Oxidizable carbon and energy sources include methylpyruvate, acetate, formate, β-hydroxybutyrate, propionate, sebacic acid, succinate, L-asparagine, L-aspartic acid, L-glutamic acid, L-leucine, L-proline, methanol, ethanol, and glycerol.

The following compounds are not utilized: dextrin, glycogen, xylitol, citrate, α-ketoglutarate, α-ketovalerate, malonate, D-alanine, L-phenylalanine, D-serine, L-threonine, D,L-carnitine, inosine, uridine, 2,3-butanediol, and glucose-1-phosphate, D-galacturonic acid, and D-gluconic acid.

Optimal pH, 7. Optimal temperature, 35°C; range, 15–45°C. Maximum growth rates (μmax) are 0.37 h^{-1} under aerobic conditions, 0.23 h^{-1} under mixed oxic–nitrate conditions, and 0.11 h^{-1} under strict anaerobic conditions.

The type strain can co-respire oxygen and nitrogen oxides under O_2-saturated conditions with activity and synthesis of the four denitrifying enzymes, regardless of the aeration conditions. A similar behavior is observed with *Paracoccus pantotrophus*, *Alcaligenes faecalis* strain TUD, and *Thauera mechernichensis*.

Lipase activity occurs.

The mol% G + C of the DNA is: 65.

Type strain: SGLY2, LMG 18919.

GenBank accession number (16S rRNA): U89333.

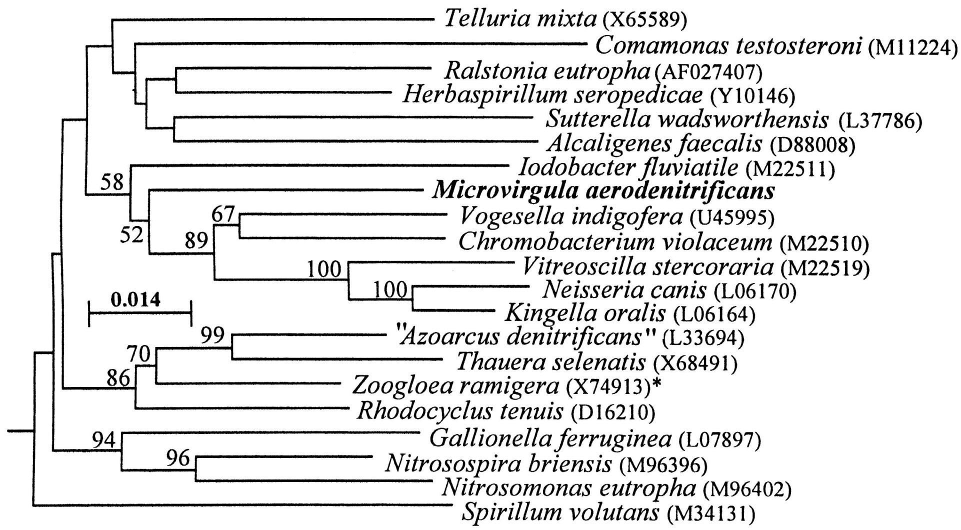

FIGURE BXII.β.72. Phylogenetic tree showing the relationship of *Microvirgula aerodenitrificans* to other members of the class *Betaproteobacteria*. This tree was inferred from 16S rRNA gene sequence data by the neighbor-joining method (Saitou and Nei, 1987). A total of 1120 nucleotide positions were included in the analysis. The tree was rooted with the sequence of *Paracoccus denitrificans*. The scale bar indicates the percentage difference per nucleotide position using the Jukes and Cantor correction (Jukes and Cantor, 1969). Numbers refer to bootstrap values up to 50% for each node out of a total of 500 replicate samplings (Felsenstein, 1985). *, accession number corresponds to strain ATCC 19544. Names are given as cited in the GenBank database. (Reproduced with permission from D. Patureau et al., International Journal of Systematic Bacteriology *48:* 775–782, 1998, ©International Union of Microbiological Societies.)

Genus X. **Prolinoborus** *Pot, Willems, Gillis and De Ley 1992b, 52*[VP]

NOEL R. KRIEG

Pro.li.no'bo.rus. L. n. *prolina* the amino acid proline; Gr. adj. *boros* voracious M.L. masc. n. *Prolinoborus* (bacteria) that readily consume proline.

Straight rods, 0.7–0.9 μm in width.. Cells are approximately 5–10 μm in length, but old cultures may contain cells up to 42 μm long. Curved or S-shaped variants have been reported to occur in one strain after prolonged serial transfer. A polar membrane underlies the cytoplasmic membrane. **Intracellular poly-β-hydroxybutyrate granules are present** in the rods. Extensive conversion of the rod-shaped cells to round forms (**"coccoid bodies"**) occurs in older cultures. **Upon initial isolation, the cells form highly viscous flocs, within which the cells swim steadily in straight lines.** The floc-forming ability is gradually lost during subsequent serial transfers, and the growth eventually becomes turbid. Cells have **bipolar flagellar fascicles composed of up to 11 flagella**. The fascicles can be seen clearly by dark-field microscopy and show **unusual and distinctive behavior** when the cells are suspended in ordinary, nonviscous media: helical wave propagation with waves progressing from base to tip, an ability to coil up like springs, and basal bending accompanied by a change in wavelength. **In such nonviscous media the cells do not swim; instead, they exhibit an ineffectual "floundering about" movement;** however, when they are suspended in a medium of high viscosity (10–200 centipoise, obtained by the use of agents such as DNA or methylcellulose "400 centipoise"), they swim steadily in straight lines. Optimal temperature, 30°C; no growth at 20°C or 40°C. **Catalase and oxidase positive. Carbohydrates are not catabolized.** Pyruvate and proline are the most effective sole carbon sources. **Proline can be used a sole source of nitrogen and carbon. Nitrogenase activity** (ability to reduce acetylene) **occurs under microaerobic conditions**. Habitat: pond water.

The mol% G + C of the DNA is: 62–65.

Type species: **Prolinoborus fasciculus** (Strength, Isani, Linn, Williams, Vandermolen, Laughon and Krieg 1976) Pot, Willems, Gillis and De Ley 1992b, 53 (*Aquaspirillum fasciculus* Strength, Isani, Linn, Williams, Vandermolen, Laughon and Krieg 1976, 266.)

FURTHER DESCRIPTIVE INFORMATION

The cell morphology and behavior of the flagellar fascicles is illustrated in Fig. BXII.β.73 and BXII.β.74.

Upon initial isolation, the cells form highly viscous flocs which, when homogenized in a small quantity of water, contain free-swimming cells that move in straight lines within the viscous matrix. The tailing flagellar fascicle is extended behind each cell, while the leading fascicle is either coiled into a polar loop or coiled around the cell. Free cells or cells at the periphery of the flocs are not motile, or their motility is irregular over short distances. After several serial transfers, the floc-forming ability is gradually lost, and the cells no longer swim, although the flagellar fascicles exhibit helical wave propagation, basal bending, and the ability to coil up like springs. The ability to swim only in viscous media may represent an adaptation to the viscous conditions that occur within cell flocs.

The mass conversion of the rod form to the coccoid form is

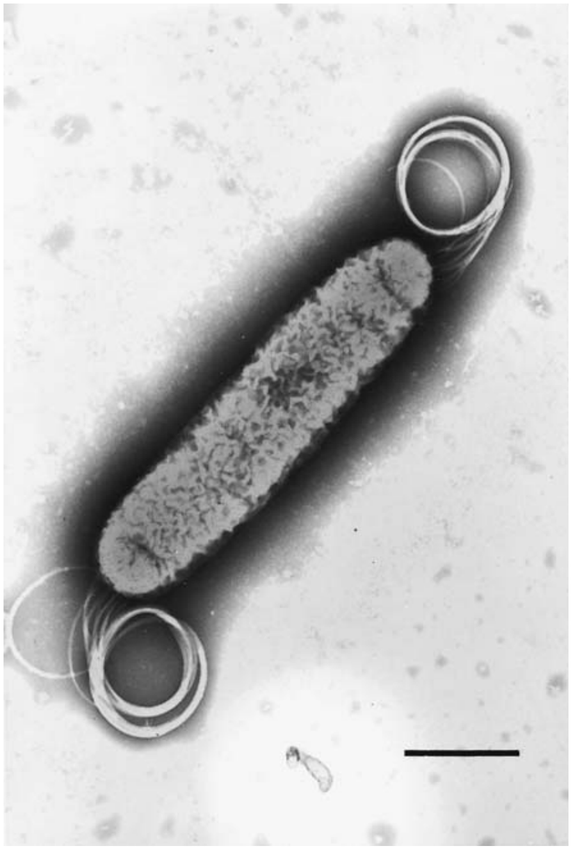

FIGURE BXII.β.73. Formalin-fixed cells of *Prolinoborus fasciculus* showing the bipolar fascicles of flagella coiled into loops. When the fascicles are extended, they have a helical configuration with several waves. Bar = 1.0 μm. (Reproduced with permission from W.J. Strength and N.R. Krieg, Canadian Journal of Microbiology *17:* 1133–1137, 1971, ©National Research Council of Canada.)

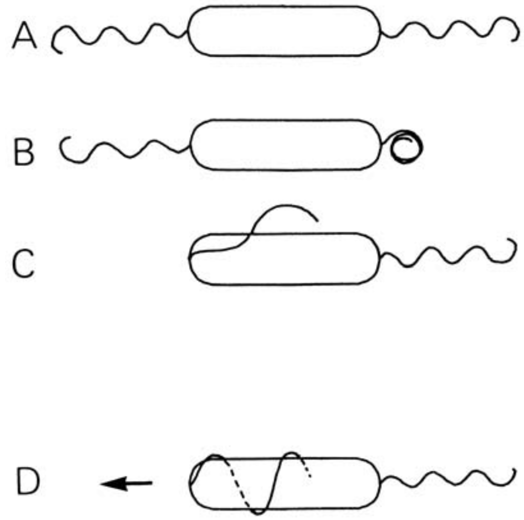

FIGURE BXII.β.74. Flagellar behavior in *P. fasciculus*. *A*–*C*, flagellar orientation observed in nonviscous media: *A*, flagellar fascicles extended; *B*, coiling into a polar loop; and *C*, basal bending accompanied by a change in wavelength. *D*, orientation of the fascicles in motile cells suspended in a viscous medium; the arrow indicates the direction of swimming.

shown in Fig. BXII.β.75. Koechlein and Krieg (1998) have found that chloramphenicol does not prevent the conversion of the rods to the coccoid form. Attempts to obtain variants that do not convert to the coccoid form have been unsuccessful. Although the coccoid form fluoresces with acridine orange, extensive rRNA degradation has occurred, as indicated by agarose gel electrophoresis. Poly-β-hydroxybutyrate, abundant in the vegetative rods, is not detectable in the coccoid cells. The results suggest that the coccoid form of *P. fasciculus* may be a degenerative form, rather than part of a life cycle.

Enrichment and Isolation Procedures

In studies by Strength et al. (1976), organisms with the characteristic morphological features were found to reach maximal numbers in the surface scum of pond water–hay infusions in 3 d at 30°C. Some enrichment can be achieved by subsequent cultivation of the scum in Pringsheim soil medium[1]. A loopful of surface pellicle from a 4-d-old enrichment culture is transferred to 10 ml of sterile water. After vigorous shaking to disperse the cell flocs, the suspension is serially diluted in sterile water, and each dilution is used to seed plates of melted, cooled PR medium[2] containing 0.75% agar. After 36 h at 30°C, numerous small (0.1–0.4 mm diameter), white, irregularly shaped colonies (as well as other types of colonies) develop. Each small colony is removed with sterile capillary tubes under a dissecting microscope and the agar plug containing the isolated colony is blown out into a tube containing semisolid (0.15% agar) PR medium. The agar plugs are crushed with a glass rod after the transfer.

After growth occurs, the organisms can be transferred to PFS[3] broth. On initial isolation, the organism forms highly viscous flocs. This floc-forming ability is gradually lost during subsequent transfers, and eventually the strains exhibit homogeneous, turbid growth.

Maintenance Procedures

Strains can be maintained by serial transfer at 48-h intervals in semisolid PFS medium. Incubation beyond 48 h usually results in lack of viability, probably because of extensive formation of the coccoid form. For long-term preservation, centrifuged cells are suspended to high density in PFS broth containing 15% glycerol and stored in liquid nitrogen.

1. Pringsheim soil medium (Rittenberg and Rittenberg, 1962): place one wheat or barley grain in a large test tube, and cover it with 3–4 cm of garden soil. Fill the tube almost to the top with tap water. Sterilize the medium at 121°C for 30 min.

2. Proline-salts (PR) medium of Strength et al. (1976) (g/l): L-proline, 0.5; K_2HPO_4, 0.45; $MgSO_4 \cdot 7H_2O$, 0.25; $MnSO_4 \cdot H_2O$, 0.001; and $FeCl_3 \cdot 6H_2O$, 0.001. Adjust to pH 7.0 with KOH.

3. Peptone-fumarate-salts (PFS) broth of Strength et al. (1976) (g/l): Bacto peptone (Difco), 10.0; fumaric acid, 2.0; $(NH_4)_2SO_4$, 1.0; $MgSO_4 \cdot 7H_2O$, 0.5; $FeCl_3 \cdot 6H_2O$, 0.002; $MnSO_4 \cdot H_2O$, 0.002; Adjust to pH 7.0 with KOH. The medium can be used in liquid, semisolid (0.15% agar), or solid (1.5% agar) form.

Procedures for Testing Special Characters

Cultures to be tested for nitrogenase activity should be cultured in nitrogen-free, semisolid malate medium (see the genus *Azospirillum*) supplemented with 0.005% yeast extract. Cultures are incubated for 3 d at 30°C and then sealed with rubber vaccine-bottle stoppers. Acetylene is injected to a final concentration of 10% (v/v), and the cultures are tested for ethylene production by gas chromatography after 1 h of further incubation. Controls using liquid rather than semisolid medium and semisolid medium containing 0.1% $(NH_4)_2SO_4$ should be negative for ethylene production.

Differentiation of the genus *Prolinoborus* from other genera

In most of its physiological properties, *Prolinoborus* is similar to aerobic, heterotrophic, freshwater spirilla such as *Aquaspirillum serpens* (its closest relative). However, the rod shape of the cells, floc formation, and especially the unusual behavior of the flagellar fascicles clearly differentiate *Prolinoborus* from these spirilla. The unusual flagellar behavior, formation of viscous flocs, ability to use proline as a sole carbon and nitrogen source, inability to use carbohydrates, and nitrogenase activity readily differentiate *Prolinoborus* from other aerobic Gram-negative freshwater rods.

Taxonomic Comments

Prolinoborus fasciculus was initially classified in the genus *Aquaspirillum* by Strength et al. (1976). However, DNA–rRNA hybridization studies by Pot et al. (1992b) indicated that the genus *Prolinoborus* belongs to rRNA superfamily III (now the class *Betaproteobacteria*), with a difference in $T_{m(e)}$ of more than 6°C with its closest relative, *Aquaspirillum serpens*. Pot et al. regarded this $T_{m(e)}$ difference as support for the classification of *A. fasciculus* into a new genus, *Prolinoborus*. *Prolinoborus fasciculus* is currently the only species in this genus.

List of species of the genus Prolinoborus

1. **Prolinoborus fasciculus** (Strength, Isani, Linn, Williams, Vandermolen, Laughon and Krieg 1976) Pot, Willems, Gillis and De Ley 1992b, 53^{VP} (*Aquaspirillum fasciculus* Strength, Isani, Linn, Williams, Vandermolen, Laughon and Krieg 1976, 266.)
fas.ci' cu.lus. L. masc. dim. n. *fasciculus* a small bundle.

The characteristics are as described for the genus, with the following additional information. No water-soluble brown pigment is formed in the presence of 0.1% tyrosine or tryptophan. Growth occurs in the presence of 1% oxgall. No growth occurs in the presence of 1% glycine and 3% NaCl. No hydrolysis of casein, starch, esculin, or hippurate. Gelatin is hydrolyzed in 4 d at 30°C. Anaerobic growth occurs with nitrate. KNO_3 is reduced only to KNO_2. Phosphatase and urease positive. Indole negative.

Sole carbon sources, as determined by the method of Strength et al. (1976) include succinate, fumarate, malate, oxaloacetate, pyruvate, lactate, β-hydroxybutyrate, L-alanine, L-glutamate, L-aspartate, L-glutamine, L-asparagine, L-proline, and L-arginine. The following carbon sources are not used: citrate, α-ketoglutarate, malonate, acetate, propionate, butyrate, ethanol, *n*-propanol, *n*-butanol, glycerol, D-fructose, D-glucose, D-xylose, L-arabinose, L-histidine, L-tyrosine, L-phenylalanine, L-hydroxyproline, L-ornithine, L-lysine, L-methionine, L-serine, L-cysteine, L-leucine, L-isoleucine, L-valine, and L-tryptophan.

The mol% G + C of the DNA is: 62–65 (T_m).

Type strain: ATCC 27740, LMG 6233.

Genus XI. **Simonsiella** *Schmid* in *Simons 1922, 504*[AL]

BRIAN P. HEDLUND AND TONE TØNJUM

Si.mon.si.el′ la. M.L. dim. *-ella* ending; M.L. fem. n. *Simonsiella* (organism of) Simons; named for H. Simons, who studied the species of this genus.

Organisms that exist in characteristic **multicellular filaments** that are **flat rather than cylindrical** and often segmented into groups of eight cells. The **width of an individual cell is greater than its length**. **The long axis of an individual cell is perpendicular to the long axis of the filament.** The diameter of the filaments (the width of the individual cells) may vary from about 2.0 to 8.0 μm, and the length of filaments may vary from about 10.0 to over 50.0 μm. Individual cells within the filaments may be from about 0.5 to 1.3 μm long. In thin sections cut perpendicular to the long axis of the filament, the **cells are flattened and curved to yield a crescent-shaped, convex–concave (dorsal–ventral) asymmetry**. The **ends of the individual filaments are rounded**. Gram negative. **Gliding motility** of the entire filament in the direction of the long axis when the flat side of the filament is in contact with a surface. Chemoorganotrophs. Aerobic. Some may produce acid aerobically from carbohydrates. Optimal temperature: 37°C. **Found in the oral cavity of warm-blooded vertebrates.**

The mol% G + C of the DNA is: 41–55.

Type species: **Simonsiella muelleri** Schmid *in* Simons 1922, 504.

FURTHER DESCRIPTIVE INFORMATION

The genus *Simonsiella* is characterized by a unique multicellular morphology. The filaments of *Simonsiella* are distinctive and members of this genus can be recognized by their morphology alone (Figs. BXII.β.76, BXII.β.77, and BXII.β.78). The dorsal-ventral flattening of the filaments is quite striking, as is the fact that the individual cells of the filament are wider than they are long if the long axis of the filament is considered to represent the length of the cells. The cells toward either end of the filament decrease in width, and the terminal cells may be rounded, giving the filaments a tapered appearance with rounded ends. In isolated colonies, some of the filaments may be turned on their sides, which shows the flattening quite clearly. Starr and Skerman (1965) suggested that this type of structure should be called a trichome—chain of closely apposed bacterial cells—found, for example, in certain genera of the cyanobacteria, the genus *Toxothrix* and the genus *Caryophanon*. From the convex (bottom) side of the filaments there are numerous fine fibrils (Fig. BXII.β.78), which appear to be involved in the adhesion of the filaments to a surface and perhaps in locomotion (Pangborn et al., 1977). In thin sections, the cells appear to have a typical Gram-negative cell wall structure.

Individual filaments glide over the agar surface only when the broad, ventral surface is in contact with the agar. Movement of the filaments over the agar leaves depressed tracks in the agar surface (Fig. BXII.β.77), perhaps indicating a change in the structure of the agar (Pangborn et al., 1977). No flagella have been demonstrated, but the presence of pili (fimbriae) should be assessed. The speed of gliding varies from about 5 to 24 μm/min (Buchanan and Kuhn, 1978). Colonies on BSTSY agar (see Enrichment and Isolation Procedures) may have a pale yellow pigmentation. Most, but not all, strains produce a zone of hemolysis on agar containing horse, sheep, or rabbit blood. No resting stage has been detected.

All isolates of *Simonsiella* are chemoorganotrophic, and the nutrition of the isolates (as well as their classification) parallels their source of origin. The isolates from sheep (*S. crassa*) are generally the most physiologically active, being both proteolytic and saccharolytic (Tables BXII.β.96, BXII.β.97, BXII.β.98, BXII.β.99, and BXII.β.100). In contrast, the isolates from dogs (*S. steedae*) are neither proteolytic nor saccharolytic. Kuhn et al. (1978) have described over 50 isolates of *Simonsiella*. All strains are aerobic, possess cytochrome oxidase, and produce catalase. Good growth occurs between 3° and 40°C, is optimal at 37°C, and does not occur at 45°C. Growth occurs in 1% NaCl but not

in 2% NaCl. No strains hydrolyze starch or agar or produce urease or indole. No strains produce acid from cellobiose, dulcitol, erythritol, galactose, glycerol, inositol, lactose, mannose, melibiose, melizitose, raffinose, rhamnose, salicin, sorbitol, sorbose, or xylose. Some species may produce acid from other carbohydrates. A rich medium is best for growth, and the addition of serum to the medium has been found to be necessary for some strains and to be advantageous for all other strains (Kuhn et al., 1978).

The cell-bound fatty acid profiles of 48 strains of *Simonsiella* matched the general pattern of Gram-negative bacteria, in which high percentages of even-numbered saturated and monounsaturated fatty acids occur (Jenkins et al., 1977). Tetradecanoic acid was the predominant saturated fatty acid followed by hexadecanoic acid. 9-Hexadecanoic and 9-octadecanoic acids were the predominant monounsaturated fatty acids. Results of stepwise discriminant analysis of the mean relative percentages of tetradecanoic, hexadecanoic, and 9-octadecanoic acids demonstrated that 85% of the isolates (with two cat strains and one dog strain being the exceptions) were correctly identified in their source-of-origin groups.

Habitat In healthy human populations, the incidence of *Simonsiella* is in the range of 30–40% (Simons, 1922; Kuhn et al., 1974). Children possibly have a higher incidence than adults (Fellinger, 1924; Richardson et al., 1966). In dogs and cats *Simonsiella* are common and abundant, the incidence approaching 100% in specimens from the palate or from the buccal cavity (Nyby et al., 1977). In specimens from oral cavities and gingival margins, simonsiellas are less likely to be found (~20% incidence; Saphir and Carter, 1976; Bailie et al., 1978). The incidence varies not only with the site in the mouth from which the specimens are obtained, but also with the method of observation. Direct microscopy yields a higher incidence than cultivation, and microscopic observation of oral specimens growing on plates gives a higher yield than the detection of macroscopic colonies after prolonged incubation (Richardson et al., 1966; Saphir and Carter, 1976; Bailie et al., 1978). Even though these bacteria have been considered as members of the normal flora (Kuhn et al., 1974), they are often underrecognized or not even mentioned as part of the oral microflora. Pathological changes of disease have not been associated with the presence of *Simonsiella* in the mouth. In fact, the incidence of *Simonsiella* in human patients with obvious oral pathology has been considerably lower than in groups of healthy people (Simons, 1922; Bruckner and Fahey, 1969). Despite their low pathogenicity, *Simonsiella* spp. have been isolated from erosive lesions of the human oral cavity (Carandina et al., 1984) and from the gastric aspirate of a neonate (Whitehouse et al., 1987).

Phylogeny and classification Steed designated the family *Simonsiellaceae* to include *Simonsiella* and the morphologically similar genus *Alysiella* (Steed, 1962). Rossau and co-workers demonstrated close relationships between *Simonsiella* strains and strains of *Neisseria*, *Kingella*, *Eikenella*, and *Alysiella* by DNA–rRNA hybridization and suggested that *Simonsiella* should be included in the emended family *Neisseriaceae* (Rossau et al., 1989). Dewhirst et al. (1989) found that the type strain of *S. muelleri* by 16S rRNA sequence analysis clustered within the *Neisseriaceae* in the *Betaproteobacteria*. Appropriately, these authors also supported the emended family *Neisseriaceae* to include genus *Simonsiella*.

Kuhn et al. (1977, 1978) have isolated nearly 50 strains of *Simonsiella* from dogs, cats, sheep, and humans. Based on morphology, physiology, and the mol% G + C of the DNA, the strains can be separated into distinct groups that correlated with their source of origin. Three of these groups (dogs, sheep, and humans) have been designated as separate species, while the isolates from cats and other vertebrates need additional characterization

before any decisions about species designations can be made (Kuhn et al., 1978; Kuhn and Gregory, 1978). Numerical taxonomy studies showed that most of the *Simonsiella* strains grouped according to the mammalian host from which they were isolated (Kuhn et al., 1978; Heiske and Mutters, 1994) (Tables BXII.β.96, BXII.β.97, BXII.β.98, BXII.β.99, and BXII.β.100). *Simonsiella* isolates from humans and sheep were each monophyletic in a dendrogram derived from the numerical taxonomy data. Isolates from cats and dogs tended to cluster together with strains from the same host; however, neither group was strictly monophyletic based on the phenotypic data. These observations led to the proposal that each of these mammals hosts a unique type of *Simonsiella* (Kuhn et al., 1978). Kuhn suggested that these host groups represented ecospecies: species of bacteria that each occupied a niche in a unique ecosystem, in this case the mouths of different animals. Accordingly, three of the *Simonsiella* groups were assigned to separate species. *S. muelleri*, *S. crassa*, and *S. steedae* were proposed for *Simonsiella* strains native to humans, sheep, and dogs, respectively. Hedlund and Staley assessed the relationships between *Simonsiella* strains and other members of the *Neisseriaceae* further by 16S rDNA sequence analysis of 16 *Simonsiella* strains (Hedlund and Staley, 2002) (Fig. BXII.β.79). Most *Simonsiella* strains grouped according to established *Simonsiella* species designations and the mammalian hosts from which they were isolated. The host groups corresponded to the three existing *Simonsiella* species— *S. muelleri*, *S. steedae*, and *S. crassa* —which are commensals of humans, dogs, and sheep, respectively. The fourth group consisted of *Simonsiella* isolates from domestic cats, and the phenotypic results previously obtained by Kuhn were common to the *Simonsiella* cat isolates (Kuhn et al., 1978). Although this entity was phylogenetically more diverse than the other groups and phenotypically similar to *S. steedae*, the distinct phylogeny and ecological habitat of this group supported the establishment of a new species. Thus, the phylogeny together with phenotypic data supported the suggestion of "*S. kuhniae*" to encompass *Simonsiella* strains isolated from domestic

cats, as proposed by Hedlund and Staley (2002). Hedlund and Staley (2002) have provided evidence that the different *Simonsiella* strains may have co-evolved with their respective hosts. The bacteria seem to be evolving more rapidly than their hosts, most likely because they are growing more quickly (Interview with J.T. Staley in Stencel, C. Microbial diversity: Eyeing the big picture. ASM News 66:146, 2000). These considerations indicate that one needs to look beyond 16S rDNA for phylogenetic analysis of these species.

Members of the genus *Simonsiella* possess a morphology that is striking and unique among bacteria. For this reason it could be expected that they would make up a coherent phylogenetic group that excluded other bacteria. However, the *Simonsiella* are polyphyletic in 16S rDNA based phylogenetic analysis (Fig. BXII.β.61 in Chapter *Neisseriales*; Hedlund and Staley, 2002). Such instabilities may be attributable to horizontal gene transfer between members of the *Neisseriaceae*, including *Simonsiella*. Most members of the family *Neisseriaceae* are naturally competent for transformation (Bøvre, 1980). The discrepancies between 16S rDNA phylogenies of the genus *Neisseria* and those derived from analyses of other loci (Smith et al., 1999b) or from chemotaxonomic data (Barrett and Sneath, 1994) have suggested that the irregularities in the phylogenetic trees were due to interspecies gene exchange and that certain *Neisseria* 16S rDNA sequences are hybrids (Zhou et al., 1997; also see chapter on Genus *Neisseria*). Thus, members of the genus *Neisseria* could have acquired and recombined with *Simonsiella* 16S rDNA sequences. It is not known whether *Simonsiella* strains themselves are competent; if they are, the horizontal gene transfer from *Neisseria* or other oral flora to *Simonsiella* could have added to the phylogenetic complexity.

Enrichment and Isolation Procedures

At the present time, there are no enrichment procedures for *Simonsiella*. Isolation directly from the oral cavity has been achieved by several people, however. The easiest method for isolation of *Simonsiella* was described by Kuhn et al. (1978). A sterile cotton swab is rubbed over the palate, tongue, or inner surface of the cheeks of the animal and immediately rolled over the surface of a thin layer of BSTSY agar (tryptic soy broth without dextrose (Difco), 27.5 g; yeast extract (Difco), 4 g; agar, 15.0 g; water, 900 ml; and sterile bovine serum, 100 ml, which is added after autoclaving and cooling the other ingredients to 45°C) in a plastic Petri dish. Without delay, the dish is then placed into a 37°C incubator for about 6–10 h. During this short incubation period the filaments glide away from the oral epithelial cells and multiply. The Petri dish is then scanned via a microscope with a magnification of up to ×125 or a dissecting microscope. Isolated filaments or microcolonies are picked from the agar surface and transferred to fresh plates of BSTSY agar. Suitable instruments for transfer could include a dissecting needle, inoculating needle, toothpick, dental probe, light bulb filament, or other fine-tipped instrument. Macroscopically visible colonies generally appear within 16–24 h after transfer. Although this method was used to isolate nearly 50 strains of *Simonsiella*, some strains did not grow on this medium and could not be isolated.

Steed (1962) isolated *Simonsiella* from sheep with a medium consisting of Oxoid nutrient agar plus 10% horse or ox serum. This medium was not suitable for the isolation of strains from humans (Kuhn et al.,1978). Berger (1963) used blood agar to detect and isolate *Simonsiella*, but this medium suffers from the opaqueness of the blood, which prevents easy observation of the colonies with a microscope.

TABLE BXII.β.100. Cellular carbohydrate patterns in *Simonsiella* and *Alysiella* species (selected from Heiske and Mutters, 1994)

[a]Number of strains tested.

[b]% of total carbohydrate amounts: 0, absent; 1, 0.1–0.5%; 2, 0.51–1.0%; 3, 1.1–3.0%; 4, 3.1–6.0%; 5, 6.1–10.0%; 6, 10.1–20.0%; 7, 20.1–30.0%; 8, 30.1–50.0% (RT value of *n*-ocradecane, 14.11).

[c](A), peracetylated aldononitrile; (O), peracetylated O-methyloxime; C-6, unknown carbohydrate with six C atoms; phenyl, prenylated carbohydrate; no specification of reaction type, only acetylation could be observed (in case of sugar alcohols, amino sugars, and similar).

Maintenance Procedures

Freshly isolated cultures should be grown at 37°C and transferred about every 2–3 d to the same medium on which they were isolated. Older cultures must be transferred at intervals of about 1 week.

Refrigeration of cultures is not recommended for preservation, but they can be preserved by freezing in liquid nitrogen using glycerol as a cryoprotectant or by lyophilization.

Procedures for Testing Special Characters

The procedures for characterizing *Simonsiella* were first described by Steed (1962) and later modified by Kuhn et al. (1978). The procedures generally parallel those that are commonly used for other taxa, except that for *Simonsiella* most media contain 10% serum. All incubations are carried out at 37°C. The procedures below are from Kuhn et al. (1978).

Casein hydrolysis BSTSY agar containing 2% skim milk is inoculated, incubated for 3 d, and examined for evidence of hydrolysis.

Starch hydrolysis TSY agar (BSTSY agar without serum) containing 5% soluble starch is inoculated, incubated for 4 d, and then flooded with Lugol' s iodine.

Gelatin hydrolysis TSY broth containing 10% serum and 12% gelatin is inoculated and tested for liquefaction after 5 d of incubation by chilling the tube to 4°C.

Peptonization of litmus milk Litmus milk (Difco) containing 10% serum is inoculated and examined for peptonization over a 14-d incubation period.

Action on carbohydrates A medium is poured into Petri dishes, inoculated, and examined after 48 h for the production of acid (yellow color). It consists of the following ingredients:

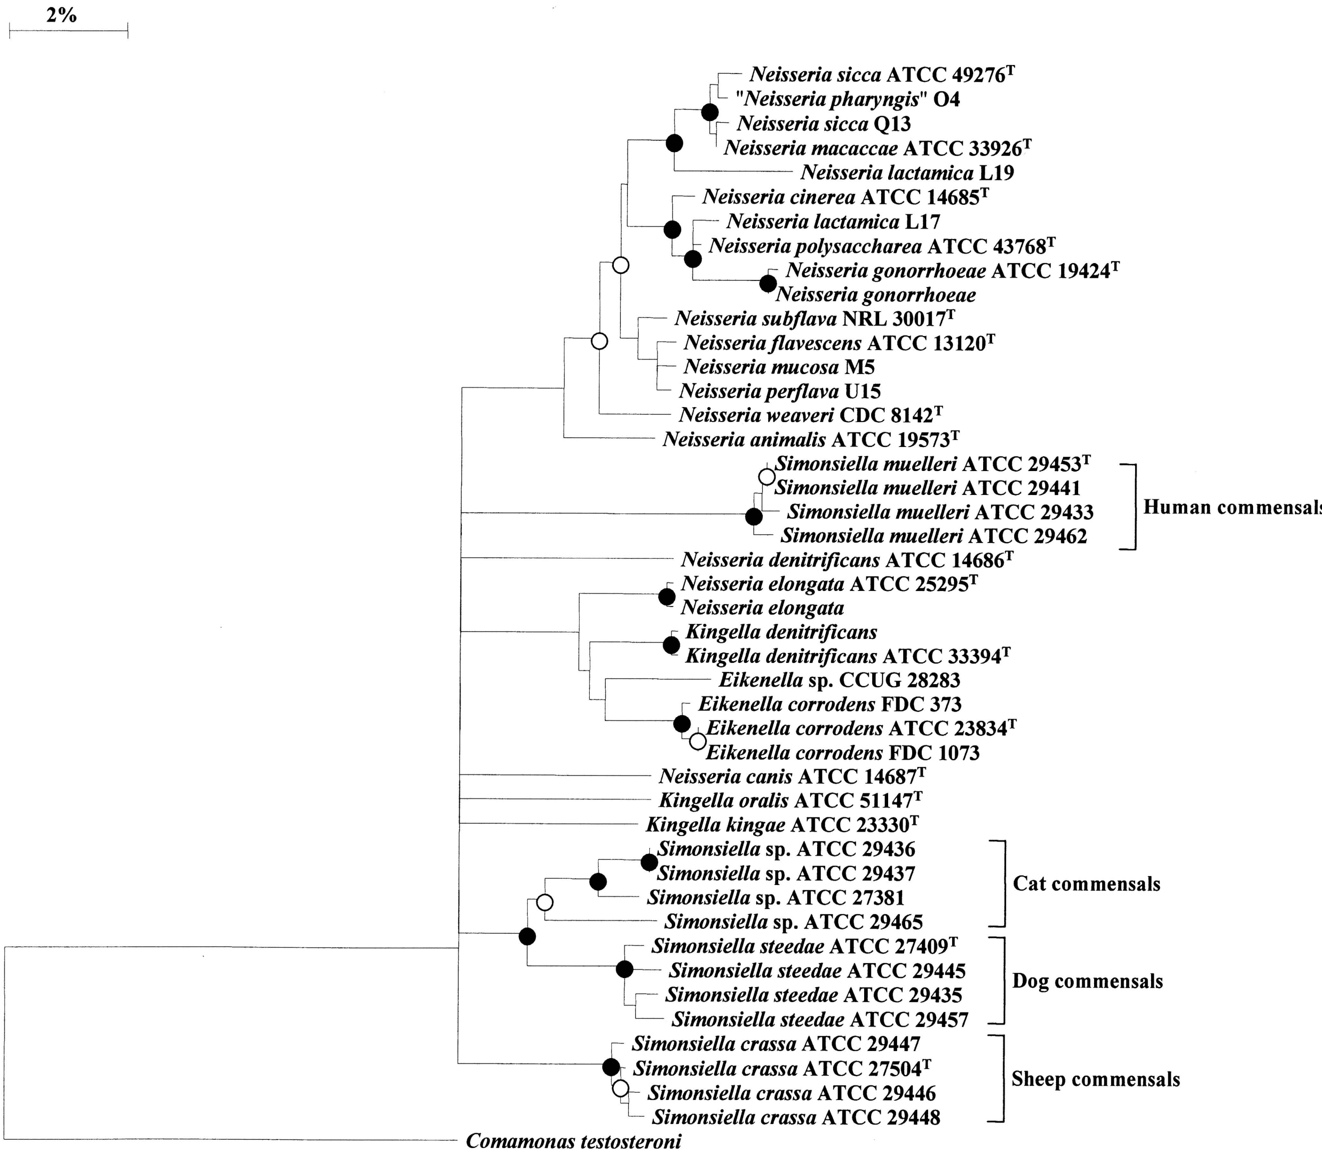

FIGURE BXII.β.79. Phylogenetic neighbor-joining tree of the genus *Simonsiella* of the family *Neisseriaceae* based on nucleotide sequence of the 16S rRNA genes. *Comamonas testosteroni* was used as an outgroup. ●, Nodes with >90% bootstrap support for all analyses; ○, with >75% bootstrap support. Values below 50% are not shown. Bar = 2% nucleotide divergence. (Reproduced with permission from B.P. Hedlund and J.T. Staley, Journal of Systematic and Evolutionary Microbiology *52:* 1377–1382, 2002, ©International Union of Microbiological Societies.)

phenol red broth (Difco), 1.6%; yeast extract (Difco), 0.2%; agar (Difco), 1.5%; phenol red (Hartman Leddon Co., Philadelphia, Pennsylvania), 0.007%; serum, 10%; and carbohydrate, 1%.

Indole production BSTSY broth containing 1% tryptone is inoculated, incubated for 3 d, and examined for evidence of indole production with Kovac's reagent.

Nitrate reduction TSY broth containing 0.2% KNO_3 in a Durham tube assembly is inoculated and examined for 5 d by the dimethyl-α-naphtholamine/sulfanilic acid method (Miller and Neville, 1976).

Differentiation of the genus *Simonsiella* from other genera

The unusual morphology of the *Simonsiella* filament serves to differentiate the genus from all other procaryotic organisms. *Alysiella* resembles *Simonsiella*, but filaments of *Alysiella* do not show the unusual dorsal-ventral differentiation and do not have rounded ends, and the individual cells are paired within the filament.

Caryophanon filaments may be mistaken for *Simonsiella* in stained preparations. However, in live preparations the cylindrical form of *Caryophanon* and the flattened shape of *Simonsiella* are easily distinguished. Also, *Caryophanon* are motile by flagella; they do not glide.

Taxonomic Comments

The citation "Schmid *in* Simons" following the generic name in the title is the result of Simons (1922) crediting the name *Simonsiella* to G. Schmid. However, no record can be found that Schmid published the name *Simonsiella.*

When Simons (1922) first described the genus *Simonsiella*

from the human oral cavity, he named two species *S. muelleri* and *S. crassa*, which he differentiated based on the width of the filaments. Later, Steed (1962), examining strains from sheep, and Berger (1963), examining strains from guinea pigs, named their isolates *S. crassa* and *S. muelleri*, respectively, because of the similarity in filament width to those known species. When Kuhn et al. (1978) carried out an extensive investigation of 49 isolates from humans, dogs, cats, and sheep, they determined that each animal had its own species and that filament width was not a suitable indicator for the differentiation of species.

Simonsiella has been reported from the oral cavity of many warm-blooded vertebrates including cats, chickens, cows, dogs, goats, guinea pigs, humans, horses, pigs, rabbits, and sheep. Only those from cats, dogs, humans, and sheep have been described in detail (Steed, 1962; Kuhn et al., 1978). When those from other animals are sufficiently characterized, it may be necessary to revise the number of species within this genus and the means of differentiation among the species. Moreover, some *Simonsiella* have been refractory to isolation, possibly indicating that they were a different strain or species (Kuhn et al., 1978) from those that grew and were isolated on BSTSY agar.

Kuhn et al. (1978) characterized several *Simonsiella* strains from cats. 16S rDNA sequence analysis of *Simonsiella* strains indicated that they are members of the family *Neisseriaceae* (Hedlund and Staley, 2002).

Acknowledgments

The information provided in the first version of *Bergey's Manual of Systematic Bacteriology* (1984) by J.M. Larkin is greatly acknowledged. The contribution of J.T. Staley to the phylogenetic analysis of *Simonsiella* is deeply appreciated.

Differentiation of the species of the genus *Simonsiella*

Some differential features of the four recognized species of *Simonsiella* are shown in Tables BXII.β.96, BXII.β.97, BXII.β.98, BXII.β.99, and BXII.β.100.

List of species of the genus Simonsiella

1. **Simonsiella muelleri** Schmid *in* Simons 1922, 504[AL]
muel′ le.ri. M.L. gen. n. *muelleri* Müller, named for R. Müller, who first described these organisms.

See Tables BXII.β.96, BXII.β.97, BXII.β.98, BXII.β.99, and BXII.β.100 and the generic description for many features. The long axis of the cells (width of filament) varies from 2.1 to 3.5 μm, with an average of about 2.5–3.2 μm; the short axis (length of individual cell) varies from about 0.5 to 0.9 μm, with an average of about 0.8 μm. Casein, gelatin, esculin, and hippurate are not hydrolyzed. No change occurs in litmus milk. The ability to reduce nitrates varies among strains, with about half of them being positive; when reduction occurs, nitrite is produced, and a few strains produce N_2 gas. H_2S production is variable and inconsistent. Found in the oral cavity of humans.

The mol% G + C of the DNA is: 40–42 (Bd) for 16 of 18 strains; two other strains had a G + C mol% 44 and 50 (Bd).

Type strain: ATCC 29453, CCUG 30554, CIP 103436, DSM 2579, ICPB 3636, LMG 7828.

GenBank accession number (16S rRNA): M59071, AF328147.

2. **Simonsiella crassa** Schmid *in* Simons 1922, 504[AL]
cras′ sa. L. fem. adj. *crassa* thick.

See Tables BXII.β.96, BXII.β.97, BXII.β.98, BXII.β.99, and BXII.β.100 and the generic description for many features. The long axis of the cells (width of filament) varies from 1.9 to 3.6 μm, with an average of about 2.9–3.5 μm; the short axis (length of individual cell) varies from 0.7 to 0.9 μm, with an average of about 0.8 μm. Steed (1962) reported that her isolates produced acid from inulin and that four of six isolates produced acid from arabinose. Kuhn et al. (1978) reported negative results with both carbohydrates for her isolates, as well as for one of Steed's strains. The discrepancy may be due to differences in the method of testing. Gelatin and casein are hydrolyzed. Litmus milk is peptonized. Nitrate is reduced to nitrogen gas. MR-negative. VP-negative. Steed reported that all of her isolates produced H_2S, but Kuhn et al. (1978) stated that H_2S production is variable and inconsistent. Found in the oral cavity of sheep.

The mol% G + C of the DNA is: 44–45 (Bd).

Type strain: ATCC 27504, CCUG 25927, CIP 103341, DSM 2578, ICPB 3651, LMG 782, NCTC 10283.

GenBank accession number (16S rRNA): AF328141.

3. **Simonsiella steedae** Kuhn and Gregory 1978, 13[AL]
stee′ dae. M.L. gen. n. *steedae* of Steed; named for P. Steed (Glaister) who first isolated axenic cultures of *Simonsiella* and erected the family *Simonsiellaceae*.

See Tables BXII.β.96, BXII.β.97, BXII.β.98, BXII.β.99, and BXII.β.100 and the generic description for many features. The long axis of the cells (width of filament) varies from 2.5 to 7.1 μm, with an average of about 3.1–3.8 μm; the short axis (length of individual cell) varies from 0.7 to 1.3 μm, with an average of about 1.1 μm. Casein, gelatin, esculin, and hippurate are not hydrolyzed. No change in litmus milk. Most strains reduce nitrate to nitrite without gas production. H_2S production is variable and inconsistent. Found in the oral cavity of dogs.

The mol% G + C of the DNA is: 48–52 (Bd).

Type strain: ATCC 27409, CCUG 30555, CIP 103435, DSM 2580, ICPB 3604, LMG 7830.

GenBank accession number (16S rRNA): AF328153.

4. **"Simonsiella kuhniae"**
kuhn.i.ae. F.L. gen. n. *kuhniae* of Kuhn, named after Daisy A. Kuhn, in honor of her work on the isolation, characterization, and autecology of *Simonsiella* in domestic animals and humans.

Multicellular filaments, segmented into groups of 8–12 cells; cells possess dorsal-ventral asymmetry, gliding on ventral surface. Cell width 2.7–4.4 μm; cell length 0.5–1.1 μm; cell thickness 0.5–1.1 μm. Terminal segments often decreased in size. Colonies are entire, low convex <1–2 mm diameter, smooth and butyrous, opaque with pale, nondiffusible yellow pigmentation. Strict aerobe. Catalase and oxidase positive. Chemoorganotrophic. Acid not produced from D-glucose, maltose, D-ribose, D-fructose, sucrose, mannitol, salicin. Weakly proteolytic on casein. No activity on gelatin, inspissated serum, or litmus milk. Growth at 37°C, pH 7.2, and pH 8.0; no growth at 27°C, 43°C, or pH 6.0. Nitrate may or may not be reduced. Found in the oral cavity of domestic cats, *Felis domesticus*.

Deposited strain: ATCC 29436, ICPB 3618.

GenBank accession number (16S rRNA): AF328149.

Additional Remarks: Strains ATCC 29437 (ICPB 3619), ATCC 27381 (ICPB 3601), and ATCC 29465 (ICPB 3648) also belong to this species.

Genus XII. **Vitreoscilla** *Pringsheim 1949c, 70*[AL]

William R. Strohl

Vit.re.os.cil'la. L. adj. *vitreus* glassy, clear; L. n. *oscillum* a swing; M.L. fem. n. *Vitreoscilla* transparent oscillator.

Cylindrical cells (two species) or sausage-shaped cells (one species) ranging from 1.0 to 3.0 μm in diameter. The organisms occur as **colorless filaments** with lengths up to several hundred μm. Two species have cells that are not normally visible within filaments; one species has cells that are clearly visible within the filaments. **Gram negative. Gliding motility.** No locomotor organelles known. **Resting stages are not known. Sheaths and holdfasts are not produced. Nonpigmented. Aerobic to microaerophilic**, having a respiratory type of metabolism with oxygen as the terminal electron acceptor. No growth anaerobically. **Sulfur inclusions are not formed from hydrogen sulfide or thiosulfate. Chemoorganotrophic**. Two species are oligotrophic and grow best at low nutrient concentrations; one species can grow luxuriantly on rich media, e.g., 0.5% peptone broth. Various organic acids and amino acids are used as carbon and energy sources. Found in dung, soil, water with decaying plant material, sediments, and in association with oscillatorian mats.

The mol% G + C of the DNA is: 42–63.

Type species: **Vitreoscilla beggiatoides** Pringsheim 1949c, 70, emend. Strohl, Schmidt, Lawry, Mezzino and Larkin 1986a, 311.

Further descriptive information

Morphological characteristics The genus *Vitreoscilla* consists of two morphological types. One type is characterized by *V. beggiatoides* (the type species) and *V. filiformis*. The cells are ultrastructurally similar to those of *Beggiatoa* in having (i) continuous outer layers of the filaments (Figs. BXII.β.80 and BXII.β.81), (ii) extra cell wall layers outside of the "lipopolysaccharide-like" layer (Strohl et al., 1986a), (iii) large accumulations of poly-β-hydroxybutyrate (PHB; sometimes >50% of dry cell mass), and (iv) membrane invaginations in the cytoplasm. If these filaments are mechanically broken up into individual cells, the cells die—an indication that these are truly multicellular bacteria like the beggiatoas. The cells within a filament of these species divide via septation, with only the cytoplasmic membrane and peptidoglycan layers invaginating, like the closure of an iris diaphragm, as in *Beggiatoa* (Strohl and Larkin, 1978a). In thin sections observed by transmission electron microscopy, cells of *V. beggiatoides* and *V. filiformis* appear similar to cells of *Beggiatoa* (Strohl et al., 1986a). Furthermore, the sacrificial-cell-death life cycle described for beggiatoas (Strohl and Larkin, 1978a) appears to apply to *V. beggiatoides* as well, and may also occur with *V. filiformis* strains.

The second morphological type of *Vitreoscilla* is exemplified by *V. stercoraria*. Cells of this species have discontinuous outer layers (Figs. BXII.β.82 and BXII.β.83), and the filaments appear similar to chains of bacilli. The cells are held together by a ruthenium-red-staining material, but they can be mechanically broken apart without accompanying massive cell death. Multicellular filaments are formed seemingly only because the cells do not completely detach after division. Reports have indicated that certain growth conditions promote growth of *V. stercoraria* as single

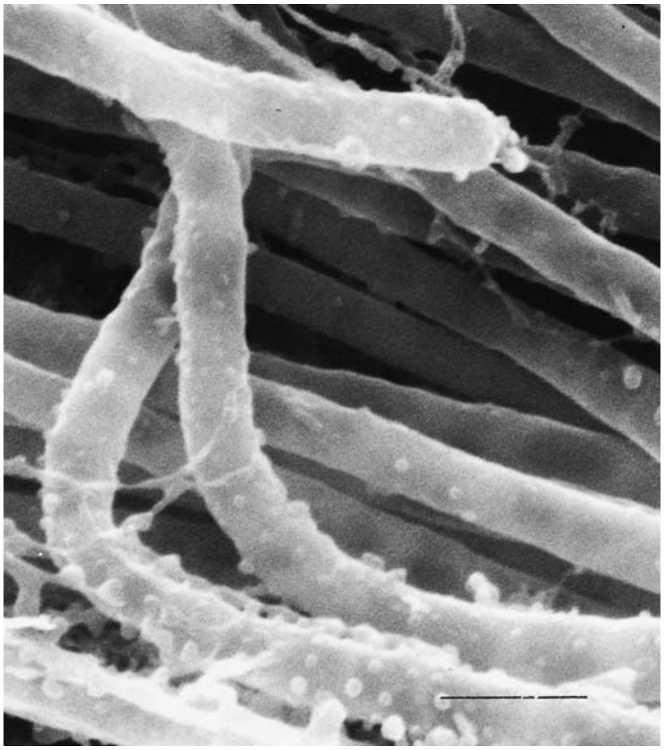

FIGURE BXII.β.81. Scanning electron micrograph of *V. beggiatoides* strain B23SS, with continuous cell envelope and slime-like matrix shown. Bar = 5 μm.

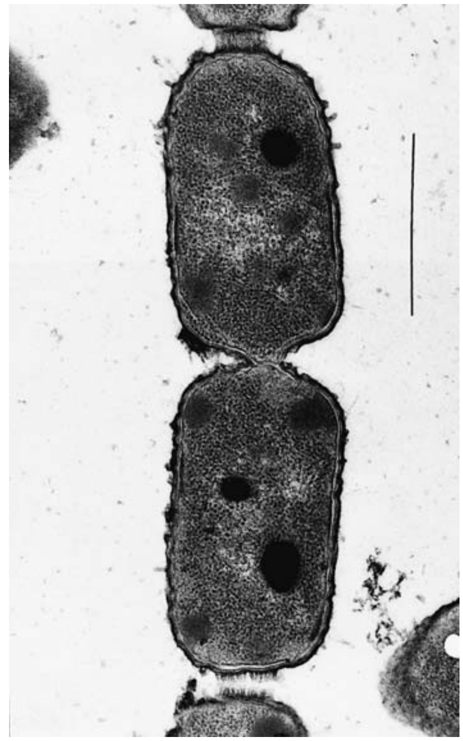

FIGURE BXII.β.82. Thin-section micrograph of ruthenium-red-stained *V. stercoraria* VT-1, with chains of cells held together by connecting material, and the Gram-negative cell envelope shown. Bar = 1 μm.

cells (Brzin, 1966a, b). Ultrastructurally, *V. stercoraria* cells have a typical Gram-negative cell envelope, with the addition of an external, ruthenium-red-staining surface layer (Fig. BXII.β.82; Strohl et al., 1986a). Perhaps the most notable feature of *V. stercoraria* is the presence in the cells of a bacterial form of hemoglobin (Wakabayashi et al., 1986; Khosla and Bailey, 1988b). The *V. stercoraria* hemoglobin gene has been cloned, sequenced, and characterized in detail, and has been used in recombinant form in several attempts to improve oxygen transfer to industrially significant organisms (Khosla and Bailey, 1988a; Brunker et al., 1998).

Cultural conditions For all *Vitreoscilla* species, the growth conditions determine the shape and characteristics of the colonies. On agar media containing low amounts of nutrients, wavy, curly, or spiral colonies are produced, from which trichomes glide radially outward from the central colony area. On solid media containing high nutrient concentrations, the trichomes spread very little and can form drop-like colonies resembling those of most eubacteria.

Nutritional characteristics *Vitreoscilla* species were formerly differentiated based on trichome size alone, although critical nutritional (Strohl et al., 1986a) and phylogenetic (Stahl et al., 1987; Dewhirst et al., 1989) differences among them are now known. *V. beggiatoides* and *V. filiformis* strains grow best on media with very low nutrient concentrations (e.g., 0.05–0.1% peptone, acetate, etc.), but differ in the nutrients utilized. *V. beggiatoides* can grow on a simple defined medium containing acetate, ammonium, and basal salts and is fairly restrictive in the nutrients it utilizes, i.e., certain C_2–C_5 organic acids and amino acids. *V. filiformis* can grow on the minimal medium described above, but it also can utilize glucose and citrate. Neither species, however, tolerates high concentrations of nutrients or nutritionally rich media well. Similarly, neither species grows to great cell masses, with 50–80 mg/l of dry cell mass being the approximate maximum. These organisms can withstand moderate concentrations of sulfide, even though they do not form sulfur depositions from it. *V. beggiatoides* B23SS and three *V. filiformis* strains can fix molecular nitrogen, as determined by acetylene reduction (Polman and Larkin, 1990). In all four cases, the presence of a fixed ammonium salt source in the medium abolishes the ability of the organisms to reduce acetylene (Polman and Larkin, 1990).

Vitreoscilla stercoraria differs from the other two species in that it grows luxuriantly on rich media (0.5% peptone, w/v). *V. stercoraria* is an obligate amino-acid-utilizing organism with fairly complex nutritional requirements (Mayfield and Kester, 1972, 1975), although it does not utilize glucose. *V. stercoraria* grows very well in nutritionally complex and rich media, and it achieves much higher cell masses during growth than do the other vitreoscillas.

Metabolic characteristics Cultures of *V. beggiatoides* and *V. filiformis* are able to oxidize both the methyl and carboxyl carbons of acetate to CO_2 (Strohl et al., 1986b). The rate of acetate oxidation is very high, as it is with the beggiatoas. These organisms may use the glyoxylate bypass cycle when growing on acetate, but this has been investigated very little. *V. stercoraria* contains all of the enzymes of the tricarboxylic and glyoxylate bypass cycles (W.R. Strohl and G.W. Luli, unpublished data). The activities of the enzymes isocitrate lyase and malate synthase are stimulated significantly by the addition of 1% sodium acetate to the *V. ster-*

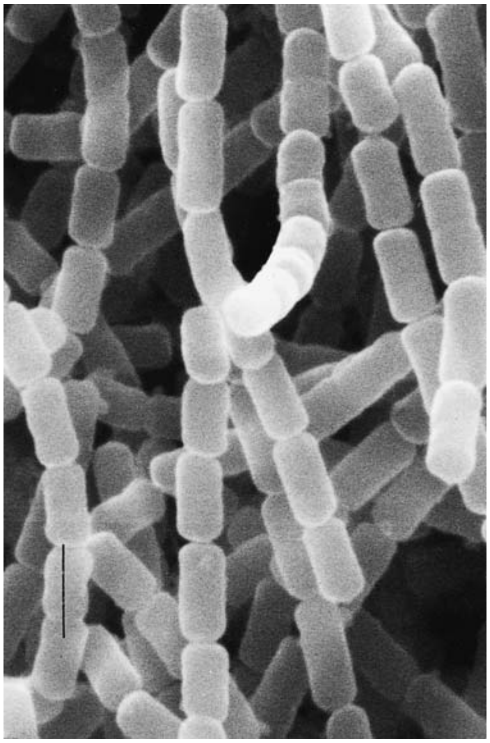

FIGURE BXII.β.83. Scanning electron micrograph of *V. stercoraria* strain VT-1, with the discontinuous cell walls and the connecting material between the cells shown. Bar = 1 μm.

coraria growth medium (W.R. Strohl and G.W. Luli, unpublished data). This is in apparent contradiction to Pringsheim's original statement that acetate does not stimulate growth of *V. stercoraria* (Pringsheim, 1951).

Plasmids *V. beggiatoides* and *V. filiformis* strains are apparently devoid of small plasmids such as the 12.3 and 12.8 × 10^6 M_r (18.9 and 19.7 kb, respectively) plasmids observed in *Beggiatoa alba* (Minges et al., 1983). Strains of *V. stercoraria* contain small plasmids with an apparent 1.4 × 10^6 M_r (~2.2 kb; Minges et al., 1983). No functions have yet been ascribed to these plasmids. DNA transformation procedures have been described for *V. stercoraria* (Navani et al., 1996), but not for the trichome-forming vitreoscillas.

Habitat Vitreoscillas of the *V. stercoraria* type are usually found in dung, soil, water with decaying plant material, and in association with oscillatorian mats (Pringsheim, 1949c, 1951). *V. beggiatoides* strain B23SS (group B strains, as described in Strohl and Larkin, 1978b) was isolated from a sandy, lightly sulfide-emanating sediment that also included sulfur-containing beggiatoas.

Enrichment and Isolation Procedures

Enrichment and isolation procedures for *V. beggiatoides*, *V. filiformis*, and other trichome-forming strains are basically the same as those described in the chapter on the genus *Beggiatoa* (this volume; see also Pringsheim, 1964 and Strohl and Larkin, 1978b). The medium used, however, should reflect the type of *Vitreoscilla* being sought (i.e., lack of sulfide in the media and the type and amount of organic supplements). A medium that is excellent for the isolation and maintenance of *V. beggiatoides* is "MY medium", described in the article on *Beggiatoa* (this volume), but without the added reduced sulfur source. For *V. filiformis* and similar strains, a modification of MY medium in which glucose or citrate is substituted for acetate might be more appropriate.

For isolation of *V. stercoraria*, small samples of dung can be placed directly onto plates containing a nutritionally rich medium. After several days, trichomes gliding away from the inoculum can be observed with a dissecting microscope. Those filaments can be retrieved with a flame-sterilized 26-gauge needle, as described for *Beggiatoa*. A good medium for this purpose is 0.1-CAYTS medium, which contains 0.1% each of casitone, tryptone, sodium acetate, and yeast extract.

Maintenance Procedures

Vitreoscillas can survive for about three weeks on plates of standard media employed for their growth. In general, the lower the concentration of nutrients in the media, the longer the time of survival. Care should be taken to transfer from the edges of the spreading colonies, so as to transfer the youngest and most active filaments. *V. stercoraria* can be lyophilized. *V. beggiatoides* and *V. filiformis* cannot be lyophilized, but they can be stored at −70°C or −196°C in the presence of 20–30% glycerol.

Procedures for Testing Special Characters

Because the larger species of *Vitreoscilla* are distinguished from beggiatoas by their inability to deposit sulfur, it is critical that the tests for sulfide oxidation and sulfur deposition be sensitive and reproducible. Investigators frequently have viewed the filaments with a phase microscope and assumed that refractile objects are sulfur. In fact, the strains now included in *V. filiformis* were once considered to be *Beggiatoa* strains because the phase-bright bodies (presumably polyphosphate) in these organisms were interpreted as sulfur (Pringsheim, 1964; Kowallik and Pringsheim, 1966).

One method for determining if inclusions contain sulfur is a chemical analysis of ethanol-extracted (Jørgensen and Fenchel, 1974) or carbon-disulfide-extracted (Nelson and Castenholz, 1981) filaments. A much more sensitive, but more difficult and expensive, method for analyzing sulfur deposition is through the oxidation of ^{35}S-labeled Na_2S at a physiological pH to internal $^{35}S^0$ (Strohl and Schmidt, 1984; Strohl et al., 1986a; Schmidt et al., 1987b). Controls should be included for the adsorption of $Na_2{}^{35}S$ by autoclaved cells and for $Na_2{}^{35}S$ assimilation by known sulfide-oxidizing organisms (e.g., *Beggiatoa* species) and non-sulfide-oxidizing organisms (e.g., *V. stercoraria*). Once it is demonstrated that labeled sulfide is assimilated, it should be at least 50–70% extractable by washing with warm ethanol or, alternatively, ~90% extractable by warm ethanol treatment followed by a wash with ethanol/diethyl ether (1:1) (W.R. Strohl, unpublished data).

Differentiation of the genus *Vitreoscilla* from other genera

Although the vitreoscillas make up a heterogeneous group, they still can be differentiated from members of other genera (Table BXII.β.101). The primary distinguishing characteristics include their ability to glide but not deposit sulfur, their inability to produce sheaths or holdfasts, and their absence of pigmentation.

Taxonomic Comments

Briefly, the three species that currently make up the genus *Vitreoscilla* are not phylogenetically coherent, and it is proposed that

each of the three species within the genus *Vitreoscilla* should be placed into a separate genus. While these organisms share some general features, they are vastly different in morphological, physiological, and phylogenetic characteristics.

Phylogenetic analyses have clarified the taxonomy of these organisms to some degree. Whereas the resemblance of *Vitreoscilla* filaments to those of cyanobacteria caused Pringsheim to label them as colorless forms of cyanobacteria (Pringsheim, 1949c), none of the species is phylogenetically related to any cyanobacterium (Reichenbach et al., 1986; Stahl et al., 1987). Moreover, phylogenetic analysis of the vitreoscillas, beggiatoas, and similar organisms has demonstrated that gliding motility is not a particularly useful taxonomic or phylogenetic marker, as has been pointed out by Stahl et al. (1987). In another example, members of the gliding cytophagas are now grouped together with non-gliding flavobacteria and bacteroides, and, in some instances, former *Cytophaga* species have been reclassified as *Flavobacterium* species (Nakagawa and Yamasato, 1993).

Sequence analysis of 5S rRNA has placed *V. beggiatoides* strain B23SS (the neotype strain) in the γ3-subgroup (Woese, 1987) of the *Gammaproteobacteria* (Stahl et al., 1987) (Fig. BXII.β.84A). The authors state that *V. beggiatoides* is "specifically, but distantly, related to *B. alba*" strain B18LD (type strain), and point out that the evolutionary distance between the two organisms is greater than that separating *E. coli* and *Proteus vulgaris* (Stahl et al., 1987; see also Fig. BXII.β.84A).

Similar 5S rRNA analysis indicates that *V. stercoraria* VT1 and two strains of *V. filiformis* (ATCC 15551 and L-1401-7) are members of the *Betaproteobacteria* (Stahl et al., 1987) (Fig. BXII.β.84A). The 5S rRNA analyses carried out by Stahl et al. (1987) indicate that *V. filiformis* is related to *Rhodocyclus gelatinosus* in the *Chromobacterium* branch of the β-subdivision. Our revised analysis of the 5S rRNA sequence of *V. filiformis* places it in the *Rubrivivax*–*Leptothrix* sub-branch (Kalmbach et al., 1999) of the β1 subgroup of the *Proteobacteria*, most closely related to *Thiomonas cuprina* and *Leptothrix discophora* (Fig. BXII.β.84A).

Based on early 5S rRNA sequence data, *V. stercoraria* was originally placed at the base of the β1-β2 subgroups (Stahl et al., 1987) or within the β2 subgroup (Woese, 1987) of the β-*Proteobacteria*, and was considered to be somewhat related to *Neisseria* (Stahl et al., 1987). Later 16S rRNA analyses by Dewhirst et al. (1989) have confirmed the phylogenetic relatedness of *V. stercoraria* and *Neisseria* species (see Fig. BXII.β.84B), although those authors argued against including *V. stercoraria* in the *Neisseriaceae*. They pointed out that although the 16S rRNA of *V. stercoraria* has an average sequence identity of 93.7% with members of *Neisseria* (they average 95.5% within the genus), it should be separated from them because it lacks a key unique "*Neisseria* signature" sequence, it is a free-living organism, and it is oxidase negative (Dewhirst et al., 1989). It should be noted, however, that the current "Taxonomy" browser of the National Center for Biotechnology Information places the genus *Vitreoscilla* within the family *Neisseriaceae* (based on the 16S rRNA sequences of *V. stercoraria*).

Certain unclassified *Vitreoscilla* strains, morphologically similar to *V. stercoraria* (Costerton et al., 1961; Nichols et al., 1986; Strohl et al., 1986a), should now be considered as strains of *V. stercoraria*. Strain VT-1 is physiologically identical with *V. stercoraria* ATCC 15218, the type strain of the species (Strohl et al., 1986a). *Vitreoscilla* strains 389 and 390 (Costerton et al., 1961) have also been determined to be nearly 100% related by DNA hybridization to *Vitreoscilla stercoraria* strain ATCC 15218 (Nichols et al., 1986). On the other hand, *Filibacter limicola*, an organism morphologically similar to *V. stercoraria*, has been shown to be completely unrelated to *V. stercoraria* (Clausen et al., 1985; Nichols et al., 1986).

Additional 16S rRNA sequences analyses and strain–strain nucleic acid hybridizations are clearly needed to place these organisms into their proper taxonomic locations with respect to related organisms. In particular, a serious taxonomic problem, which needs to be rectified, exists with the genus *Vitreoscilla*. *V. beggiatoides* was designated as the type species of the genus, based on the description of vitreoscillas as *Beggiatoa*-like organisms that do not deposit sulfur from hydrogen sulfide (Pringsheim, 1949c, 1951). Until the mid-1980s, however, the only well-characterized species of *Vitreoscilla* was *V. stercoraria*, since no other species from Pringsheim's collection had survived (Koch, 1964). Thus, strains did not exist for the type species of the genus until the description (Strohl et al., 1986a) of strains that fit the original description of *V. beggiatoides*. Now that the neotype strain of *V. beggiatoides* has been reasonably well characterized, and has been phylogenetically placed near, yet far enough to be distinct from, *Beggiatoa alba* in the class *Gammaproteobacteria*, the genus *Vitreoscilla* should be modified to contain only this single species. *V. stercoraria* is morphologically, ultrastructurally, nutritionally, physiologically, and ecologically very different from the other species (Strohl et al., 1986a) (Table BXII.β.102; Figs. BXII.β.80, BXII.β.81, BXII.β.82, BXII.β.83, and BXII.β.84). *V. stercoraria* and *V. filiformis*, both members of the class *Betaproteobacteria*, are not related to *V. beggiatoides*. Interestingly, *V. filiformis*, which more closely resembles *V. beggiatoides* morphologically, physiologically, and ecologically, is actually more closely related to *V. stercoraria*, although these two organisms are reasonably separated within the *Betaproteobacteria*. Because *V. beggiatoides* is the type species and the intent of the genus was to contain non-sulfur-depositing, beggiatoa-like organisms, it is proposed that *V. filiformis* and *V. stercoraria* be removed from the genus. *V. filiformis* and *V. stercoraria* should be taxonomically reclassified into separate genera more in line with their phylogenetic lineages. A fourth species, *"Vitreoscilla proteolytica"*, was proposed in 1970 (Perschmann and Gräf, 1970) but the strain described possesses carotenoids (a characteristic never ascribed to *Vitreoscilla*), was never accepted as a new species of *Vitreoscilla*, and has not been further characterized phylogenetically; therefore it will not be considered here.

Acknowledgments

I sincerely thank Annaliesa Anderson for her considerable assistance with the phylogenetic analysis of the vitreoscillas. I also thank Bo B. Jørgensen for sharing a preliminary version of the *Thioploca* chapter, which helped to stimulate thoughts about the taxonomy of these organisms.

Gliding motility	+	+	−	−	+
Flagellated	−	−	+	−	−
Filament formation	+	+	+	−	+
Individual cells observable within filaments	±	−	+	na	−
Cell division in two planes	−	−	−	+	−
Coccoid	−	−	−	+	−
Class:					
Betaproteobacteria	+		+	+	
Gammaproteobacteria	+	+			+

[a]Symbols: +, positive in >90% of strains; −, negative in >90% of strains; ±, positive in 10–90% of strains; na, not applicable.

The characteristics are as described for the genus and as listed in Table BXII.β.102, with the following additional features. Cells are cylindrical, 2.5–3.0 × 3–6 μm, and occur in filaments. The cells are not normally visible within the filaments. The filaments have a length of up to several hundred μm. Filaments lack visible septation, and the ends of the filaments are rounded. Necridia and hormogonia are produced. Motile by a gliding motility with speeds of ~3 μm/sec. Produce colonies of the circuitans type when grown on low-nutrient media and of the linguiformis type when grown in high-nutrient media. Trichomes often glide singly, away from other trichomes. Sulfur is not deposited when cells are grown on sulfide; however, sulfide at a concentration of ~1 mM is apparently not inhibitory. PHB is always present when cells are cultured on acetate-containing media and often comprises >50% of the cell dry weight. Polyphosphate bodies are often present.

Grows best at low nutrient concentrations. Acetate, ethanol, and some C_4 organic acids are utilized as sole carbon and energy sources. Ammonium and nitrate are used as nitrogen sources. Microaerophilic to aerobic. Gelatin, starch, and casein are not hydrolyzed. Catalase negative. Cytochrome oxidase positive. Growth occurs in 0.5% but not 1.0% NaCl. Sensitive to the antibiotics polymyxin B, neomycin, and furadantin/macrodantin; resistant to the antibiotics bacitracin and streptomycin. Found in sandy, but lightly sulfide-emanating, sediments of freshwater streams. Phylogenetic analysis places this species within the class *Gammaproteobacteria*, relatively close to *Beggiatoa alba*.

The mol% G + C of the DNA is: 42 (T_m, Bd).

Type strain: B23SS, ATCC 43189.

2. **Vitreoscilla filiformis** Strohl, Schmidt, Lawry, Mezzino and Larkin 1986a, 310[VP]

fi.li.for′ mis. L. n. *filum* a thread; L. n. *forma* shape; M.L. adj. *filiformis* thread-shaped.

The characteristics are as described for the genus and as listed in Table BXII.β.102, with the following additional features. Cells occur in flexible filaments with diameters of about 1.0–1.5 μm and, when cells are grown in liquid media, lengths of up to several hundred μm. Filament width may vary slightly. The cells are not clearly visible within the filaments, although slight indentations of the trichomes may sometimes be observed at septal regions between cells. The filament walls are continuous, and the ends of the filaments are rounded. Hormogonia are sometimes produced. Motile by gliding motility; gliding is relatively slow, at ~0.1–0.5 μm/sec. Produce linguiformis-type colonies. PHB and condensed phosphate deposits may be present.

Growth is best at low nutrient concentrations. Can use many 2-, 3-, 4-, and 6-carbon organic acids, several amino acids, ethanol, and glucose as sole carbon and energy sources. Organic and inorganic forms of nitrogen can be used as nitrogen sources. Nitrate is reduced to nitrite. Aerobic to microaerophilic. Gelatin and starch are weakly hydrolyzed. Casein is not hydrolyzed. Catalase negative, cytochrome oxidase positive. No growth occurs in the presence of 0.5% NaCl. Sensitive to the antibiotics bacitracin, streptomycin, furadantin/macrodantin, and polymyxin B. Found in freshwater sediments, usually in association with decaying matter. Phylogenetic analysis of *V. filiformis* places it into the *Betaproteobacteria*, with the closest relatives being *Thiomonas cuprina* and *Leptothrix*.

The mol% G + C of the DNA is: 59–63 (T_m).

Type strain: L1401-2, ATCC 43190.

3. **Vitreoscilla stercoraria** Pringsheim 1951, 136[AL] emend. Strohl, Schmidt, Lawry, Mezzino and Larkin 1986a, 312.

ster.co.ra′ ri.a. L. fem. adj. *stercoraria* pertaining to dung.

Cells usually occur as flexible chains with diameters of about 1.0 μm and, when grown in liquid media, lengths of up to about 100 μm. Deep constrictions separate the individual cells, yielding discontinuous filaments. Cells can occur singly, especially if grown at temperatures of ~22°C. The cells are sausage-shaped, 1.0 × 1.5–12.0 μm, and are connected in filaments by extracellular material. Division is by binary fission. PHB and condensed phosphate deposits may be present.

Grows luxuriantly on rich media such as 0.5% peptone broth. Growth occurs on Casamino acids plus acetate. Requires amino acids; arginine, tyrosine, tryptophan, and glutamine are required for good growth. Combinations of amino acids from the glutamate and aspartate families plus arginine are required minimally for growth. Cytochromes *a*, *c*, and the non-CO-binding *b* are not present. Contains unique bacterial hemoglobin. Aerobic. No growth microaerophilically or anaerobically. Catalase positive. Cytochrome oxidase negative. Gelatin, casein, and starch not hydrolyzed. Usually isolated from cow dung. Phylogenetic analysis of *V. stercoraria* places it into the class *Betaproteobacteria*, with the closest relatives being members of the genus, *Neisseria*.

The mol% G + C of the DNA is: 50–51 (Bd).

Type strain: SAG 1488-6, ATCC 15218, DSM 513.

GenBank accession number (16S rRNA): L06174.

TABLE BXII.β.102. Differential characteristics of the species of the genus *Vitreoscilla*[a]

Mol% G + C of DNA	42	59–63	50–51

[a]For symbols see standard definitions; L, linguiformis type colonies; C, circuitans type colonies (see Pringsheim, 1964 and Strohl and Larkin, 1978b for a description of these colony types); nd, not determined.

[b]Cells within filaments having continuous cell walls share the outer cell wall layers, with at most only shallow constrictions between cells noticeable (cf. Figs. BXII.β.80 and BXII.β.81). Strains having discontinuous filament cell walls consist of chains of individual cells held together by connective material (c.f. Figs. BXII.β.82 and BXII.β.83).

Genus XIII. **Vogesella** *Grimes, Woese, Macdonell and Colwell 1997, 25*[VP]

NOEL R. KRIEG

Vo.ges.el′la. Ger. *Voges* proper name; M.L. *-ella* dim. ending; M.L. fem. n. *Vogesella* named after Otto Voges to honor his original isolation of *Bacillus indigoferus* on gelatin plates inoculated with tap water from the central water supply system in Kiel, Germany, in 1893.

Straight rods, 0.5 × 3.5 μm, mainly occurring singly but also in pairs and short chains. Occasional vibrioid rods may occur. Most strains form filamentous rods and long chains when grown on nitrogen-limiting agar. **Motile by means of a single polar flagellum.** Poly-β-hydroxybutyrate granules occur, especially under nitrogen limitation. **Colonies are a deep royal blue with a metallic copper-colored sheen at 36 to 48 h, due to production of indigoidine** ($C_{10}H_8N_4O_4$ or 5,5′-diamino-4,4′-dihydroxy-3,3′-diazadiphenoquinone-[2,2′]). **Oxidase and catalase positive. Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. All strains can carry out denitrification with production of gas. **Nonfermentative.** Citrate, several amino acids and peptides, and some monosaccharides are utilized as carbon sources. Starch, pectin, and sugars associated with pectin (i.e., arabinose and galactose) are not metabolized. Nonlipolytic. **Casein, gelatin, and esculin are not hydrolyzed. Indole positive.** Belong to the *Betaproteobacteria* and are closely related to the genus *Chromobacterium.* Occur in freshwater habitats and oxidation pond sediment.

The mol% G + C of the DNA is: 65.4–68.8.

Type species: **Vogesella indigofera** (Voges 1893) Grimes, Woese, Macdonell and Colwell 1997, 25 (*Pseudomonas indigofera* (Voges 1893) Migula 1900, 950; *Bacillus indigoferus* Voges 1893, 307.)

FURTHER DESCRIPTIVE INFORMATION

Colonies begin as translucent slightly yellowish colonies at early stages of growth (i.e., 16 to 20 h), then assume a faint bluish hue (24 h), and finally become a deep royal blue with a metallic copper-colored sheen (36 to 48 h). The pigment is localized within the cytoplasmic membrane (Kolar, 1974). Slightly acidic conditions (ca. pH 6.5) favor pigment production on plate count agar (PCA, Difco Laboratories, Detroit, MI). Excess pigment may occur in the colonies in the form of bluish crystals. When a colony is removed from an agar plate, a blue imprint or stain is left in the agar. Abundant blue pigmentation occurs on PCA, Thayer-Martin agar, chocolate agar, blood agar, *Pseudomonas* F agar, and especially chalk agar (Starr et al., 1960). Indigoidine production appears to be a stable trait of *Vogesella* strains.

Violacein (a violet pigment characteristic of *Chromobacterium* and *Janthinobacterium* species) and pyoverdin are not formed. All *Vogesella* strains exhibit a very weak fluorescence on chalk agar with short-wavelength UV illumination.

Growth occurs at 4°C and 37°C but not at 2°C and 40°C. Growth occurs at pH 6.2 and most strains grow at pH 8.6, but not at pH 4.0.

DNase is produced. The following tests are negative: methyl red; Voges–Proskauer; malonate; H_2S production; arginine, lysine, ornithine, and tryptophan decarboxylases; phenylalanine deaminase; urease; hydrolysis of esculin, *o*-nitrophenyl-β-D-galactopyranoside (ONPG), Tween 80, and corn oil.

All or most strains can use D-fructose, D-glucose, glycerol, ethanol, D-alanine, L-alanine, L-arginine, L-histidine, L-ornithine, L-proline, γ-aminobutyrate, fumarate, and putrescine as sole carbon sources. Propionate is not used.

Blue-pigmented bacteria appear to be a consistent feature of freshwater bacterial communities in terms of temporal and spatial distribution (Grimes et al., 1997).

Enrichment and Isolation Procedures

Isolates can be selected from PCA plates that have been spread with water or sediment samples and incubated at 20 to 25°C for 48 h. Colonies are selected that have a blue pigmentation and a metallic copper-colored sheen.

Maintenance Procedures

Pure cultures can be maintained in deeps of 0.5 × plate count broth (Difco) containing 0.3% agar (Difco) and stored at room temperature (ca. 20°C). Cultures maintained in this manner can remain viable for more than 10 years. Cultures can also be stored indefinitely under liquid nitrogen in tryptic soy broth (Difco) containing 5% glycerol.

Differentiation of the genus *Vogesella* from other genera

Arthrobacter spp., *Corynebacterium insidiosum*, and *Erwinia chrysanthemi* also form indigoidine. *Arthrobacter* and *Corynebacterium* are Gram positive, whereas *Vogesella* is Gram negative. Unlike *Vogesella*, *Erwinia* has peritrichous flagella, is oxidase negative, and can ferment sugars.

Chromobacterium species form violet-pigmented colonies that might be confused with those of *Vogesella*, although the pigment is violacein, not indigoidine. Unlike *Vogesella*, *Chromobacterium* is facultatively anaerobic, has a mainly fermentative attack on carbohydrates, is indole negative, digests casein, and does not denitrify.

Janthinobacterium species, which have an oxidative type of metabolism, produce violet-pigmented colonies due to formation of violacein. Unlike *Vogesella* strains, *Janthinobacterium* is indole negative, hydrolyzes esculin, does not grow at 37°C, and does not denitrify.

Taxonomic Comments

A phylogenetic study of 13 new isolates by Grimes et al. (1997), in which both 5S rRNA and 16S rRNA analyses were employed, indicated that the isolates were closely related to each other and to strains *Pseudomonas indigofera* ATCC 19706^T and *P. indigofera* ATCC 14036. In addition, both 5S rRNA and 16S rRNA analyses demonstrated that the new isolates and strains ATCC 19706^T and ATCC 14036 were members of the *Betaproteobacteria*. Moreover, although these strains were closely related to *Chromobacterium violaceum* ATCC 12742^T, they were sufficiently distinct to warrant placement in a new genus, *Vogesella*.

List of species of the genus Vogesella

1. **Vogesella indigofera** (Voges 1893) Grimes, Woese, Macdonell and Colwell 1997, 25^{VP} (*Pseudomonas indigofera* (Voges 1893) Migula 1900, 950; *Bacillus indigoferus* Voges 1893, 307.)
   in.di.go'fe.ra. Fr. n. *indigo* the dye indigo [from India]; L. suff. *fer* from L. v. *fero* to bear; M.L. adj. *indigofera* bearing indigo.

The characteristics are as described for the genus.

The mol% G + C of the DNA is: 65.4–68.8 (T_m).

Type strain: ATCC 19706, CCUG 2873, CCUG 32860, CIP 103306, DSM 3303, LMG 6867.

GenBank accession number (16S rRNA): U45995.

Genus Incertae Sedis XIV. **Catenococcus** *Sorokin 1994, 852^{VP} (Effective publication: Sorokin 1992, 2291)*

Dimitry Y. Sorokin

Caten.o.coc'cus. L. n. *catena* chain; Gr. n. *coccus* berry; *Catenococcus* a chain of berries.

Cells **coccoid**, occurring mostly in **chains**. **Gram negative. Nonmotile.** Metabolism **respiratory** and **fermentative**; **facultative anaerobe**. Neutrophilic and mesophilic. **Obligately heterotrophic**; able to utilize some sugars, sugar alcohols, and organic acids as carbon and energy sources. **Oxidize thiosulfate, sulfide, and S^0 incompletely to tetrathionate** during heterotrophic growth. Able to **reduce S^0** and **ferric iron** in the presence of fermentable substrate under microaerobic and anaerobic conditions. Oxidase and catalase positive.

Isolated from sulfidic marine water.

The mol% G + C of the DNA is: 49.8 ± 0.5 (T_m).

Type species: **Catenococcus thiocycli** Sorokin 1994, 852 (*Catenococcus thiocyclus* (sic)) (Effective publication: Sorokin 1992, 2291.)

Further descriptive information

Cells grown in batch culture occur in long chains (Fig. BXII.β.85A and B), connected by slime discs. Cells grown in continuous cultures usually occur in pairs or in short chains. The cell wall has a structure that is typical of Gram-negative bacteria (Fig. BXII.β.85C). Growth is NaCl-dependent and occurs over a range of 0.5–8% (w/v) NaCl (optimal, 2.5–3.5%). Cell wall stability demands high Mg^{2+} concentrations. The pH range for growth is 5.6–7.8 (optimal, 6.7–6.9). Growth above pH 7.5 and with low Mg^{2+} concentrations results in sphaeroplast formation and rapid cell lysis. The temperature range for growth is 10–35°C (optimal, 25–28°C).

Catenococcus grows best aerobically with starch and sugars (D-glucose, D-maltose, sucrose, D-fructose, L-arabinose, D-trehalose, and D-cellobiose) as carbon and energy sources, presumably because of slight acidification of the medium. All of these sugars also support anaerobic growth, except L-arabinose. The main products of glucose fermentation are formate and acetate. Aerobic growth also occurs with acetate, succinate, malate, fumarate, pyruvate, gluconate, citrate, D-lactate, malonate, 2-oxoglutarate, propionate, butyrate, ethanol, propanol, glycerol, D-mannitol, L-aspartate, L-glutamate, L-proline, L-cysteine, and L-histidine. Growth is vitamin independent. Tween-80 and gelatin are not hydrolyzed. Ammonium salts, nitrate, and nitrite serve as nitrogen sources. Nitrate is reduced to nitrite.

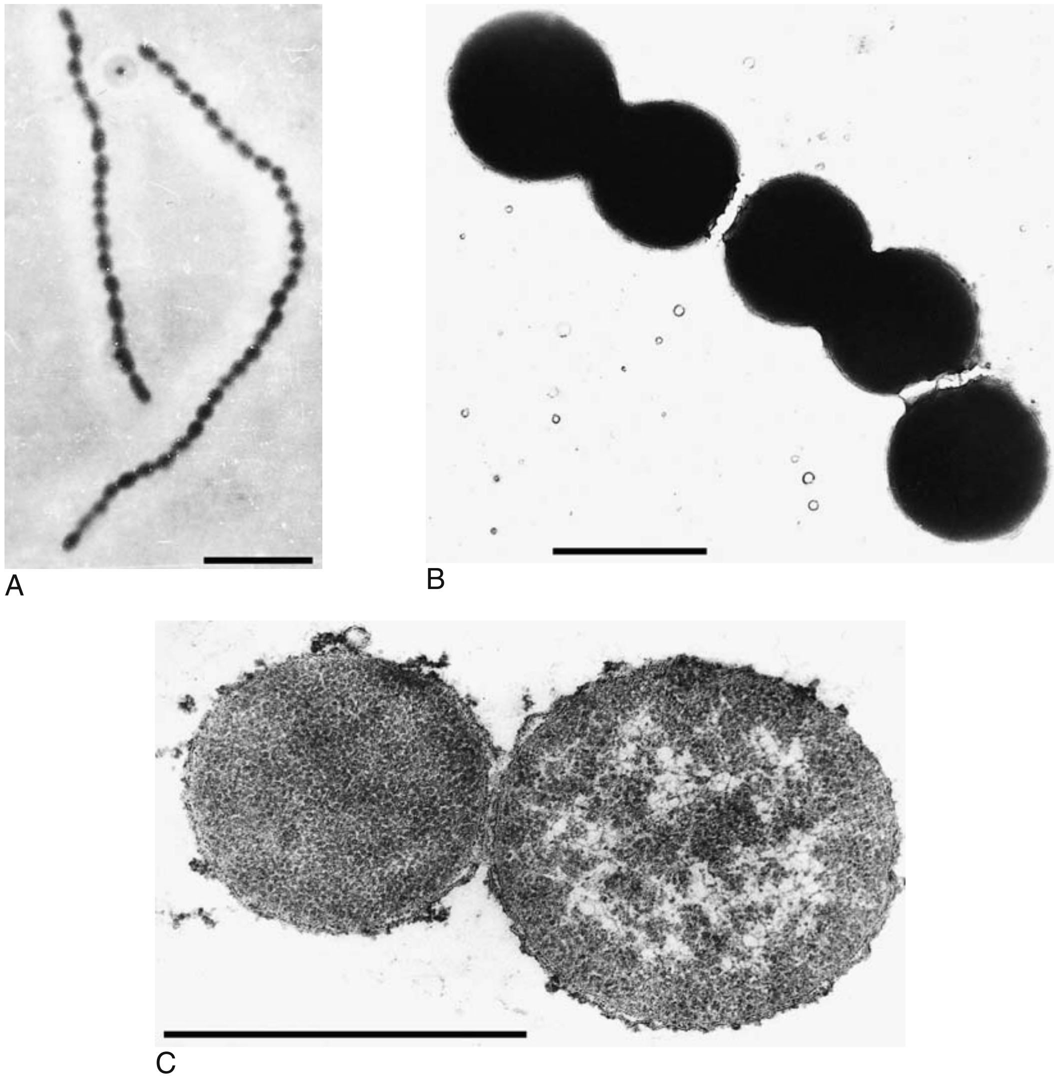

FIGURE BXII.β.85. Morphology of *Catenococcus thiocycli*. *(A)* phase-contrast photograph (Bar = 10 μm); *(B)* electron micrograph, total preparation stained with ammonium molybdate (Bar = 1 μm); *(C)* electron micrograph, thin section, stained with uranyl acetate + lead citrate (Bar = 1 μm).

Cultures oxidize thiosulfate to tetrathionate with high activity and sulfide to S^0 with much less activity. They are unable to grow autotrophically with reduced sulfur compounds, but can utilize metabolic energy released during thiosulfate oxidation to tetrathionate, as has been revealed in chemostat experiments (thiosulfate-dependent yield increase), and with washed cells (thiosulfate-dependent ATP synthesis). These data can be taken to imply the ability of *C. thiocycli* to grow chemolithoheterotrophically. Moreover, the bacterium is also capable of the reduction of S^0 to sulfide and of ferric iron to ferrous iron in the presence of glucose under either microaerobic or anaerobic conditions. However, these reactions do not support anaerobic respiration.

C. thiocycli is sensitive to chloramphenicol, streptomycin, tetracycline, erythromycin, ampicillin, kanamycin, colistin sulfate, nitrofurantoin, sulfafurazole, and penicillin G.

C. thiocycli has been isolated as a dominant tetrathionate-forming heterotroph from a near-shore volcanic thermal region (Papua, New Guinea) rich in sulfide and ferric iron. Its versatile metabolic potential suggests that such heterotrophs may play an important role in inorganic, as well as organic, cycling.

Enrichment and Isolation Procedures

Catenococcus can be enriched, isolated, and successfully grown on a medium with the following composition (g/l): NaCl, 25; NH_4Cl, 0.5; potassium phosphate buffer pH 7, 2–5; $MgSO_4 \cdot 7H_2O$, 0.5–1; $CaCl_2 \cdot 2H_2O$, 0.1; yeast extract, 0.05; acetate or D-glucose, 10–20 mM; sodium thiosulfate, 20 mM; trace elements (Pfennig and Lippert, 1966), 1 ml/l.

Maintenance Procedures

Active cultures can be maintained in liquid culture or on agar slants at 4°C for 6 months without significant loss of viability. They survive lyophilization and may also be stored in liquid nitrogen.

Differentiation of the genus *Catenococcus* from other genera

C. thiocycli differs from the morphologically similar *Paracoccus* by its low mol% G + C and inability to grow autotrophically, from *Neisseria* by its fermentative potential, and from fermentative bac-

teria by its morphology. The main differences between *Catenococcus* and *Neisseria* are given in Table BXII.β.103.

Taxonomic Comments

At the time this genus was described, phylogenetic analysis was not widespread. Therefore, until recently, the true relatives of this organism and its taxonomy remained unclear. Based on phenotypic characteristics, *Catenococcus* was placed in the family *Neisseriaceae* of the *Betaproteobacteria*, which includes mostly nonfermentative, often pathogenic, coccoid bacteria. Recently, partial 16S rDNA sequencing of *C. thiocycli* was performed which demonstrated that this bacterium is within the radiation of the *Vibrionaceae* of the *Gammaproteobacteria* and is closely related to *Listonella pelagia* (96% sequence identity). The fermentative capability of *C. thiocycli* is in agreement with this positioning, but strong morphological differences exist between *Catenococcus* and all other members of the *Vibrionaceae*.

TABLE BXII.β.103. Comparison of *Catenococcus thiocycli* with the genus *Neisseria*

Characteristic	*C. thiocycli*	*Neisseria*
Morphology	Cocci in chains	Diplococci or cocci in short chains; one species rod-shaped
Division	One plane	Two planes
Acid production from sugars	+	D
Anaerobic growth with sugars	+	−
Anaerobic growth with nitrite	−	D
Mol% G + C	49.8	46.5–55.6
Habitat	Sulfidic seawater	Mammalian material

List of species of the genus Catenococcus

1. **Catenococcus thiocycli** Sorokin 1994, 852[VP] (*Catenococcus thiocyclus* (sic)) (Effective publication: Sorokin 1992, 2291.)
thi.o.cy′ cli. Gr. n. *thios* sulfur; Gr. n. *cyclos* circle.

Characteristics are those of the genus. The type strain was isolated from sulfidic seawater in Papua New Guinea.

The mol% G + C of the DNA is: 49.8 ± 0.5 (T_m).

Type strain: TG 5-3, ATCC 51228, DSM 9165, LMD 92.12.

Genus Incertae Sedis XV. **Morococcus** *Long, Sly, Pham and Davis 1981, 300[VP]*

Lindsay I. Sly

Mo.ro.coc′ cus. L. neut. n. *morum* mulberry; Gr. n. *coccus* a grain or berry; M.L. masc. n. *Morococcus* the mulberry coccus.

Colorless, **spherical organisms**, <1 μm in diameter, bound firmly together in tightly packed, **mulberry-like aggregates** of 10–20 cells, with **adjacent sides often flattened**. **Gram negative**. **Nonmotile**. Endospores not formed. **Aerobic**. Nitrate is reduced. Catalase and cytochrome oxidase are produced. H_2S is produced. Acid is produced from carbohydrates. **Hemolytic**. Complex growth factors not required. Growth occurs between 23° and 42°C and between pH 5.5 and 9.0. Ecological niche unknown, but originally isolated from a human brain abscess.

The mol% G + C of the DNA is: 52.

Type species: **Morococcus cerebrosus** Long, Sly, Pham and Davis 1981, 300.

Further descriptive information

The description of the genus *Morococcus* is based on the characteristics of a single isolate designated as the type strain of the type species *Morococcus cerebrosus.* Thus, the diversity of the species characteristics is unknown. The type strain was isolated from a cerebellar abscess in a 54-year-old woman in 1971 in Australia. The following comments are based on the original description by Long et al. (1981). The type strain grows well on a variety of nutrient media including peptone yeast extract agar (PYEA) and chocolate agar. The addition of glucose enhances growth. Growth occurs on agar containing only peptone or yeast extract, but better growth occurs in media containing both components. Growth is poor on vitamin-free Casamino acids medium, but improved when yeast extract is added.

On PYEA after 24 h, colonies are 1 mm in diameter and have a frosted-glass appearance under reflected light. The colonies remain intact when moved and are difficult to emulsify. Colonies grown on sucrose peptone agar stain black with Burke iodine stain and the cells are surrounded by a slime layer when stained with nigrosin.

Colonies appear to be constructed of masses of subunits 3–5 μm in diameter. Each subunit contains 10–20 individual cells approximately 0.8 μm in diameter (Fig. BXII.β.86). Individual cells, pairs, or tetrads are rarely observed. Morphological examination by light microscopy is difficult due to the cellular aggregates (Fig. BXII.β.87). Gram stains may appear Gram positive unless the ethanol decolorization step is extended for 20–40 s, and irregular staining is often observed.

Despite obvious morphological differences, the type strains of *Morococcus cerebrosus* and *Neisseria mucosa* show considerable biochemical similarity. However, the two type strains can be differentiated by several characteristics. *Neisseria mucosa* strongly reduces litmus milk and grows on MacConkey agar, but fails to produce acid reactions in Falkow decarboxylase tests. *Morococcus cerebrosus*, on the other hand, reduces litmus milk weakly, fails to grow on MacConkey agar, and gives a strong decarboxylase reaction for ornithine.

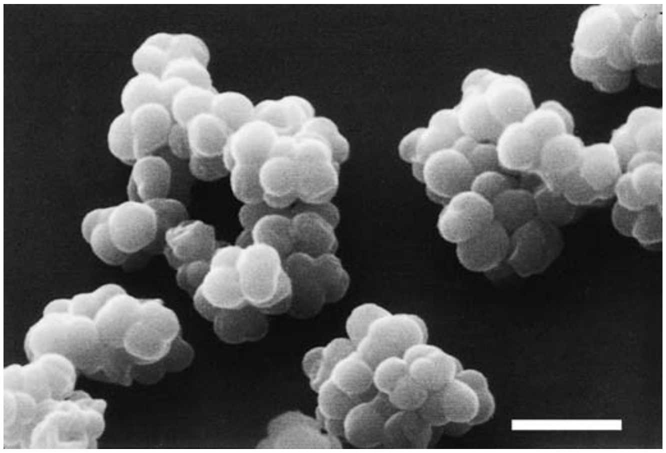

FIGURE BXII.β.86. Scanning electron micrograph of *Morococcus cerebrosus* ACM 858[T] showing mulberry-like cellular aggregates (Bar = 4 μm).

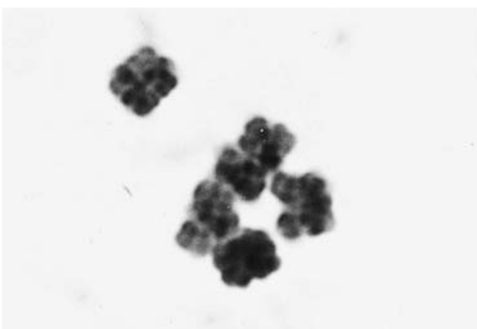

FIGURE BXII.β.87. Photomicrograph of methylene blue-stained cellular aggregates of *Morococcus cerebrosus* ACM 858[T] (× 3000 magnification).

Mice inoculated intraperitoneally with 0.5×10^6 colony-forming units of *Morococcus cerebrosus* became ruffled within 24 h but completely recovered by 48 h. Mice inoculated with 0.5×10^9 colony-forming units died within 24 h. Aggregates were observed microscopically in homogenized spleen samples from dead animals. Mice inoculated subcutaneously developed pyogenic lesions of varying sizes at the sites of inoculation and showed lymph node involvement that persisted for more than 7 d. The larger lesions contained free pus, in which the bacteria were observed by Gram staining and recovered by culture.

Antiserum raised against *Morococcus cerebrosus* in rabbits showed no affinity to *Neisseria mucosa* and when this antiserum was adsorbed with *Neisseria mucosa* it remained reactive to *Morococcus cerebrosus*, indicating the serological difference between these two type strains. These serological differences were confirmed by gel immunodiffusion and gel immunoelectrophoresis.

Maintenance Procedures

Morococcus cerebrosus may be grown on a variety of nutrient media and maintained routinely on peptone yeast extract agar (PYEA). The organism may be preserved by cryogenic storage in liquid nitrogen when suspended in PYE broth containing 10% glycerol, and by freeze drying in glucose peptone broth containing horse serum.

Differentiation of the genus *Morococcus* from other genera

The description of *Morococcus* supports its membership of the family *Neisseriaceae*. The closest phenotypic relatives are *Neisseria mucosa* and *Neisseria macacae* (Long et al. 1981; Barrett and Sneath 1994; Ben Dekhill, Stackebrandt and Sly, unpublished data). The cellular aggregates formed by *Morococcus* most clearly differentiate the genus from other members of the *Neisseriaceae*. Barrett and Sneath (1994) confirmed the unique mulberry-like aggregates of *Morococcus cerebrosus* and concluded that numerical analysis clustering supported the inclusion of the genus *Morococcus* within the *Neisseriaceae*. However, unpublished phylogenetic evidence (see Taxonomic Comments below) supports the inclusion of *Morococcus cerebrosus* in the genus *Neisseria*, a taxonomic change that would require emendation of the genus *Neisseria* to accommodate an aggregate forming species. The characteristics that differentiate the genus *Morococcus* from related Gram-negative genera with coccoid morphology are shown in Table BXII.β.104.

Taxonomic Comments

In the original description of *Morococcus cerebrosus*, Long et al. (1981) made considerable efforts to distinguish *Morococcus cerebrosus* from *Neisseria mucosa* and concluded that *Morococcus cerebrosus* could be sufficiently differentiated from *Neisseria mucosa* based on physiological, cultural, serological, and morphological characteristics to warrant its description as a separate species in a new genus. Barrett and Sneath (1994) made an extensive numerical phenotypic study of *Neisseria* including *Morococcus cerebrosus*. *M. cerebrosus* was placed alone on a separate branch as a satellite of phenon 24 that contained strains from dental plaque

TABLE BXII.β.104. Differentiation of the genus *Morococcus* from related Gram-negative genera with coccoid morphology[a]

Characteristic[b]	*Morococcus cerebrosus*	*Neisseria*	*Moraxella* (*Branhamella*)
Cellular morphology:			
Cocci	+	+	+
Rods	−	+[c]	−
Cell aggregates	+	−	−
Acid from glucose	+	D	−
Nitrate reduced	+	D	D

Mol% G + C of DNA	52	46–56	40–47

[a]Symbols: +, present in all species; −, absent in all species; (+), weak reaction; d, 11–89% of strains are positive; D, variable reaction in different species.

[b]Data from Bøvre (1984a, b), Vedros (1984).

[c]*Neisseria elongata* only.

from gorilla and cows. The neighboring cluster (phenon 25) contained one of the replicates of the type strain of *Neisseria mucosa*, although the authors regarded this relationship as unusual. The other replicate was placed in phenon 9 together with one replicate of the type strain of *Neisseria macacae*. The other replicate of *N. macacae* was placed as a satellite of phenons 9–12.

Phylogenetically, *Morococcus cerebrosus* forms a clade with *Neisseria mucosa* and *Neisseria macacae* based on 16S rRNA gene sequence similarity (Ben Dekhill, Stackebrandt, and Sly, unpublished data). *Morococcus cerebrosus* should therefore be considered a species of the genus *Neisseria* but its relationship with *Neisseria mucosa* and *Neisseria macacae* requires further investigation. In a recent study of the phylogeny of the genus *Neisseria*, Harmsen et al. (2001) showed that *Neisseria mucosa* and *Neisseria macacae* had identical 16S rDNA (*E. coli* positions 54–510) and 23S rDNA (*E. coli* position 1400–1600) sequences. Taxonomic change at this time is considered premature until further strains of *Morococcus cerebrosus* are obtained, if possible, and their relationship to *N. mucosa* and *N. macacae* is determined. However, it appears that in the 30 years since the first isolation of *M. cerebrosus* no further isolates have been reported. Aggregate formation as observed in *M. cerebrosus* is inconsistent with the description of the genus *Neisseria* and the description would require emendation to include *M. cerebrosus*.

List of species of the genus Morococcus

1. **Morococcus cerebrosus** Long, Sly, Pham and Davis 1981, 300^{VP}

   ce.re.bro′sus. L. adj. *cerebrosus* pertaining to the brain, the original source of isolation of this organism.

   Colorless, spherical organisms, less than 1 μm in diameter, bound firmly together in tightly packed, mulberry-like aggregates of 10–20 cells, with adjacent sides often flattened. Gram negative. Nonmotile. Endospores not formed. Poly-β-hydroxybutyrate not produced. Capsules are produced in sucrose-containing media.

   Growth occurs on vitamin-free Casamino acids, peptone, yeast extract, and chocolate agars. No growth occurs on Sabouraud dextrose agar, Czapek Dox agar, or peptone yeast extract agar (PYEA) containing 40% bile, 0.1% potassium tellurite, or 10% NaCl, or in glucose ammonium sulfate broth. After 24 h colonies on PYEA are convex or umbonate, entire, matt, buff colored, 1 mm in diameter, and difficult to emulsify. Colonies on sucrose agar give a black reaction with iodine. Granular growth occurs in peptone yeast extract broth. Growth occurs between 23° and 42°C, and between pH 5.5 and 9.0.

   Aerobic, but may give weak acid reactions in both tubes of the Hugh and Leifson test. Nitrate is reduced to nitrite and gas but the reaction may be variable. Litmus milk is reduced. Hemolyses horse erythrocytes. H_2S is produced from cysteine. Deoxyribonuclease, ornithine decarboxylase, catalase, cytochrome oxidase, and methyl red positive. Acid is produced from glucose, fructose, sucrose, and maltose, but not from arabinose, ribose, xylose, rhamnose, galactose, mannose, sorbose, salicin, cellobiose, lactose, melibiose, trehalose, melezitose, raffinose, dextrin, inulin, starch, ethanol, glycerol, erythritol, adonitol, arabinol, dulcitol, mannitol, sorbitol, or inositol. Citrate and malonate are not oxidized. Does not hydrolyze starch, esculin, gelatin, casein, or Tween 80. Lecithinase, phosphatase, phenylalanine deaminase, and urease are not produced. Arginine, glutamic acid, and lysine decarboxylases are not produced. Indole is not produced. Serum liquefaction is negative.

   Susceptible to the following antibiotic disks: kanamycin (30 μg), gentamicin (10 μg), streptomycin (10 μg), penicillin G (10 U), ampicillin (2 μg), erythromycin (15 μg), nalidixic acid (30 μg), chloramphenicol (10 μg), and tetracycline (10 μg). Resistant to cloxacillin (5 μg) and methicillin (5 μg).

   Antigenically unrelated to *Neisseria mucosa* ACM 1903^T (ATCC 19696^T). Pathogenic to mice. Ecological niche unknown, but originally isolated from a human brain abscess in Australia.

   The mol% G + C of the DNA is: 52 (T_m).

   Type strain: ACM 858, ATCC 33486, NCTC 11393, UQM 858.

Order V. **Nitrosomonadales** *ord. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Ni.tro.so.mo.na.da′les. M.L. fem. n. *Nitrosomonas* type genus of the order; *-ales* ending to denote order; M.L. fem. n. *Nitrosomonadales* the *Nitrosomonas* order.

The order *Nitrosomonadales* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the order contains the families *Nitrosomonadaceae*, *Gallionellaceae*, and *Spirillaceae*.

Order is morphologically, metabolically, and ecologically diverse. Includes organisms having spiral-shaped, stalked, coccal, rod-shaped, and pleomorphic cells. Includes organisms that can grow chemolithotrophically, mixotrophically, and chemoorganotrophically. Found in a variety of habitats.

Type genus: **Nitrosomonas** Winogradsky 1892, 127 (Nom. Cons. Opin. 23 Jud. Comm. 1958, 169.)

Family I. **Nitrosomonadaceae** *fam. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Ni.tro.so.mo.na.da' ce.ae. M.L. fem. n. *Nitrosomonas* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Nitrosomonadaceae* the *Nitrosomonas* family.

The family *Nitrosomonadaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Nitrosomonas* (type genus), *Nitrosolobus*, and *Nitrosospira*.

Lithoautotrophic bacteria that oxidize ammonia.

Type genus: **Nitrosomonas** Winogradsky 1892, 127 (Nom. Cons. Opin. 23 Jud. Comm. 1958, 169.)

Genus I. **Nitrosomonas** *Winogradsky 1892, 127^AL (Nom. Cons. Opin. 23 Jud. Comm. 1958, 169)*

Hans-Peter Koops and Andreas Pommerening-Röser

Ni.tro.so.mo' nas. M.L. adj. *nitrosus* nitrous; Gr. fem. n. *monas* a unit, monad; M.L. fem. n. *Nitrosomonas* nitrite monad, i.e., the monad producing nitrite.

Spherical, ellipsoidal, or rod-shaped cells (Figs. BXII.β.88a, BXII.β.89a, BXII.β.90a, and BXII.β.91a). Strains belonging to the same species are generally very similar in the shape and size of their cells. Cells occur singly or occasionally in short chains. Depending on the growth conditions, cells are **free-living or embedded in slimy aggregates**. Gram-negative cell wall, but **some marine representatives show an additional outer cell-wall layer composed of subunits arranged in a macromolecular array** (Watson and Remsen, 1969). Motile cells possess **polar flagella**. **Intracytoplasmic membranes are arranged as flattened vesicles, primarily in the peripheral cytoplasm** (Figs. BXII.β.88b, BXII.β.89b, BXII.β.90b, and BXII.β.91b). **Carboxysomes** (Fig. BXII.β.92) are

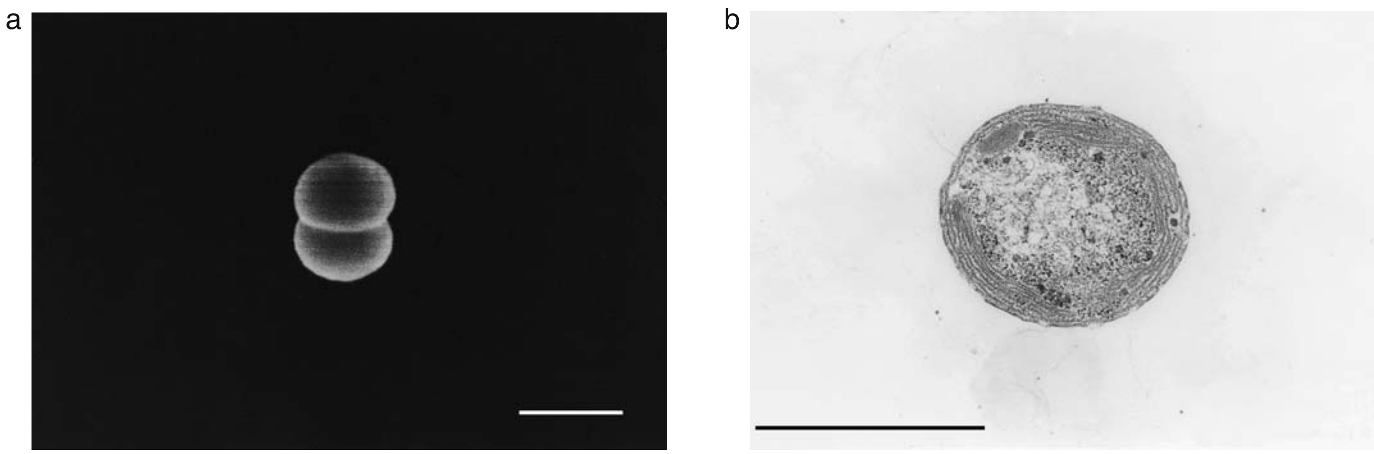

FIGURE BXII.β.88. (*a*) Scanning electron micrograph and (*b*) electron micrograph of a thin section of cells of *Nitrosomonas mobilis* (*"Nitrosococcus mobilis"*). Bars = 1 µm.

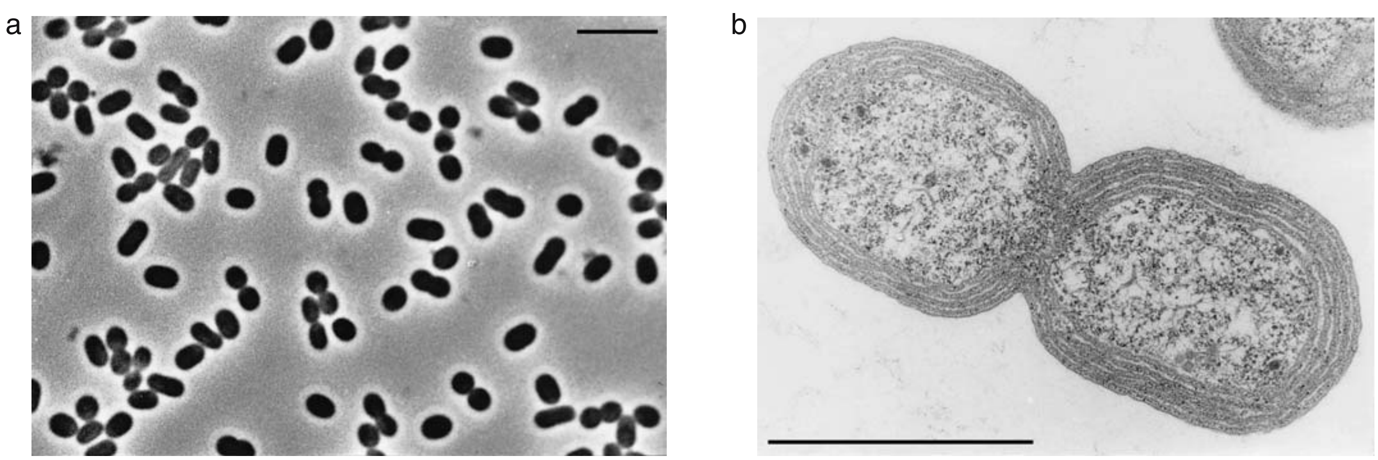

FIGURE BXII.β.89. (*a*) Phase contrast photomicrograph and (*b*) electron micrograph of a thin section of cells of *Nitrosomonas communis*. Bars = 5 µm (*a*) and 1 µm (*b*).

present in some species. **Urea** can be used as ammonia source by many, but not all, species. The K_s values for oxidation of NH_3 range between 0.6 and 158 μM. Most, if not all, species are predominantly or exclusively present in special environments.

The mol% G + C of the DNA is: 45–54 (T_m).

Type species: **Nitrosomonas europaea** Winogradsky 1892, 127, emend. mut. char. Watson 1971b, 266.

Taxonomic Comments

Eleven species of the genus *Nitrosomonas* are described. Together with other cultured, but undescribed, species of the genus and the reclassified *"Nitrosococcus mobilis"* (proposed here as *Nitrosomonas mobilis* comb. nov.), they form one of the two clusters of ammonia oxidizers within the *Betaproteobacteria*. Seven distinct phylogenetic lineages can be distinguished within this cluster, reflecting ecophysiologically distinct groupings (Table BXII.β.105).

Differentiation of the species of the genus *Nitrosomonas*

Table BXII.β.105 lists characteristic features useful for phenotypic differentiation of the cultured species of *Nitrosomonas*.

List of species of the genus Nitrosomonas

1. **Nitrosomonas europaea** Winogradsky 1892, 127[AL] emend. mut. char. Watson 1971b, 266.*
eu.ro.pae′ a. Gr. adj. *europaeus* of Europe, European.

Cells are rod shaped, with rounded or pointed ends, 0.8–1.1 × 1.0–1.7 μm, generally occurring as single cells. Gram-negative cell envelope. Motility is not observed. Carboxysomes are not present. Urease negative. At pH ~7.8, cultures tolerate ammonium salt concentrations of up to 400 mM. The K_s values of NH_3 oxidation range between 30 and 56 μM. No obligate salt requirement, but cultures exhibit salt tolerance of up to 500 mM NaCl. Most common in sewage disposal plants and in eutrophic waters, but occasionally found in soils.

**Editorial Note:* Readers are advised that although the species of *Nitrosomonas* listed here appeared on Validation List No. 83 (IJSEM 2001, *51:* 1945) type material was not deposited in two public service collections as required by Rule 27 and 30 of the Bacteriological Code as amended in 1999. As such, these names may be illegitimate and invalid, and their usage may be called into question until this matter is satisfactorily addressed.

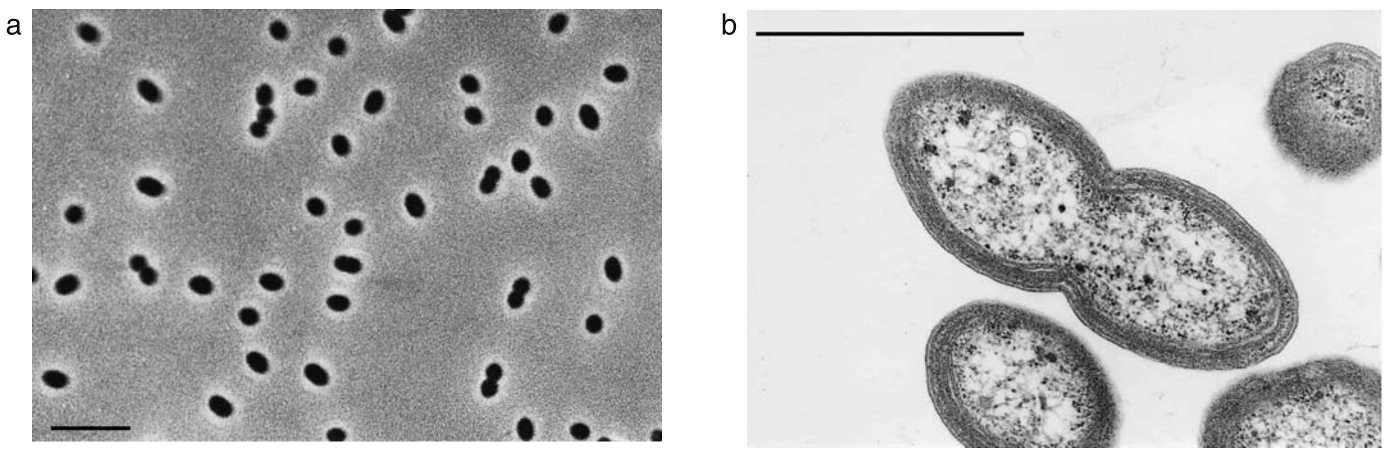

FIGURE BXII.β.90. (*a*) Phase contrast photomicrograph and (*b*) electron micrograph of a thin section of cells of *Nitrosomonas europaea*. Bars = 5 μm (*a*) and 1 μm (*b*).

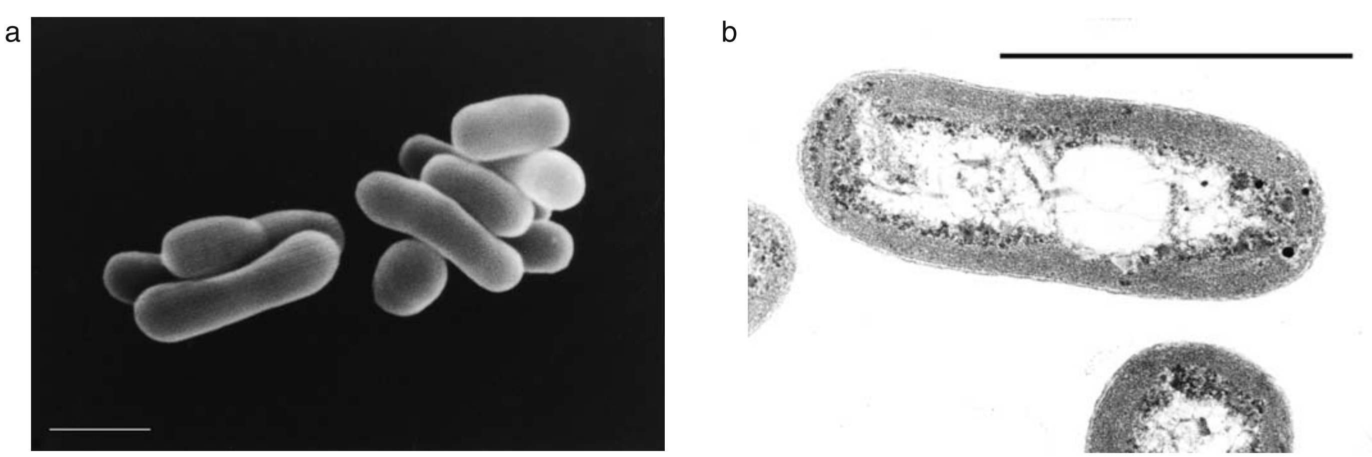

FIGURE BXII.β.91. (*a*) Scanning electron micrograph and (*b*) electron micrograph of a thin section of cells of *Nitrosomonas marina*. Bars = 1 μm.

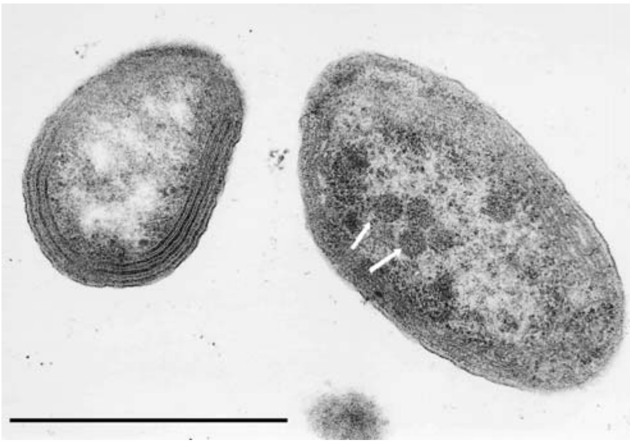

FIGURE BXII.β.92. Electron micrograph of a thin section of a cell of *Nitrosomonas eutropha* showing carboxysomes (*arrows*). Bar = 1 µm.

The mol% G + C of the DNA is: 50.6–51.4 (T_m).
Type strain: ATTC 25978.
GenBank accession number (16S rRNA): M96399.

2. **Nitrosomonas aestuarii** Koops, Böttcher, Möller, Pommerening-Röser and Stehr 1991, 1697.*
ae.stu.a'ri.i. L. n. *aestus* tides; M.L. gen. n. *aestuarii* of the estuary.

Cells are rod shaped with rounded ends, 1.0–1.3 × 1.4–2.0 µm. Gram-negative cell wall. Additional layers, as found in *N. marina*, are not observed. Nonmotile. No carboxysomes. Cells can use urea as an ammonia source. The maximal ammonium salt tolerance is about 300 mM at pH 7.8. Cultures have an obligate salt requirement, with optimum growth at NaCl concentrations around 300 mM; 700 mM NaCl is tolerated. Isolated from marine environments, chiefly coastal waters.

The mol% G + C of the DNA is: 45.7–46.3 (T_m).
Type strain: Nm 36.
GenBank accession number (16S rRNA): AJ298734.

3. **Nitrosomonas communis** Koops, Böttcher, Möller, Pommerening-Röser and Stehr 1991, 1697.
com.mu'nis. L. adj. *communis* common.

Cells are short rods or ellipsoidal with rounded ends, 1.0–1.4 × 1.7–2.2 µm. Gram-negative cell wall. Motility is not observed. No carboxysomes. Urea not used as an ammonia source. Ammonium salts tolerance is up to 200 mM at pH 7.8. The K_s value of NH_3 oxidation is 18–19 µM. No salt requirement; NaCl is tolerated up to 300 mM. Distributed mainly in agriculturally treated neutral soils.

The mol% G + C of the DNA is: 45.6–46.0 (T_m).
Deposited strain: Nm 2.
GenBank accession number (16S rRNA): AJ298732, Z46981.
Additional Remarks: At least two species, *Nitrosomonas* spp. I and II (Table BXII.β.105), exist that are physiologically not distinguishable from *N. communis* and are closely related to this species.

4. **Nitrosomonas eutropha** Koops, Böttcher, Möller, Pommerening-Röser and Stehr 1991, 1697.
eu.tro'pha. Gr. pref. *eu-* good; *trophos* one who feeds; M.L. fem. n. *eutropha* good nutrition.

Pleomorphic cells, rod to pear shaped, with one or both ends pointed, 1.0–1.3 × 1.6–2.3 µm, occasionally in short chains. Gram-negative cell wall. Most strains are motile. Carboxysomes are present. Cells are urease negative. At pH ~7.8, cultures tolerate concentrations of ammonium salts of up to 600 mM. The K_s value of ammonia oxidation is 35–36 µM. No salt requirement, but up to 500 mM NaCl is tolerated. Commonly abundant in sewage disposal plants and in eutrophic waters. Occasionally found in soils.

The mol% G + C of the DNA is: 47.9–48.5 (T_m).
Type strain: C-91, Nm 57.
GenBank accession number (16S rRNA): AJ298739, AY23795, M96402.

5. **Nitrosomonas halophila** Koops, Böttcher, Möller, Pommerening-Röser and Stehr 1991, 1698.*
hal.o'phi.la. Gr. n. *halos* salt; Gr. adj. *halophila* salt loving.

**Editorial Note:* Readers are advised that although the species of *Nitrosomonas* listed here appeared on Validation List No. 83 (IJSEM 2001, *51:* 1945) type material was not deposited in two public service collections as required by Rule 27 and 30 of the Bacteriological Code as amended in 1999. As such, these names may be illegitimate and invalid, and their usage may be called into question until this matter is satisfactorily addressed.

Carboxysomes	−	−	−	+	+	−	−	+	−	−	−	−	−	+

Cells 1.1–1.5 × 1.5–2.2 μm, with a Gram-negative cell wall. Motility has not been observed. Carboxysomes are present. Urease negative. At pH ~7.8, cultures tolerate ammonium salts of up to 400 mM. Moderately halophilic; optimal NaCl concentration around 250 mM; tolerate up to 1000 mM NaCl. Strains were isolated from a brackish water environment (North Sea) and from soda lakes.

The mol% G + C of the DNA is: 53.8 (T_m).

Type strain: Nm 1.

GenBank accession number (16S rRNA): AJ298731, Z46987.

6. **Nitrosomonas marina** Koops, Böttcher, Möller, Pommerening-Röser and Stehr 1991, 1697.*
ma.ri′ na. L. fem. adj. *marina* of the sea, marine.

Cells are generally slender rods with rounded ends, 0.7–0.9 × 1.4–2.3 μm. Gram-negative cell wall, but with an additional layer composed of subunits arranged in a macromolecular array. Motility is not observed. No carboxysomes. Cultures have an obligate salt requirement; the optimal NaCl concentration is around 400 mM; 800 mM NaCl is tolerated. Ammonium salts are tolerated at up to 200 mM at pH 7.8. Urease positive. Commonly distributed in marine environments.

The mol% G + C of the DNA is: 47.4–48.0 (T_m).

Type strain: Nm 22

GenBank accession number (16S rRNA): Z46990.

Additional Remarks: At least one further species, *Nitrosomonas* sp. III, exists (Table BXII.β.105) that is physiologically indistinguishable from *N. marina*, but cells are short rods and possess carboxysomes.

7. **Nitrosomonas mobilis** *comb. nov.* (*"Nitrosococcus mobilis"* Koops, Harms and Wehrmann 1976, 281).*
mo′ bi.lis. L. adj. *mobilis* movable.

Cells generally spherical, 1.5–1.7 μm in diameter. However, some strains are rod shaped, 1.5–1.7 × 1.7–2.5 μm. Cells occur singly, in pairs, and occasionally as short chains. Gram-negative cell wall. Motile cells have a tuft of 1–22 flagella about 12 nm wide and 3–5 μm long. No carboxysomes. Cells are moderately halophilic, with an optimum NaCl concentration of about 100 mM. NaCl is tolerated at concentrations up to 600 mM. At pH 7.8, ammonium compounds are tolerated up to 300 mM. Urease negative. Strains have been isolated from brackish water environments and sewage disposal plants.

The mol% G + C of the DNA is: 49.3 (T_m).

Type strain: Nc 2.

GenBank accession number (16S rRNA): AF287297, AJ298728, M96403.

8. **Nitrosomonas nitrosa** Koops, Böttcher, Möller, Pommerening-Röser and Stehr 1991, 1697.*
ni.tro′ sa. M.L. fem adj. *nitrosa* nitrous.

Spheres or short rods with rounded ends, 1.3–1.5 × 1.4–2.2 μm. Gram-negative cell wall. Motility not observed. Carboxysomes are present. Urea can serve as an ammonia source. Maximum tolerance of ammonium salts at pH 7.8 is 100 mM. The K_s value of NH_3 oxidation is 45–46 μM. No salt requirement; 200 mM NaCl is tolerated. Isolates originate from industrial sewage disposal plants, ponds, and occasionally rivers and soils.

The mol% G + C of the DNA is: 47.9 (T_m).

Type strain: Nm 90.

GenBank accession number (16S rRNA): AJ298740.

9. **Nitrosomonas oligotropha** Koops, Böttcher, Möller, Pommerening-Röser and Stehr 1991, 1698.*
o.li.go.tro′ pha. Gr. adj. *oligos* little; Gr. n. *trophos* one who feeds; M.L. fem. n. *oligotropha* little nutrition.

Cells are rod shaped or spherical, 0.8–1.2 × 1.1–2.4 μm in size, with rounded ends. Gram-negative cell wall. Motility not observed. Slimy cell aggregates generally occur in cultures after exponential growth has ceased. No carboxysomes. Urease positive. Sensitive to increasing concentrations (>50 mM at pH 7.8) of ammonium salts. The K_s value of NH_3 oxidation is 2.4–4.2 μM. No salt requirement. NaCl is tolerated at up to 200 mM. Most strains have been isolated from oligotrophic freshwater environments.

The mol% G + C of the DNA is: 49.5–50 (T_m).

Type strain: Nm 45.

GenBank accession number (16S rRNA): AJ298736.

10. **Nitrosomonas ureae** Koops, Böttcher, Möller, Pommerening-Röser and Stehr 1991, 1698.*
u′ re.ae. M.L. n. *urea* urea; M.L. gen. n. *ureae* of urea.

Cells are rod shaped, 0.9–1.1 × 1.5–2.5 μm, with rounded ends. Gram-negative cell wall. Motility is not observed. No carboxysomes. Urease positive. Ammonium salts are tolerated at up to 100 mM at pH 7.8. The K_s value of NH_3 oxidation is 1.9–3.6 μM. No salt requirement. NaCl is tolerated at up to 300 mM. Mainly found in oligotrophic fresh water environments and occasionally in soils.

The mol% G + C of the DNA is: 45.6–46.0 (T_m).

Type strain: Nm 10.

GenBank accession number (16S rRNA): AJ298730.

11. **"Nitrosomonas cryotolerans"** Jones, Morita, Koops and Watson 1988, 1122.
cry.o.to.le′ rans. Gr. n. *cryos* cold, frost; L. pres. part. *tolerans* tolerating; M.L. part. adj. *cryotolerans* tolerating cold.

Cells are rod shaped with rounded ends, 1.2–2.2 × 2.0–4.0 μm. Gram-negative cell wall, but with an additional outer, electron-dense layer. Besides the flattened peripheral intracytoplasmic membranes that are typical of *Nitrosomonas*, membranes may intrude deep into the cytoplasm, forming what appear to be membrane-bound vesicles. Motility not observed. No carboxysomes. Urease positive. Cultures tolerate ammonium salts at up to 400 mM at pH 7.8. Cells have an obligate salt requirement, with optimal growth around 300 mM NaCl; 600 mM NaCl is tolerated. Cultures can grow at temperatures down to −5°C. The only existing strain originates from the Gulf of Alaska.

The mol% G + C of the DNA is: 45.8 (T_m)

Deposited strain: NW430, Nm 55.

**Editorial Note:* Readers are advised that although the species of *Nitrosomonas* listed here appeared on Validation List No. 83 (IJSEM 2001, *51:* 1945) type material was not deposited in two public service collections as required by Rule 27 and 30 of the Bacteriological Code as amended in 1999. As such, these names may be illegitimate and invalid, and their usage may be called into question until this matter is satisfactorily addressed.

Genus II. **Nitrosolobus** *Watson, Graham, Remsen and Valois 1971a, 200*[AL]

Hans-Peter Koops and Andreas Pommerening-Röser

Ni.tro.so.lob′ us. M.L. *nitrosus* nitrous; M.L. n. *lobus* a lobe; M.L. fem. *nitrosolobus* nitrous lobe, a lobe producing nitrite.

Pleomorphic, lobate cells (Fig. BXII.β.93a) **that divide by constriction**. Gram-negative cell wall. Motile cells possess 1–20 **peritrichous flagella**, each 15 nm wide and 2.5–5.0 μm long. **Cells are partially compartmentalized by intracytoplasmic membranes** (Fig. BXII.β.93b). Carboxysomes are not observed. Most, but not all, strains are **urease positive**. **Glycogen inclusions and polyphosphates** are located primarily in the peripheral compartments of the cell. Commonly distributed in agricultural amended soils. Occasionally observed in freshwater environments.

The mol% G + C of the DNA is: 53.2–56.5.

Type species: **Nitrosolobus multiformis** Watson, Graham, Remsen and Valois 1971a, 200.

Differentiation of the species of the genus *Nitrosolobus*

Besides the type species, *N. multiformis*, at least one other species exists. It is distinguishable from the type species by a mol% G + C content of DNA of 56.5 and by its significantly smaller cells (0.8–1.2 × 1.0–1.5 μm). In contrast to *N. multiformis*, this species is occasionally found in sewage disposal plants. This second species of the genus *Nitrosolobus* has not yet been named.

List of species of the genus Nitrosolobus

1. **Nitrosolobus multiformis** Watson, Graham, Remsen and Valois 1971a, 200.
mul.ti.for′ mis. L. adj. *multus* many; L. n. *forma* shape; M.L. adj. *multiformis* many shapes.

The general characteristics are the same as those described for the genus. Cells are 1.0–1.2 × 1.0–2.5 μm.

The mol% G + C of the DNA is: 53.2–54.6 (Bd, T_m).

Type strain: C-71, ATCC 25196.

GenBank accession number (16S rRNA): L35509.

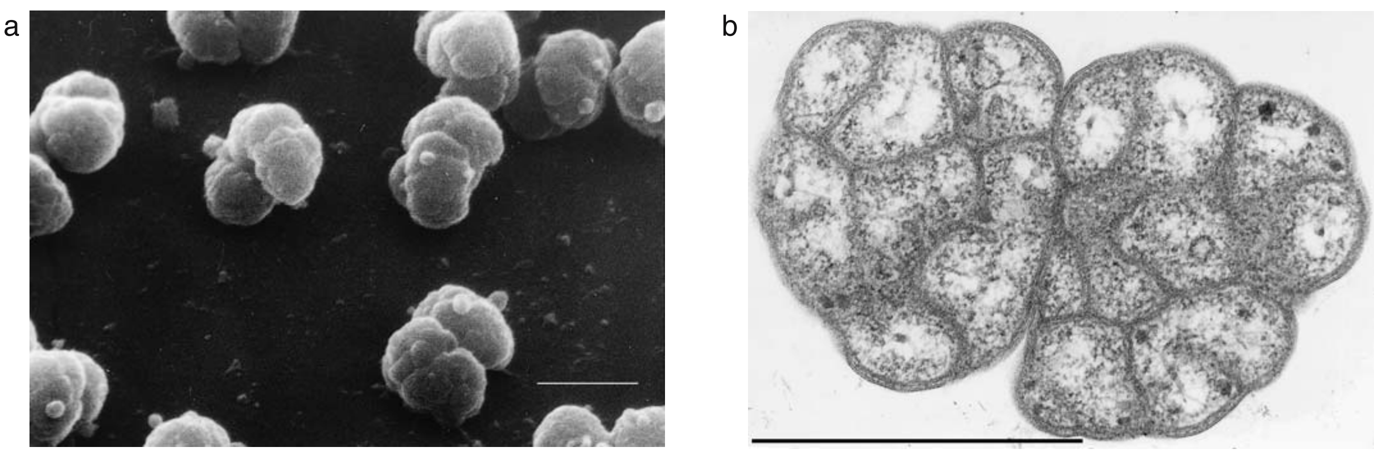

FIGURE BXII.β.93. (*a*) Scanning electron micrograph and (*b*) electron micrograph of a thin section of cells of *Nitrosolobus multiformis* and *Nitrosolobus* sp. N1 5, respectively. Bars = 1 μm.

Genus III. **Nitrosospira** *Winogradsky and Winogradsky 1933, 406*[AL]

Hans-Peter Koops and Andreas Pommerening-Röser

Ni.tro.so.spi′ ra. M.L. adj. *nitrosus* nitrous; Gr. n. *spira* a coil, spiral; M.L. fem. n. *Nitrosospira* nitrous spiral.

Cells are tightly coiled spirals (Fig. BXII.β.94a), 0.3–0.4 μm in width, with 3–20 turns. Occasionally, vibrioid cells occur in cultures. By phase-microscopy, **spherical forms** 0.8–1.2 μm in diameter may be observed in cultures. Gram-negative cell wall. **Intracytoplasmic membranes are rare** (Fig. BXII.β.94b), but tubular invaginations are observed. Motile strains possess **peritrichous flagella**. 1–6 flagella are observed, each 3–5 μm in length. Urease-positive strains, as well as urease-negative strains, exist in all species. Common in grasslands, heath, forest soils, and mountainous environments. Some strains have been isolated from building stones and from acid soils (pH 4.0–4.5). Occasionally observed in freshwater environments. Using molecular ecological methods, the existence of *Nitrosospira*-like groups in marine environment has repeatedly been indicated (Stephen et al., 1996; Phillips et al., 1999; Bano and Hollibaugh, 2000). However this has not yet been proven via isolation of strains.

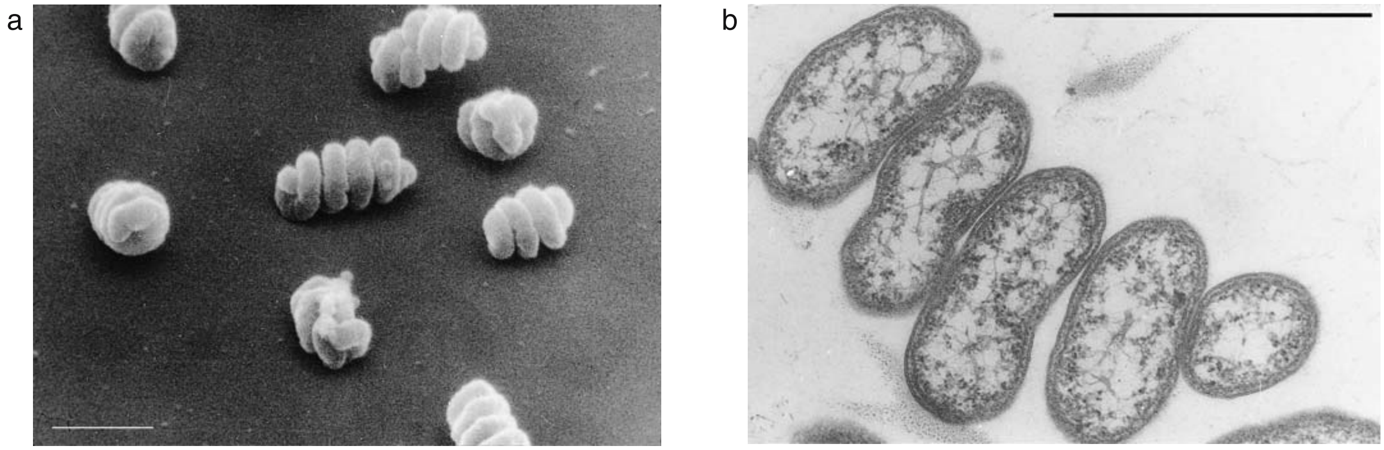

FIGURE BXII.β.94. (*a*) Scanning electron micrograph and (*b*) electron micrograph of a thin section of cells of *Nitrosospira briensis* and *Nitrosospira* sp. Nsp 17, respectively. Bars = 1 μm.

The mol% G + C of the DNA is: 53.2–55.4.

Type species: **Nitrosospira briensis** Winogradsky and Winogradsky 1933, 407.

Taxonomic Comments

Originally, two species, *N. briensis* and *"N. antarctica"*, were described by Winogradsky and Winogradsky (1933). Since significant differential characteristics were missing, *"N. antarctica"* was stated by Watson (1971a) to be a subjective synonym of *N. briensis*. However, in DNA reassociation experiments, Koops and Harms (1985) have demonstrated that at least five species of the genus *Nitrosospira* exist. Two groups, containing three and two species, respectively, could be distinguished with 52–53 and 55–56 mol% G + C of their DNA. However, new species have not been described because further phenotypic differential characteristics have not yet been determined.

List of species of the genus Nitrosospira

1. **Nitrosospira briensis** Winogradsky and Winogradsky 1933, 407.

bri.en′ sis. N.L. adj. *briensis* of Brie, a French place name.

General characteristics are those described for the genus. The original type strain has not been preserved as laboratory culture.

The mol% G + C of the DNA is: 53.8–54.1 (T_m, Bd).

Type strain: C-76.

Genus IV. **"Nitrosovibrio"** *Harms, Koops and Wehrmann 1976, 110*

Hans-Peter Koops and Andreas Pommerening-Röser

Ni.tro.so.vib′ ri.o. M.L. adj. *nitrosus* nitrous; L. v. *vibrio* to move rapidly to and from, to vibrate; M.L. masc. n. *Nitrosovibrio* a vibrio producing nitrite.

Slender, curved rods (Fig. BXII.β.95a), 0.3–0.4 × 1.1–3.0 μm. **Spherical forms**, 1.0–1.2 μm in diameter, may occur in cultures. Gram-negative cell wall. **Intracytoplasmic membranes are rare** (Fig. BXII.β.95b), but when present, appear as tubular invaginations. Motile cells possess 1–4 **subpolar to lateral flagella** (Fig. BXII.β.96), about 18 nm wide and 4.2–7.5 μm long. Carboxysomes observed in one strain. Most, but not all, strains are **urease positive**. Commonly distributed in oligotrophic soils, such as grasslands, heath, and forest soils, as well as in mountainous environments. Some isolates originate from acid tea soils and from building stones.

The mol% G + C of the DNA is: 53.9.

Type species: **"Nitrosovibrio tenuis"** Harms, Koops and Wehrmann 1976, 110.

Taxonomic Comments

Besides the type species, at least one further species exists, but has not yet been distinguished by phenotypic characters or named.

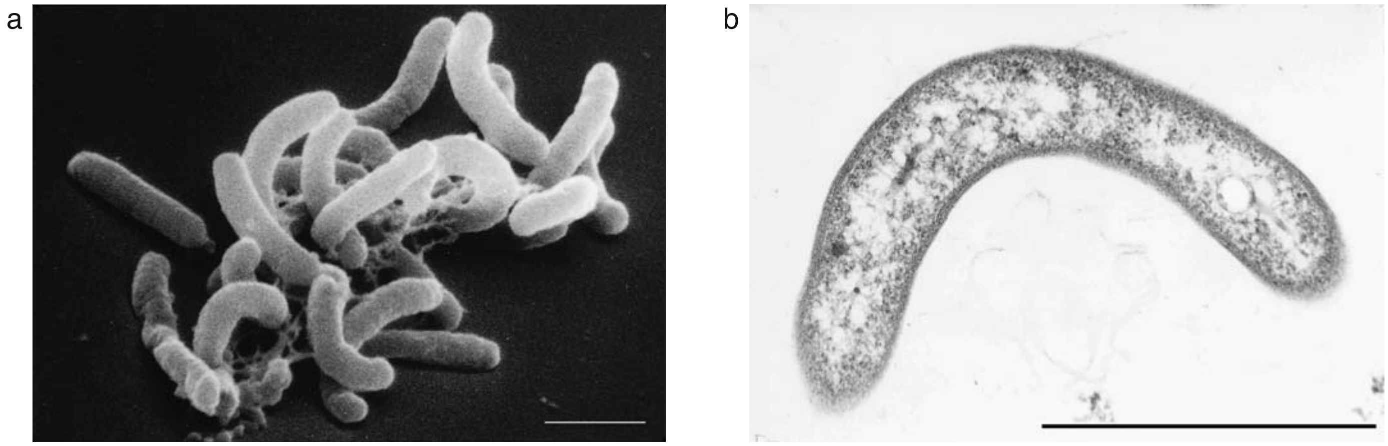

FIGURE BXII.β.95. (*a*) Scanning electron micrograph and (*b*) electron micrograph of a thin section of cells of *"Nitrosovibrio tenuis"* and *"Nitrosovibrio"* sp. Nv 12, respectively. Bars = 1 μm.

List of species of the genus "Nitrosovibrio"

1. **"Nitrosovibrio tenuis"** Harms, Koops and Wehrmann 1976, 110.
te′ nu.is. L. adj. *tenuis* slender.

Characteristics are the same as those described for the genus.

Deposited strain: Nv 1.

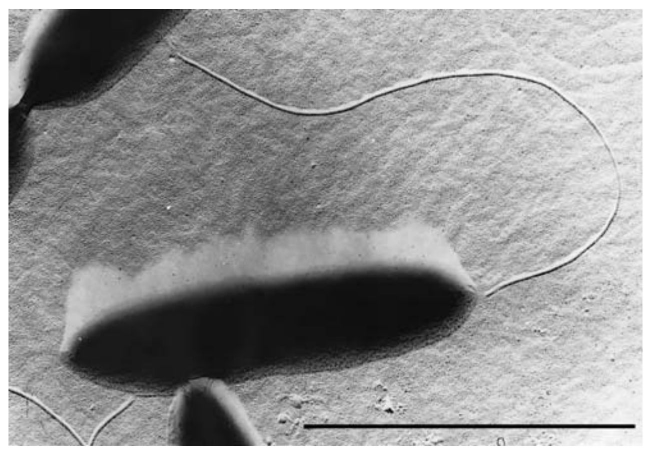

FIGURE BXII.β.96. Electron micrograph of a *"Nitrosovibrio tenuis"* cell shadowed with chromium and showing a single subpolar flagellum. Bar = 1 μm.

Family II. **Spirillaceae** Migula 1894, 237[AL]

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Spi.ril.la′ ce.ae. M.L. dim. neut. n. *Spirillum* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Spirillaceae* the *Spirillum* family.

The family *Spirillaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genus *Spirillum* (type genus).

Description is the same as for the genus *Spirillum*.

Type genus: **Spirillum** Ehrenberg 1832, 38.

Genus I. **Spirillum** *Ehrenberg 1832, 38[AL]*

NOEL R. KRIEG

Spi.ril′ lum. Gr. n. *spira* a spiral; M.L. dim. neut. n. *Spirillum* a small spiral.

Rigid, helical cells, 1.4–1.7 × 14–60 μm. A **polar membrane** underlies the cytoplasmic membrane at the cell poles and is visible in ultrathin sections. **Intracellular poly-β-hydroxybutyrate granules are formed.** Coccoid bodies are not formed. Gram negative. **Motile by large bipolar tufts of flagella** having a long wavelength and about one helical turn; these are composed of approximately 75 flagella and are easily visible by dark-field or phase-contrast microscopy. **Microaerophilic** in ordinary liquid

media, but can grow aerobically in special media or with certain supplements. Colonies on solid media can be obtained only under special conditions. Have a **strictly respiratory type of metabolism** with oxygen as the terminal electron acceptor. Growth does not occur anaerobically with nitrate. Optimal temperature, 30°C. **Oxidase and phosphatase positive. Catalase negative.** Indole and sulfatase negative. Casein, starch, esculin, gelatin, DNA, and RNA are not hydrolyzed. Inhibited by extremely low levels of hydrogen peroxide in the culture medium. NaCl levels above 0.02% are inhibitory. Phosphate levels greater than 0.01 M are inhibitory. **Carbohydrates are not catabolized.** The salts of certain organic acids are used as carbon sources; succinate is used especially well. Vitamins are not required. Occur in **stagnant, freshwater environments**.

The mol% G + C of the DNA is: 38 or 36.

Type species: **Spirillum volutans** Ehrenberg 1832, 38.

Further descriptive information

Structural features An unusual elaboration of the plasma membrane, the "polar membrane," occurs in *S. volutans*. It is attached to the inside of the plasma membrane by barlike links and is located in the region surrounding the polar flagella. Such a membrane has been found mainly in genera of helical bacteria, such as *Aquaspirillum*, *Campylobacter*, *Ectothiorhodospira*, and *Rhodospirillum*. In *Campylobacter*, it is an assembly of ATPase molecules at the poles of the cell (Brock and Murray, 1988). Intracellular poly-β-hydroxybutyrate occurs in the form of prominent granules which are refractile by phase-contrast microscopy and which stain with metachromatic stains such as Ponder's stain (Wells and Krieg, 1965) or with the fluorescent dye Nile blue A (Ostle and Holt, 1982).

Motility The cells are actively motile and swim in straight lines with frequent reversal of direction. The bipolar flagellar fascicles are exceptionally large and consist of many individual flagella (Fig. BXII.β.97). As noted by Metzner (1920), during its rotation the fore fascicle appears to describe a wide bell which is opened toward the rear of the cell; the aft fascicle extends behind the cell and appears to describe a wide goblet (Fig. BXII.β.98). There is no true anterior cell pole: when the fascicles change their orientation the cell reverses its direction of swimming (Fig. BXII.β.98). Because of the wide zones of rotation of the fascicles, Metzner believed that the mechanical effect of the flagella was mainly indirect, i.e., to cause an opposite rotation of the cell body, which, because of its helical shape, would then screw through the medium. Winet and Keller (1976) provided evidence that the aft fascicle of helical cells beats in a helical fashion just as other bacterial flagella do, and Padgett et al. (1983) reported that straight mutant cells could swim at nearly the same speed as helical cells. Thus, it is likely that the flagella operate in a manner similar to that of other bacterial flagella and that the bell and goblet conformations are merely due to the long wavelength of the flagella. Ramia and Swan (1994) have used high-speed cinemicrography to record the swimming of unipolarly flagellated cells. The geometry of these cells was numerically modeled with curved isoparametric boundary elements (from the measured geometrical parameters), and an existing boundary element method (BEM) program was applied to predict the mean swimming linear and angular speeds. Inhibition of the motility of *S. volutans* by low levels of various heavy metals and other toxicants led to development of a method for the monitoring of pollutants in industrial effluents (Bowdre and Krieg, 1974). (See Dutka et al. (1983), Goatcher et al. (1984), Moore (1984), Cortes et al. (1996), Ghosh et al. (1996) and Lacava and Ortolono (1997) for applications, modifications, and evaluations.)

Cultivation *S. volutans* is a microaerophile but can be cultivated easily in a semisolid medium, such as MPSS broth or CHSS

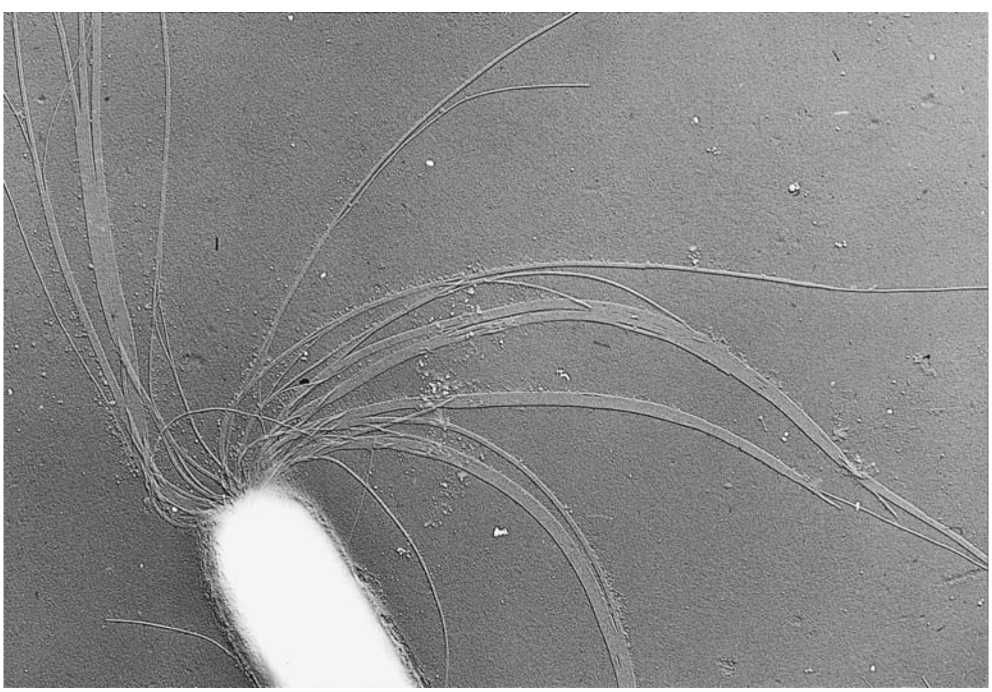

FIGURE BXII.β.97. Flagellar fascicle of *Spirillum volutans* (× 13,000).

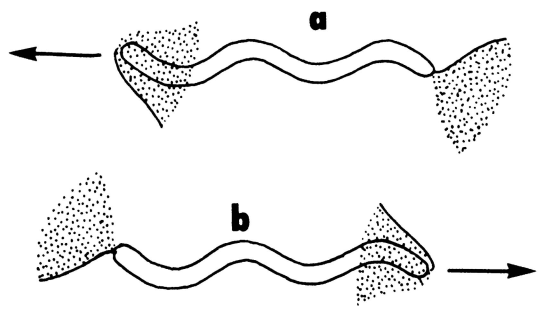

FIGURE BXII.β.98. Diagram of *Spirillum volutans* showing the orientation of the bipolar flagellar fascicles. (*a*) During swimming the fascicles form oriented cones of revolution. (*b*) During reversal of swimming direction, both fascicles reorient simultaneously. *Arrows* in (*a*) and (*b*) indicate the direction of swimming. (Reproduced with permission from J.H. Bowdre and N.R. Krieg, Virginia Polytechnic Institute and State University Water Resources Research Center Bulletin No. 69, 1974, ©Virginia Water Resources Research Center.)

broth[1] prepared with 0.15% agar, incubated under an air atmosphere. Growth is initiated as a thin band or disc several millimeters or centimeters below the surface of the medium, where the respiratory rate of the cells matches the rate of diffusion of oxygen to the cells. As the cell numbers increase, the band becomes denser and migrates closer to the surface. Dense growth just beneath the surface occurs in 48 h.

In MPSS broth, *S. volutans* grows only when incubated under atmospheres of 1–12% oxygen, despite the occurrence in the cells of a superoxide dismutase (SOD) of the iron type (Cover, 1978; Padgett, 1981). Growth does not occur under anaerobic conditions or under an air atmosphere. Addition of catalase (0.8 U/ml) or bovine erythrocyte SOD (4 U/ml) to MPSS broth allows growth to occur under an air atmosphere with static incubation; the two enzymes are most effective when used in combination (0.08 U/ml each) and exert a synergistic effect (Padgett et al., 1982). Potassium metabisulfite (0.005%), acting in conjunction with the $FeCl_3$ component of the MPSS broth, also permits aerobic growth to occur (Padgett et al., 1982).

Aerobic growth can also be obtained by the use of CHSS broth; turbid cultures are obtained in 24 h in 20 × 125-mm loosely screw-capped tubes incubated in a slanted position under an air atmosphere; daily transfer is required. The pH of the medium rises to 8.0 or higher due to oxidation of the succinate component of the medium. A chemically defined medium for *S. volutans* devised by Bowdre et al. (1976) supports growth under a 6% oxygen atmosphere. When supplemented with norepinephrine (10^{-5} to 10^{-6} M), this medium also supports growth under an air atmosphere.

Growth of *S. volutans* on the surface of solid media (MPSS or CHSS broth solidified with 15.0 g/l agar) is difficult to obtain and depends on several factors: (a) protection of the plates from exposure to illumination during preparation and incubation; (b) addition of potassium bisulfite (0.002%), catalase (130 U/ml), or SOD (30 U/ml) to the medium (the enzymes must be added aseptically to the molten medium just before dispensing into Petri dishes); and (c) incubation of the plates in an atmosphere of high humidity for 24 h prior to inoculation and for 5 d after inoculation (Padgett et al., 1982). Even with these precautions, colonies have developed only under oxygen atmospheres of 12% or less, and only 22–72% of the cells spread onto the surface of the plates develop into colonies. Colony counts approaching direct microscopic counts have been obtained by inoculating culture dilutions into a semisolid Colony Count Medium (CCM)[2] and using this to overlay a thicker layer of sterile medium, and by supplementing the medium with pyruvate, which destroys hydrogen peroxide. Both the pyruvate and the overlay are necessary for optimal results (Alban and Krieg, 1996). Colonies are pinpoint in size.

Respiration Respiration rates of *S. volutans* suspended in 0.05 M phosphate buffer are very low (Cole and Rittenberg, 1971), but are higher—and, in fact, comparable to those for aerobes—when a less inhibitory buffer is used, such as BES buffer (*N,N*- bis(2-hydroxyethyl)-2-aminoethanesulfonic acid) (Caraway and Krieg, 1974). Succinate supports the highest rate of oxygen uptake; fumarate, malate, oxaloacetate, and pyruvate are also readily oxidized. Lactate, butyrate, and β-hydroxybutyrate are oxidized to a lesser extent, and citrate, aconitate, isocitrate, α-ketoglutarate, aspartate, glutamate, casein hydrolysate, and carbohydrates are oxidized only very slightly or not at all. When placed in a nonnutritive medium, *S. volutans* continues to retain motility for up to 24 h, with intracellular poly-β-hydroxybutyrate serving as an endogenous energy source (Caraway and Krieg, 1974). Cytochromes of the *b*, *c*, and *o* types have been detected in *S. volutans*, as well as cytochrome oxidase, NADH oxidase, and various tricarboxylic acid cycle enzymes (Cole and Rittenberg, 1971). Aerotactic responses of *S. volutans* to self-created oxygen gradients have been described by Wells and Krieg (1965) and Caraway and Krieg (1974).

Sensitivity to hydrogen peroxide *S. volutans* lacks catalase and is extraordinarily sensitive to H_2O_2. Inhibition of growth occurs by addition of as little as 0.29 μM H_2O_2 to culture media (Padgett et al., 1982), and the organism is killed rapidly by levels greater than 10 μM (Alban and Krieg, 1998). Exposure of MPSS broth to moderate or strong illumination causes the generation of H_2O_2 at levels sufficient to inhibit growth, and culture media should be protected from illumination. Potassium bisulfite, and especially a combination of SOD and catalase, can help to prevent the inhibitory effects caused by illumination. A hydrogen peroxide-resistant mutant obtained by single step mutagenesis with diethyl sulfate was reported to survive and grow after exposure to 40 μM H_2O_2 and had high NADH peroxidase activity, whereas the wild type had no detectable activity; however, the mutant was no more oxygen tolerant than the wild type. The mutant con-

1. MPSS broth (g/l): Bacto peptone (Difco), 5.0; succinic acid (free acid), 1.0; $(NH_4)_2SO_4$, 1.0; $MgSO_4 \cdot 7H_2O$, 1.0; $FeCl_3 \cdot 6H_2O$, 0.002; and $MnSO_4 \cdot H_2O$, 0.002. The pH is adjusted to 6.8 with 2 N KOH before autoclaving. For CHSS broth, 2.5 g of vitamin-free, salt-free acid-hydrolyzed casein (ICN Biochemicals Inc., Aurora, Ohio) is substituted for the peptone component, and 0.1 g NaCl is added (*S. volutans* requires a low level of Na^+). Different lots of casein hydrolysate may vary in their ability to support good growth. For semisolid media, 1.5 g of agar is added.

2. CCM medium (g/l): vitamin-free, salt-free CH (ICN Biochemicals Inc., Aurora, Ohio), 2.6 g ; succinic acid (free acid), 1.0; $(NH_4)_2SO_4$, 1.0 ; $MgSO_4 \cdot 7H_2O$, 1.0; KH_2PO_4, 0.12; NaCl, 0.04; sodium pyruvate, 0.3; $FeCl_3 \cdot 6H_2O$, 0.002; and $MnSO_4 \cdot H_2O$, 0.002. The pH is adjusted to 7.3 with KOH, 0.05 g potassium metabisulfite is added, and the pH is readjusted to 7.3. Agar (7 g/l) is added and dissolved by boiling, and the medium is sterilized by autoclaving. The pH of the cooled medium after autoclaving should be 6.8. Fifteen-ml volumes of sterile semisolid medium (CCM plus 0.7% agar) are dispensed into Petri dishes and allowed to gel for 30 min. A 0.1-ml volume of dilution of the cell suspension is inoculated into 10 ml of semisolid CCM at 45°C and is poured onto the plates as an overlay. After this has gelled, the plates are incubated at 30°C in an atmosphere of O_2/N_2 (6:94) and incubated for 3–4 days.

stitutively expressed a 21.5-kDa protein that showed high relatedness to rubrerythrin and nigerythrin based on amino acid sequence comparison and was undetectable and noninducible in the wild type cells (Alban et al., 1998).

Nutrition The nutritional requirements of *S. volutans* are not well understood, since the defined medium of Bowdre et al. (1976) may not necessarily be a minimal medium. If succinate is omitted from this medium, however, no growth occurs, and omission of any of the amino acids present (threonine, methionine, histidine, isoleucine, and cystine) gives a decreased growth response. A very low level of NaCl is required. The phosphate concentration must be no higher than 10^{-4} M for aerobic growth to occur, although growth under microaerobic conditions will occur if the level is increased to 10^{-2} M. Because of the toxic effects of low levels of heavy metals, glassware used for cultivation of *S. volutans* must be cleaned with acid and washed extensively in tap and distilled water; even growth in CHSS broth is dependent upon the use of exceptionally clean glassware.

Polyamines Using a polyamine-free medium, Hamana et al. (1994) reported that *S. volutans* cells contain putrescine, cadaverine, and spermidine, but not diaminopropane, 2-hydroxyputrescine, or homospermidine.

Habitat *S. volutans* has been isolated from stagnant pond water in Virginia and from the cooling water of a sugar beet refinery in England (Rittenberg and Rittenberg, 1962; Wells and Krieg, 1965); however, the organism is widely distributed in stagnant freshwater sources and can be demonstrated in nearly any hay infusion prepared from such sources. In hay infusions, the organism occurs in greatest numbers just beneath the surface scum (composed of aerobic organisms), presumably at a location where the dissolved oxygen level is most suitable or where hydrogen peroxide is being destroyed by other bacteria.

Enrichment and Isolation Procedures

Initial enrichment from hay infusion is accomplished by inoculation of Pringsheim's soil medium (Rittenberg and Rittenberg, 1962). This medium is prepared by placing one wheat or barley grain in a large test tube, covering the grain with 3–4 cm of garden soil, filling the tube nearly to the top with tap water, and sterilizing in an autoclave. Even with this enrichment, *S. volutans* is vastly outnumbered by other bacteria. At present, the only successful method for isolation is a mechanical method based on the ability of *S. volutans* to out-swim other bacteria. This method, first devised by Giesberger (1936) for isolation of other spirilla, has been successfully used for *S. volutans* by Rittenberg and Rittenberg (1962) and Wells and Krieg (1965).

A capillary is prepared by heating sterile 5-mm glass tubing in a flame, pinching the softened portion with square-ended forceps until almost closed, then reheating the flattened portion and drawing it out. The resulting oval capillary should be 15–30 cm long and 0.1–0.3 mm in diameter. After cooling, the capillary is broken with sterile forceps at the tip and 10–20 cm of sterile medium (the supernatant fluid from Pringsheim's soil medium) are drawn into it, followed by 2–4 cm of enrichment culture. There should be no air space between the sterile medium and the culture. The tip is then sealed in a flame, leaving a small air space at the tip of the capillary. The capillary is mounted horizontally on the stage of a microscope and observed at 100X. Because of its rapid motility, *S. volutans* will often be able to outdistance the contaminants and be the first to arrive in the distal portion of the sterile medium. (*S. volutans* will frequently form a band of cells that migrates along the capillary in response to a self-created oxygen gradient; however, the migration rate of such a band is relatively slow, and it is more fruitful to watch for faster-swimming cells well in advance of such a band.) As soon as some spirilla have entered the distal regions of the sterile medium, the capillary is broken behind them and sealed in a flame. After the outside of the capillary has been sterilized with strong hypochlorite solution, and the latter removed with sterile thiosulfate solution, the tip is broken and the spirilla are expelled into a suitable medium. The medium used by Rittenberg and Rittenberg (1962) and Wells and Krieg (1965) was sterile Pringsheim's soil medium contained in a dialysis sac which was suspended in a mixed culture of other bacteria; however, it seems likely that simply expelling the spirilla into a tube of semisolid MPSS or CHSS medium might be a satisfactory alternative. Purity of the cultures is verified by microscopic examination.

Maintenance Procedures

S. volutans may be maintained in semisolid MPSS or CHSS medium at 30°C with transfer every 4–5 days. Cultures may also be maintained in CHSS broth (incubated statically under an air atmosphere) at 30°C with daily transfer.

Preservation by lyophilization has not yet been possible, but cultures may be preserved indefinitely in liquid nitrogen (Pauley and Krieg, 1974). Cells from a broth culture are harvested at 3500 × g, washed once with sterile nutrient broth, and suspended to a dense concentration in nutrient broth containing 10% (v/v) DMSO. After incubation for 30 min to allow penetration of the cells by the cryoprotective agent, the suspension is dispensed into vials. After sealing, the vials are frozen in a mixture of dry ice and alcohol and stored by submersion in liquid nitrogen.

Procedures for Testing Special Characters

The characteristics listed in Table BXII.β.106 were determined by methods described by Hylemon et al. (1973a). These authors employed PSS broth (containing 1.0% peptone) rather than MPSS broth, but the latter medium is more satisfactory. Cultures in liquid media are incubated under an atmosphere containing 6% oxygen; this oxygen level is most easily obtained by exhausting the air from the culture vessel and refilling the vessel several times with a mixture of O_2/N_2 (6:94). An alternative procedure is to exhaust the air in the culture vessel until the pressure becomes 0.29 atm, then fill the vessel with N_2 to 1 atm. For certain biochemical tests such as phosphatase activity, the surface of plates of PSS (or MPSS) medium containing 0.7% agar is inoculated heavily (to give confluent growth) and the plates are incubated in a humid atmosphere under 6% O_2.

Differentiation of the genus *Spirillum* from other genera

Table BXII.β.107 lists the features that distinguish the genus *Spirillum* from other genera of chemoheterotrophic, microaerophilic, motile, curved bacteria.

The large size of the cells, the ease with which the flagellar fascicles can be seen by phase microscopy, and the microaerophilic nature of the organism, serve to differentiate the genus from chemotrophic freshwater spirilla in the genus *Aquaspirillum*. Inhibition of growth by NaCl differentiates the genus from members of *Oceanospirillum*.

The genus *Campylobacter* exhibits certain similarities to *Spirillum*, in that both genera contain cells with polar flagella and are microaerophilic, with a strictly respiratory type of metabolism.

Neither genus can catabolize carbohydrates. The DNA base composition is similar (32–35 mol% G + C for *C. fetus*; 38 mol% G + C for *S. volutans*). Moreover, campylobacters, although nominally vibrioid in shape, can often exhibit a spirillum-like appearance, and, like *S. volutans*, *Campylobacter* species have a polar membrane. Despite these similarities, there are marked differences between the two species: *S. volutans* has a much greater cell diameter, large bipolar tufts of flagella rather than a single flagellum at one or both poles, does not form coccoid bodies, and is not associated with animals or humans.

Distinctive morphological similarities exist between *S. volutans* and members of the phototrophic genus *Thiospirillum*. *Thiospirillum jenense* has flagellar fascicles which are remarkably similar to those of *S. volutans*, and both species have cells of large diameter. However, *T. jenense* is obligately phototrophic and anaerobic, and has a higher mol% G + C for its DNA (45%).

"Aquaspirillum voronezhense" has been described by Grabovich et al. (1987) and has a cell diameter of 1.5 × 3.0 µm and large flagellar fascicles with up to 50 flagella, as well as a number of other features similar to those of *S. volutans*; however, it is aerobic, catalase- and urease-positive, forms colonies on PSS medium under aerobic conditions, and has a mol% G + C of the DNA of 58–60.

Taxonomic Comments

At present, the genus *Spirillum* is represented by only a single species, *Spirillum volutans*, of which only two isolates are available. *S. volutans* is a member of the *Betaproteobacteria* and the family *Spirillaceae*, based on the *Bergey's Manual* revision of the RDP tree.

The two species *"Spirillum minus"* and *"Spirillum pulli"* do not belong to the genus *Spirillum* and are described under *Species Incertae Sedis*.

List of species of the genus Spirillum

1. **Spirillum volutans** Ehrenberg 1832, 38[AL]
vo' lu.tans. L. v. *voluto* to tumble about; L. part. adj. *volutans* tumbling about.

The morphological characteristics are as described for the genus, listed in Tables BXII.β.106 and BXII.β.107, and depicted in Figs. BXII.β.98 and BXII.β.99. Isolated from stagnant freshwater sources.

The mol% G + C of the DNA is: 38 (T_m) or 36 (Bd).
Type strain: ATCC 19554.
GenBank accession number (16S rRNA): M34131.
Additional Remarks: Reference strain ATCC 19553.

Other Organisms

1. *"Sporospirillum"* Delaporte 1964, 257.
spo.ro.spi.ril' lum. Gr. n. *sporos* a seed (spore); Gr. n. *spira* a spiral; M.L. dim. n. *spirillum* a small spiral; M.L. neut. n. *Sporospirillum* a small spore (-forming) spiral.

Rigid, helical bacteria of enormous size, 1.8–4.8 × 40–100 µm. Structures that morphologically resemble endospores occur within the cells, but their thermal resistance has not been determined. The sporelike structures have the ability to rotate and to migrate within the cytoplasm of the bacteria. They initially develop near the cell poles and later migrate to the center where they are released after the cell ruptures and disintegrates. The Gram reaction has not been reported. The cells are motile, but no organs of locomotion are evident. The relationship of the cells to oxygen is unknown. Occur in the intestinal contents of tadpoles. Have not been isolated. No type species designated.

a. *"Sporospirillum praeclarum"* (Collin 1913) Delaporte 1964, 259 (*Spirillum praeclarum* Collin 1913, 62.)
prae.cla' rum. L. adj. *praeclarum* distinguished, famous.

Cells 3.0–4.0 × 50–100 µm. Diameter of helix, 5–10 µm. Wavelength, 17–23 µm. A single endospore is present, 3–4 × 9–12 µm.

b. *"Sporospirillum gyrini"* Delaporte 1964, 259.
gy.ri' ni. L. n. *gyrinus* a tadpole; L. gen. n. *gyrini* of a tadpole.

Cells 1.8–2.6 × 40–100 µm. Diameter of helix 3–6 µm. Wavelength, 13–20 µm. A single endospore is present, 2 × 5–7 µm.

c. *"Sporospirillum bisporum"* Delaporte 1964, 260.
bi.spo' rum. L. adv. *bis* twice; G. n. *sporos* a seed; M.L. gen. pl. n. *bisporum* of two seeds (spores).

Cells 3.5–4.8 × 50–90 µm. Diameter of helix, 11–15 µm. Wavelength, 27–35 µm. At each pole an endospore occurs, 2–4 × 10–14 µm.

Species Incertae Sedis

1. **"Aquaspirillum voronezhense"** Grabovich, Churikova, Chernykh, Kononyhina and Popravko 1987, 666.
vo.ro.ne.zhen' se. M.L. adj. *voronezhense* pertaining to the town of Voronezh.

This species has cells that resemble *Spirillum volutans* in size but the mol% G + C of the DNA differs markedly. Consequently, the placement of this species is uncertain.

Helical cells 1.5–3.0 µm wide, with 1–3 turns per cell. Diameter of helix, 2.9–6.8 µm. Motile by means of bipolar flagellar fascicles, each fascicle being composed of up to 50 flagella. Gram negative. Poly-β-hydroxybutyrate and volutin are accumulated within the cells. S^0 is accumulated in the presence of sulfides. Colonies are flat and nonpigmented with a diameter of 1–4 mm. Aerobic. Optimal pH for growth, 7.2–8.5; pH range for growth, 6.0–9.0. No growth occurs in the presence of 3% NaCl. Optimal temperature for growth, 28°C. Chemoorganotrophic. Carbohydrates are not utilized. A wide range of organic acids, including acetate, succinate, malate, fumarate, benzoate, α-ketoglutarate, oxaloacetate, pyruvate, salicylate, lactate, and glyoxylate, can be utilized as carbon sources. Citrate, ethanol, glycerol, butanol, and mannitol are not utilized. Utilization of isocitrate, aconitate, oxalate, and formate differs among strains. Aspartate can be utilized as a carbon source; utilization of proline, tyrosine, histidine, glycine, glutamine, and valine differs among strains. Tryptophan, methionine, serine, lysine, phenylalanine, asparagine, cysteine, cystine, alanine, leucine, valine, arginine, and ornithine are not utilized. Vitamins are required. Sources of nitrogen used by the type strain include ammonium salts, casein hydrolysate, yeast extract, peptone, aspartate, glutamate, cysteine; utilization of serine differs among strains. Nitrate, nitrite, and methionine are not utilized. Starch, casein, and gelatin

TABLE BXII.β.106. Characteristics of *Spirillum volutans*

Characteristics	Reaction or Result
Cell diameter, μm[a]	1.4–1.7
Wavelength, μm[a]	16–28
Diameter of helix, μm[a]	5–8
Length of helix, μm[a]	14–60
Number of turns[a]	1–5
Intracellular poly-β-hydroxybutyrate granules present[a]	+
Coccoid bodies present in older cultures[a]	−
Bipolar tufts of flagella present[a]	+
Oxidase (moistened test disc inoculated with centrifuged cells)[a]	+
Catalase[b]	−[c]
Phosphatase (0.01% phenolphthalein diphosphate)[d]	+
Sulfatase (0.01% phenolphthalein disulfate)[d]	−
H_2S from 0.2% cysteine (detector strip)[a]	+
Liquefaction of 12% gelatin[a]	−
Hydrolysis of casein (single-strength milk)[d]	−
Hydrolysis of esculin[a]	−
Hydrolysis of 0.1% DNA or RNA (clear zone after acidification)[d]	−
Indole production from 0.1% tryptophan[a]	−
Hydrolysis of 10% soluble starch[d]	−
Aerobic reduction of 0.1% KNO_3[a]	−
Aerobic reduction of 0.1% H_2SeO_2 (by pink color)[a]	−
Visible growth with 1% bile or 1% glycine[a]	−
Anaerobic growth with 0.1% KNO_3 (sealed with petrolatum)[b]	−
Acid reaction from carbohydrates (38 compounds tested)[e]	−
Urease[f]	−
Mol% G + C of DNA (T_m)	38

[a]Basal medium is PSS broth.

[b]Basal medium is PSS broth + 0.15% agar.

[c]When a few drops of 3% H_2O_2 are added, a few bubbles of oxygen form after 30-min incubation. However, this reaction is probably attributable to the alkalinity of the cultures rather than to catalase activity.

[d]Basal medium is PSS broth + 0.7% agar.

[e]Basal medium is PSS broth lacking succinate and with peptone decreased to 0.2%; 0.0018% phenol red indicator added.

[f]Cells suspended in distilled water to a dense, milky concentration; 0.5 ml added to 2.0 ml of the following medium: BES buffer, 0.1065%; urea, 2.0%; phenol red, 0.001%; pH 7.0. Controls without urea are used. The test is incubated for 24 h.

are not hydrolyzed. Nitrates are not reduced to nitrites. Anaerobic growth does not occur with nitrate, sulfate, thiosulfate, or fumarate as terminal electron acceptors. Catalase, oxidase, and urease positive. Indole negative. H_2S is formed from cysteine. Colored products are formed in media containing benzoate. Source of isolates: sludge in a purification system air tank for the treatment of domestic sewage.

The mol% G + C of the DNA is: 58.5–60.0 (method unknown).

Deposited strain: D-419.

Additional Remarks: Reference strain D-420.

2. **"Spirillum minus"** Carter 1888, 47 (*Spirillum minor* (sic) Carter 1888, 47.)

mi′ nus. L. neut. adj. *minus* less, smaller.

"Spirillum minus" and *"Spirillum pulli"* (below) do not belong to the genera *Aquaspirillum*, *Oceanospirillum*, or *Spirillum*, and their placement is uncertain. Studies of these species have been hampered by lack of reproducible *in vitro* cultivation methods. They do not appear on the *Approved Lists of Bacterial Names* because no type or reference strains are available, and the organisms are not well characterized. The disease syndromes caused by these species are distinct and recognizable, however. If possible, neotype strains should be designated and either maintained by animal passage or preserved in a recognized culture collection.

Rigid cells; usually described as spiral with two or three turns, although the waves have been reported to be planar (McDermott, 1928). The ends of the cell may be blunt or pointed. Cell size ~0.2 × 3–5 μm; wavelength, 0.8–1.0 μm. Actively motile by one or more flagella at each pole.

Causes one of the two forms of rat-bite fever in man. The disease caused by *"S. minus"* is often termed "Sodoku"; it occurs worldwide but has its greatest frequency in the Far East. The organisms are usually transmitted to humans through the bite of an infected rat, although mice, squirrels and rodent-ingesting animals such as cats, dogs, ferrets, and weasels have also been implicated. *"S. minus"* appears to be a natural parasite of rats, which act as carriers; the infection is usually not lethal in rats. The natural infection frequency for rats varies from country to country but may be as high as 25% (see Babudieri, 1973, for pertinent literature).

The clinical aspects of rat-bite fever and the distinctions between the form caused by *"S. minus"* and that caused by *Streptobacillus moniliformis* have been summarized by Joklik et al. (1980) and by Rogosa (1980). Experimental infections of humans and animals by *"S. minus"* have been described by Babudieri (1973).

"S. minus" is best observed in blood or exudates from patients by dark-field or phase-contrast microscopy of wet mounts; staining with Giemsa or Wright's stain or by silver impregnation is also useful.

"S. minus" is cultured *in vivo* by intraperitoneal inoculation of patients' blood or exudates from lesions, or blood from naturally infected rats, into spirillum-free mice or guinea pigs (Rogosa, 1980); mice are the animals most susceptible to *"S. minus"* infection (Babudieri, 1973). It is questionable whether the organism has ever been cultured successfully in artificial media. Numerous attempts have failed, and various claims of successful cultivation have been unable to be confirmed. One report that may indicate successful cultivation is that of Hitzig and Liebesman (1944), who inoculated blood from a patient into 2% dextrose–veal infusion broth and into 10% tomato extract–veal infusion broth. The addition of citrated human or rabbit blood was required for successful subculturing; also, the organisms initially required incubation in a candle jar but eventually were able to grow aerobically after five months of serial transfer. Confirmation of this report is needed. Considering the morphology, pathogenicity, and sources of *"S. minus"*, serious attention should be given to the possibility that the organism might belong to, or be related to, the genus *Campylobacter*, and the microaerophilic techniques employed for campylobacters might also prove useful for *"S. minus"*.

Deposited strain: none.

3. **"Spirillum pulli"** Mathey 1956, 745.

pul′ li. L. gen. n. *pulli* of a young chicken.

Rigid spiral cells. By dark-field microscopy, the cell size is ~1 × 5–12 μm. Actively motile by means of a single flagellum at each end of the cell.

Believed to be the cause of a diphtheroid stomatitis in the mouths of adult chickens. The lesions are yellowish

TABLE BXII.β.107. Differential features of the genus *Spirillum* and other chemoheterotrophic, motile, aerobic or microaerophilic, Gram-negative vibrioid or helical bacteria[a]

[a]Symbols: +, all species positive except where noted; –, all species negative except where noted; D, differs among species.

[b]*A. delicatum* is mainly vibrioid.

[c]Some cells in *Azospirillum* cultures are straight rods.

[d]Chains of *Campylobacter* cells may have a helical appearance. *Campylobacter rectus*, *Campylobacter showae*, and *Campylobacter gracilis* are straight rods.

[e]*H. trogontum* and *H. bilis* are fusiform straight rods. *H. bizzozeronii* and *H. felis* cells are long helices. *H. cholecystus* cells are coccoid to short curved rods.

[f]Some cells in cultures of *Herbaspirillum* are helical.

[g]All wild-type strains of *Bdellovibrio* upon initial isolation are dependent on intraperiplasmic growth in susceptible bacterial prey. Mutants capable of axenic growth (prey-independent strains) have been derived from the predacious strains, and some strains are facultative, i.e., capable of growth in the presence or absence of prey cells.

[h]*A. delicatum* has mainly a single flagellum at one pole; *A. polymorphum* has mainly a single flagellum at each pole; and *A. arcticum* has a single polar flagellum.

[i]*Campylobacter gracilis* is nonmotile.

[j]*H. cinaedi*, *H. fennelliae*, *H. hepaticus*, *H. pametensis*, *H. pullorum*, and *H. rodentium* have a single flagellum at one of both poles.

[k]*H. pullorum* and *H. rodentium* do not have sheathed flagella.

[l]Especially (or in the case of azospirilla, only) when cells are grown on solid media.

[m]*H. mustelae* is reported to have multiple lateral flagella in addition to polar flagella.

[n]*A. arcticum* is positive.

[o]*A. nitrofigilis* requires Na^+. Marine bdellovibrios require Na^+.

[p]*A. peregrinum* and some strains of *A. itersonii* have nitrogenase activity. *C. nitrofigilis* has nitrogenase activity.

[q]*Arcobacter* species can grow aerobically but may be microaerophilic on primary isolation. *A. nitrofigilis* can grow aerobically on complex media such as *Brucella* agar.

[r]*A. gracile*, *A. itersonii*, *A. peregrinum*, and *A. arcticum* can catabolize a very restricted variety of sugars.

[s]*A. gracile* can produce acid from glucose aerobically. *A. itersonii* can produce acid from glucose anaerobically but not aerobically. *A. arcticum* can grow on glucose, fructose, and ribose but not on other carbohydrates.

[t]Some strains of *C. lari* are urease positive.

[u]*H. cinaedi* and *H. fennelliae* are urease negative.

[v]*C. nitrofigilis* occurs in the roots of salt-marsh grasses.

[w]*A. arcticum* occurs in arctic sediments.

[x]"*Sporospirillum*" spp. are motile but no organelles of locomotion have been observed.

[y]*O. pusillum* has mainly a single flagellum at each pole.

[z]Although *Wolinella succinogenes* has been regarded as anaerobic, it is in fact a microaerophile. It is capable of respiring with oxygen when it is provided at low concentrations and cannot grow under an air atmosphere. It can also grow anaerobically by using fumarate, polysulfide, or S^0 as a terminal electron acceptor for anaerobic respiration. For further information see Wolin et al. (1961) and Ringel et al. (1996).

[aa]Occurs in sewage waters.

[a]Symbols: +, all species positive except where noted; −, all species negative except where noted; D, differs among species.

[b]*A. delicatum* is mainly vibrioid.

[c]Some cells in *Azospirillum* cultures are straight rods.

[d]Chains of *Campylobacter* cells may have a helical appearance. *Campylobacter rectus*, *Campylobacter showae*, and *Campylobacter gracilis* are straight rods.

[e]*H. trogontum* and *H. bilis* are fusiform straight rods. *H. bizzozeronii* and *H. felis* cells are long helices. *H. cholecystus* cells are coccoid to short curved rods.

[f]Some cells in cultures of *Herbaspirillum* are helical.

[g]All wild-type strains of *Bdellovibrio* upon initial isolation are dependent on intraperiplasmic growth in susceptible bacterial prey. Mutants capable of axenic growth (prey-independent strains) have been derived from the predacious strains, and some strains are facultative, i.e., capable of growth in the presence or absence of prey cells.

[h]*A. delicatum* has mainly a single flagellum at one pole; *A. polymorphum* has mainly a single flagellum at each pole; and *A. arcticum* has a single polar flagellum.

[i]*Campylobacter gracilis* is nonmotile.

[j]*H. cinaedi*, *H. fennelliae*, *H. hepaticus*, *H. pametensis*, *H. pullorum*, and *H. rodentium* have a single flagellum at one of both poles.

[k]*H. pullorum* and *H. rodentium* do not have sheathed flagella.

[l]Especially (or in the case of azospirilla, only) when cells are grown on solid media.

[m]*H. mustelae* is reported to have multiple lateral flagella in addition to polar flagella.

[n]*A. arcticum* is positive.

[o]*A. nitrofigilis* requires Na^+. Marine bdellovibrios require Na^+.

[p]*A. peregrinum* and some strains of *A. itersonii* have nitrogenase activity. *C. nitrofigilis* has nitrogenase activity.

[q]*Arcobacter* species can grow aerobically but may be microaerophilic on primary isolation. *A. nitrofigilis* can grow aerobically on complex media such as *Brucella* agar.

[r]*A. gracile*, *A. itersonii*, *A. peregrinum*, and *A. arcticum* can catabolize a very restricted variety of sugars.

[s]*A. gracile* can produce acid from glucose aerobically. *A. itersonii* can produce acid from glucose anaerobically but not aerobically. *A. arcticum* can grow on glucose, fructose, and ribose but not on other carbohydrates.

[t]Some strains of *C. lari* are urease positive.

[u]*H. cinaedi* and *H. fennelliae* are urease negative.

[v]*C. nitrofigilis* occurs in the roots of salt-marsh grasses.

[w]*A. arcticum* occurs in arctic sediments.

[x]"*Sporospirillum*" spp. are motile but no organelles of locomotion have been observed.

[y]*O. pusillum* has mainly a single flagellum at each pole.

[z]Although *Wolinella succinogenes* has been regarded as anaerobic, it is in fact a microaerophile. It is capable of respiring with oxygen when it is provided at low concentrations and cannot grow under an air atmosphere. It can also grow anaerobically by using fumarate, polysulfide, or S^0 as a terminal electron acceptor for anaerobic respiration. For further information see Wolin et al. (1961) and Ringel et al. (1996).

[aa]Occurs in sewage waters.

white, rather firm, and adherent to the underlying tissue; often they are symmetrical ovoids, one at each side of the lower jaw. Lesions also occur on the palate, the lower surface of the tongue, on the floor of the mouth, between the larynx and the transverse row of papillae on the tongue, around the larynx, and on the walls of the pharynx. The lesions vary in size from approximately 2 to 20 mm.

Attempts to culture *"S. pulli"* in artificial media have been unsuccessful. Experimental passage of the disease in chickens has been accomplished by contact and by experimental inoculation.

Deposited strain: none.

Family III. **Gallionellaceae** Henrici and Johnson 1935b, 4[AL]

George M. Garrity, Julia A. Bell and Timothy Lilburn

Gal.li.o.nel.la' ce.ae. M.L. fem. n. *Gallionella* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Gallionellaceae* the *Gallionella* family.

The family *Gallionellaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genus *Gallionella* (type genus).

Description is the same as for the genus *Gallionella*.

Type genus: **Gallionella** Ehrenberg 1838, 166.

Genus I. **Gallionella** *Ehrenberg 1838, 166*[AL]

Lotta E-L. Hallbeck and Karsten Pedersen

Gal.li.o.nel' la. M.L. dim. ending *-ella* ; M.L. fem. n. *Gallionella* named for B. Gaillon, a customs agent and zoologist (1782–1839) in Dieppe, France.

Gram-negative, **bean-shaped cells**, usually 0.5–0.8 × 1.6–2.5 µm, that secrete an extracellular **twisted stalk** from the concave side, 0.3–0.5 µm in width and up to 400 µm or more in length. The stalk is composed of numerous 2 nm-wide fibers and is produced under microaerophilic conditions when cells are in late exponential or stationary growth phase. Motile by means of a polar flagellum. **Microaerophilic**; **chemolithotrophic growth** can be obtained *in vitro* using oxygen and ferrous iron concentration gradients in a salt medium with **CO_2 as sole carbon source** (Table BXII.β.108). **Mixotrophic metabolism** has been demonstrated with glucose, fructose, and sucrose. Can be found where anaerobic **groundwater with ferrous iron** reaches an oxygen-containing environment. Belongs to the ***Betaproteobacteria***, family *Gallionellaceae*, with one known species, *G. ferruginea*. Most closely related species according to 16S rDNA sequence analysis is the chemolithotroph *Nitrosospira multiformis*, distantly related with a 16S rDNA sequence similarity of 90%.

The mol% G + C of the DNA is: 51–54.6 (Hanert, 1989).

Type species: **Gallionella ferruginea** Ehrenberg 1838, 166.

Further descriptive information

The 16S rRNA gene of *Gallionella ferruginea* (strain Johan) has been sequenced between base numbers 47 and 1405 (*E. coli* numbering) (Hallbeck et al., 1993). Phylogenetic analysis of these sequence data placed *Gallionella* among the *Betaproteobacteria*. *G. ferruginea* is distant from other species in the tree, with a 10% sequence difference compared to the closest species, the chemolithotroph *Nitrosospira multiformis*. The remote position of *G. ferruginea* in relation to other species and its utilization of iron as energy source and electron donor compared to ammonia for the closest gene cluster, *Nitrosomonadaceae*, indicate that a separate family, *Gallionellaceae*, is justified. There is only one named species at this time. The capacity for chemolithotrophic iron oxidation among bacteria has been suggested to be evolutionarily widespread (Lane et al., 1992). This is supported by, for instance, the phylogenetic distance (85% 16S rRNA gene sequence similarity) between *Gallionella* and the iron-oxidizing genus *Thiobacillus*.

The size, shape, and ultrastructure of *Gallionella* are illustrated in Figs. BXII.β.99, BXII.β.100, BXII.β.101, and BXII.β.102. Cells are curved, bean-shaped, and may have a polar flagellum (Fig. BXII.β.99). A twisted extracellular stalk is secreted from the concave side of the cell (Figs. BXII.β.100 and BXII.β.101A). It consists of numerous 2 nm-wide fibers at the point of excretion (Vatter and Wolfe, 1956). The stalk becomes continuously encrusted with precipitated ferric iron oxide (Fig. BXII.β.101B), which may totally cover old stalks. The composition of the stalk has not been conclusively demonstrated, but inorganic as well as organic compositions have been suggested. Hanert (1989) proposed the stalk to consist of colloidal ferric hydroxide, based on its disappearance in 0.12% sodium thioglycolate. Hallbeck and Pedersen (1995) found a higher carbon-to-nitrogen ratio (C/N 6.8) in stalk-forming cultures compared to a non-stalk-forming culture (C/N = 4.3), and concluded the stalk to be composed of an extracellular carbon skeleton without a dominating protein component. The cell wall is Gram-negative (Fig. BXII.β.102D–E).

Two strains of *Gallionella* have been described (Table BXII.β.109). Strain BD from a drainpipe in Braunschweig was described by Hanert (1989) and strain Johan from a 60 m-deep drinking water well was described by Hallbeck and Pedersen (1990, 1991, 1995) and Hallbeck et al. (1993). Strain BD was reported to have intracytoplasmic membranes (Hanert, 1989) while strain Johan does not (Fig. BXII.β.102). The isolation procedure for *Gallionella* is by serial dilution and therefore the possibility of contaminants in the cultures cannot be conclusively excluded. Serial thin sectioning should show a stalk connected to the sectioned cell, as in Figure BXII.β.102A–C, to confirm it to be a cell of *Gallionella*. Inclusions that might be poly-β-hydroxybutyrate have been noted but apart from this, strain Johan does not show any specific intracellular fine structures (Fig. BXII.β.102D–E).

Gallionella can be cultured *in vitro* in screw-capped test tubes using oxygen and ferrous iron concentration gradients in a salt medium with carbon dioxide as sole carbon source (Fig. BXII.β.103). Solid-phase ferrous iron is placed on the bottom of the tube in a fresh, autoclaved, and oxygen-free salt medium. With this procedure, the concentration of ferrous iron will decrease from the bottom to the top of the tube as it dissolves and diffuses away from the solid phase. Oxygen will decrease in concentration from the top of the tube downwards as it diffuses into the salt medium from the air above the medium. The optimal growth temperature is 17–20°C and temperatures above 25–30°C are lethal. Iron sulfide or iron carbonate can be used as a source of ferrous iron. The culture grows to a maximum of 5×10^6 cells/ml culture (Fig. BXII.β.101C), which makes many traditional techniques for strain characterization impossible. Strain BD develops small, circular, colonies attached to the wall of the tube, 3–5 d after inoculation. Strain Johan predominantly forms a ring at a specific level in the concentration gradient. The cells of strain Johan colonize as new rings from upper levels in the tube as the culture gets old, i.e., 10 days or more. Eventually, most of the tube will be filled by a brittle mass of stalks, iron oxides, and cells. Hallbeck and Pedersen (1990) have demonstrated that *Gallionella* strain Johan is free living *in vitro* in its exponential growth phase and does not produce stalks until late exponential and stationary phases. The generation time at optimal temperature for strain Johan is 8.3 h. Stalk production continues for many days in stationary phase. Some cell division may still occur but not at the growth rate observed during the first 4–5 d after inoculation. The maximum mean stalk length per cell of strain Johan has been determined to be 60 μm in a 16-day-old culture. Individual cells may produce much longer stalks; 400 μm has been reported for a single cell of strain BD. With prolonged subculturing on iron carbonate as energy source, some of the *Gallionella* strain Johan cultures were found to have irreversibly lost their ability to form a stalk (Hallbeck et al., 1993). Their identity was confirmed by 16S rRNA gene sequencing. They still form a ring of oxidized iron as the stalk-forming variant does, but the ring is very thin.

Gallionella is chemolithotrophic with ferrous iron as energy source and electron donor and with carbon dioxide as sole carbon source. CO_2 fixation by strain Johan was revealed using hydrogen [^{14}C]-carbonate (Hallbeck and Pedersen, 1991), while *in vivo* activity of the Calvin cycle key enzyme, ribulose bisphosphate-carboxylase, has been reported for strain BD (Hanert, 1989). Mixotrophic metabolism has been shown on glucose, fructose, and sucrose. Growth did not occur on these sugars without ferrous iron and carbon dioxide. Ammonium and nitrate can be used as nitrogen sources; the capacity for nitrogen fixation is unknown.

The environment where stalk-forming *Gallionella* can be found, commonly attached to surfaces, is slowly flowing groundwater that is rich in ferrous iron but has a low organic carbon content. Typical places to search for *Gallionella* are in drainpipes, storage basins for groundwater from deep wells, in tunnels, and on rock walls with seeping groundwater. A common feature of these environments is that cold (below 20°C), reduced, anaerobic, and ferrous-iron-bearing groundwater reaches an oxygen-containing atmosphere. Such environments are suitable for chemolithotrophic growth with ferrous iron as energy source and electron donor, and oxygen as electron acceptor. A slow flow, supplying ferrous iron and possibly carbonate from the groundwater to the attached cells, seems to be an absolute prerequisite for growth of *Gallionella.* In this situation, the stalk may act as a holdfast and prevent the cells from being washed out to a more oxidized environment without ferrous iron.

Hallbeck and Pedersen (1995) have demonstrated an additional function for the stalk. The iron oxidation that occurs in a typical *Gallionella* environment can be differentiated into two

(continued)

parts: a) The respiratory iron oxidation performed by the cells in their energy metabolism and b) the nonmetabolic iron oxidation induced by the increasing oxygen tension as the anoxic groundwater reaches the atmosphere. Ferrous iron reacting with oxygen participates in a chain of reactions yielding highly reactive oxygen such as perhydroxyl (HO_2), hydrogen peroxide (H_2O_2), and the hydroxyl radical (HO) (Stumm and Morgan, 1996). The survival of stalk-forming *Gallionella* strain Johan (Sta$^+$) in media with low and high potential for oxygen radical formation was compared with a variant of strain Johan that irreversibly lost the ability to form a stalk (Sta$^-$) (Hallbeck and Pedersen, 1995). It was found that *Gallionella* Sta$^+$ survived longer (9 weeks) than Sta$^-$ (6 weeks) in cultures with a high potential for oxygen radical formation. It was therefore suggested that the stalk of *Gallionella* protects the cells against the toxic oxygen species discussed above, by directing the oxidation of iron to the stalk. This phe-

TABLE BXII.β.108. Characteristics for identification of the genus *Gallionella*

Characteristic	*Gallionella*
Cell morphology	Bean shaped
Cell dimension, µm	0.5–0.8 × 0.8–2.5
Produce an extracellular twisted stalk composed of numerous 2 nm-wide fibers	+
Grows with CO_2 as sole carbon source	+
Grows with ferrous iron as energy source	+
Temperature range (°C)	5–25
Optimal temperature (°C)	17–20
pH range	5.0–6.5
Motile	+

nomenon could be compared to the action of the protein ferritin, proposed to perform iron oxidation in both procaryotic and eucaryotic cells (Artymiuk et al., 1991). It is not known whether the iron oxidation on the stalk is enzymatic or the stalk acts as a surface catalyst for the oxidation reaction. Thus, the stalk acts as a holdfast that allows *Gallionella* to colonize and survive in an ecological niche, with high ferrous iron content and some oxygen, that is unavailable for bacteria without a defense system against the oxygen radicals formed during inorganic oxidation of ferrous iron.

Enrichment and Isolation Procedures

Various media for enrichment and cultivation of *Gallionella* have been tested. To create proper growth conditions, ferrous iron and CO_2 must be in the medium. Lieske (1911) designed a culture medium composed of carbonic water and metallic iron. The use of iron sulfide as a source of reduced iron was first suggested by Van Niel (Vatter and Wolfe, 1956). Kucera and Wolfe (1957) published a growth medium composed of a salt solution and iron sulfide, which made it possible to obtain pure cultures of *Gallionella*. The salt solution was initially prepared with tap water, because the medium lacked a crucial component. This component was later found to be calcium. Since then the ferrous iron medium has been widely used with some minor modifications.

TABLE BXII.β.109. Differential characteristics of *Gallionella ferruginea* strains Johan and BD

Characteristic	*Gallionella ferruginea* strain Johan	*Gallionella ferruginea* strain BD
Cells bean-shaped	+	+
Cell dimensions (μm)	0.5–0.8 × 1.6–2.5	0.5–0.7 × 0.8–1.8
Temperature range for growth (°C)	5–25	nd
Optimal temperature (°C)	20	17
pH range for exponential growth	5.0–6.5	nd
Generation time in exponential growth	8.3 h	nd
Motility without stalks	+	+
Motility with stalks	−	−
Stalks not produced in exponential growth phases	+	nd
Length of stalks (μm)	average 60/cell	up to 400/cell
Maximum cell number in *in vitro* culture (cells/ml)	5×10^6	nd
Colony form *in vitro*	Ring on the tube wall	Circular colonies
Growth with CO_2 as sole carbon source	+	+
Growth with ferrous iron as sole energy source	+	+

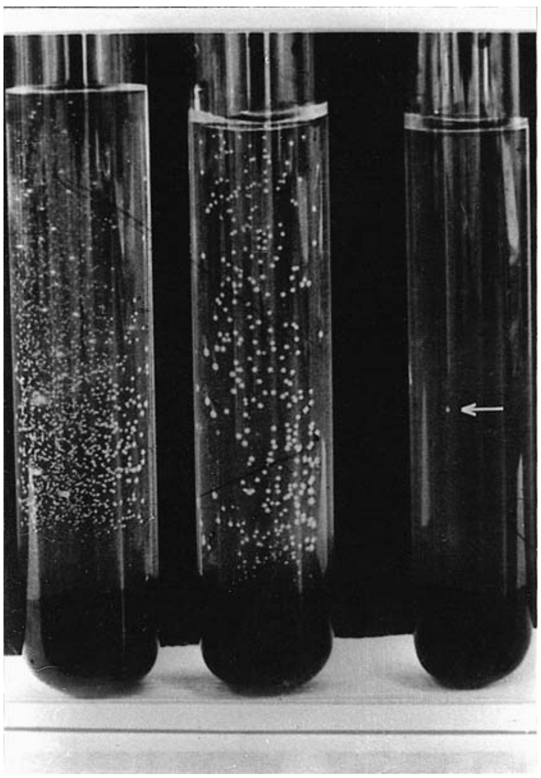

FIGURE BXII.β.103. Isolation procedure for *G. ferruginea* strain BD (*arrow*, one-colony culture). (Reproduced with permission from H.H. Hanert, Archives of Microbiology *60:* 348–376, 1968, ©Springer-Verlag, Berlin.)

Wolfe's modified medium is made as follows: Screw-capped tubes (180 × 16 mm) are filled with 10 ml salt medium consisting of 1.0 g NH_4Cl, 0.4 g $MgSO_4 \cdot 7H_2O$, 0.1 g $CaCl_2 \cdot 2H_2O$, 0.05 g K_2HPO_4 and 1 liter double-distilled water. The salt medium is autoclaved, chilled to 5°C and infused with sterile filtered CO_2 to pH 4.6–4.8. A ferrous sulfide or ferrous carbonate precipitate (0.5 ml) is added slowly to the bottom of the tubes with a Pasteur pipette and the tubes are left for four to six hours to allow gradient conditions to establish before inoculation. The ferrous sulfide and ferrous carbonate have to be prepared in the laboratory. Ferrous sulfide is prepared by dissolving 7.8 g $FeSO_4(N_6H_4)_2SO_4$ (Mohr's salt) and 4.8 g sodium sulfide separately, each in 200 ml boiling, distilled water and subsequently pouring the ferrous solution into the sulfide solution. Use two 500 ml beakers, mix with a glass rod. Fill the beaker up to the top and seal with a rubber stopper to avoid oxidation of the ferrous iron. Let the iron sulfide sediment for at least four hours. Decant and wash with boiling water five times. Centrifuge at high velocity, collect the iron sulfide in small bottles, fill up with water and close with an airtight lid. Sterilize at 121°C for 20 min. Store cool in airtight vials. Ferrous carbonate is prepared by dissolving 3.9 g $FeSO_4(NH_4)_2SO_4$ and 1.0 g anhydrous Na_2CO_3 separately, each in 100 ml boiling distilled water, and subsequently pouring the carbonate solution into the ferrous solution, preferably under a nitrogen atmosphere. The precipitated ferrous carbonate is then washed five times with boiling double-distilled water and sterilized in closed vials at 121°C for 20 min. Store cool in airtight vials. It is recommended that all solutions used for preparation of the medium and source of ferrous iron are filter sterilized (0.2 μm) to remove any cells or particles that may give a background during microscopic counts.

Isolation by serial dilution and serial transfer has been applied successfully to *Gallionella* strains BD and Johan (Fig. BXII.β.103). For strain BD, an enrichment test tube with colonies attached to the wall of the test tube is washed several times (Hanert, 1989). One colony is subsequently suspended in 10 ml fresh sterile medium and inoculated into new test tubes with Wolfe's modified medium at dilutions of maximally 10^{-6} (30–50 parallel cultures starting with a 10^{-4} serial dilution). Five to ten serial transfers, each starting from one colony, are necessary to achieve pure cultures in this manner. This procedure requires up to 10 weeks but is a very certain method for continually reducing the number of contaminants and obtaining a pure culture. Purity is checked microscopically and by use of a variety of heterotrophic and autotrophic media i.e., yeast extract bouillon, nutrient agar, *Nitrosomonas* medium, and *Thiobacillus ferrooxidans* medium. Stalk material of strain Johan can be collected, suspended in new medium, diluted and inoculated according to the strain BD procedure.

Maintenance Procedures

Maintaining pure stock cultures of *Gallionella* strain BD and Johan over the past years was performed using the described culture conditions with serial dilution transfers every four to eight weeks. Preservation of *Gallionella* culture material for at least 13 weeks by freezing at −80°C in 15% glycerol has been reported

by Nunley and Krieg (1968). This procedure, however, did not result in survival of strain Johan.

Taxonomic Comments

The genus *Gallionella* is characterized by its chemolithotrophic growth with ferrous iron, and its production of a twisted stalk consisting of a bundle of numerous fibers that makes *Gallionella* very easy to identify. *Gallionella* has been described under several different names such as *Spirophyllum ferrugineum* (Ehrenberg, 1836; Adler, 1904), *Didymohelix ferrugineum* (Griffith, 1853), *Gloeosphaera ferruginea* (Rabenhorst, 1854), and *Gallionella filamenta* (Balashova, 1967a, b). Most, if not all, of the attempts to categorize species of the genus *Gallionella* under various names arise from observed differences in the appearance of the stalk. The current phylogenetic position of the family *Gallionellaceae* is based on only a single 16S rRNA gene sequence of *Gallionella.*

More than 160 years ago, in 1836, Ehrenberg first discovered the stalks of *Gallionella* when he studied ochre masses. In this description (Ehrenberg, 1836), *Gallionella* was referred to as a fossil infusorian and he called it "die Eisenochertierchen", the small iron ochre animal. Haeckel (1866) presented a phylogenetic tree that for the first time included the kingdom *Monera* for unicellular organisms and Zopf (1879) first included *Gallionella* with the *Bacteria. Gallionella* has been observed and described by many more scientists since these early days, and there has been continuous discussion about its morphology and physiology, but most studies have focused on the stalks. Beger and Bringmann (1953) and van Iterson (1958) have summarized the first 100 years of discussion about the intriguing characteristics of *Gallionella.* Winogradsky (1888, 1922) proposed an autolithotrophic life for the so-called "iron bacteria", including *Gallionella.* He mentioned *Leptothrix, Cladothrix,* and *Gallionella* as examples of lithotrophic iron bacteria. Adler (1904) found only small amounts of *Gallionella* in fresh water from Karlspader, but when the water was left in bottles for several days they "ausserordentlich stark vermehrt" i.e., they had grown, or more correctly, the stalks had become elongated. Lieske (1911) succeeded in the cultivation of *Gallionella* in carbonic water with metallic iron as ferrous iron source. In 1924–1929, Cholodny made microscopic studies on cover slips that he had submerged in habitats of *Gallionella* (Cholodny, 1924, 1929). He sketched admirable pictures of cells attached to the end of stalks, and he showed that the stalk was excreted by the cell and was not a living part of it. Teichmann (1935) made cultures according to Lieske (1911) and found a great number of bean-shaped cells in the fluid. This observation influenced Pringsheim (1949b) to suggest that "It is not impossible that motile cells are formed under certain conditions", a conclusion in accordance with current knowledge of free-living cells in exponential growth phase. Beger and Bringmann (1953) made comparisons between earlier drawings of the stalk of *Gallionella* and their own electron microscopy studies and proposed that the genus *Gallionella* consisted of five species. Vatter and Wolfe (1956) presented electron microscopy images of cells with stalks and in 1957, Kucera and Wolfe (1957) introduced an excellent growth medium containing iron sulfide as the source of ferrous iron. Wolfe could have succeeded in working with *Gallionella* but he concluded that "these organisms (iron bacteria) are too difficult to be profitable" (Wolfe, 1964). In 1958, a thesis on *Gallionella* was presented by van Iterson (1958). Excellent electron microscopy images of the organism were presented and it was suggested that the stalk was a living part of the organism with sporangia in the form of membrane sacs on the stalk. Balashova (1967a,b, 1968) and Balashova and Cherni (1970) made electron microscopy observations of the stalk and concluded that the stalk might have zoogloeal forms and budding cells on the stalks. Hanert (1989) made detailed studies on stalk elongation using single cells and measurements of iron oxidation in both natural samples and lab cultures. Intracytoplasmic membranes and evidence for autotrophic growth was presented. In 1990, Lütters-Czekalla (1990) reported growth of *Gallionella* BD with reduced sulfur compounds as electron donor instead of ferrous iron. This observation remains to be confirmed. In 1990–1995 Hallbeck and Pedersen (1990, 1991, 1995) and Hallbeck et al. (1993) reported the 16S rDNA sequence of *Gallionella* and showed that *Gallionella* has a free-living stage without a stalk in exponential growth phase. They demonstrated chemolithotrophic growth with CO_2 as the sole carbon source and mixotrophic metabolism. They also demonstrated an organic composition of the stalk and found that the stalk was important for survival in the environments where *Gallionella* is found. A thesis summarizing these results was published in 1993 (see further reading).

Acknowledgments

We are grateful to Professor W.G. Ghiorse for many valuable discussions about *Gallionella* and its life style and to Professor Grant Ferris for valuable comments on the manuscript. Our work with *Gallionella* was supported by the Swedish Natural Science Research Council.

Hallbeck, L. 1993. On the biology of the iron-oxidizing and stalk-forming bacterium *Gallionella ferruginea*, Thesis, Göteborg University, Göteborg Sweden.

List of species of the genus Gallionella

1. **Gallionella ferruginea** Ehrenberg 1838, 166[AL]

fer.ru.gi' ne.a. L. fem. adj. *ferruginea* rust-colored.

Morphology and description the same as those of the genus. Organisms occur in groundwater habitats, especially in places where iron-bearing groundwater reaches an oxygen-containing environment. Microaerophilic, possibly facultatively anaerobic, chemolithotrophic, and mixotrophic. Gram negative. G + C buoyant density was calculated by using a micromethod with novel collimating optics (Hanert 1989). (*E. coli* B was used as a reference.)

The mol% G + C of the DNA is: 51–54.6. (Bd).

Type strain: no culture isolated.

GenBank accession number (16S rRNA): L07897.

Order VI. **Rhodocyclales** *ord. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Rho.do.cy.cla′ les. M.L. masc. n. *Rhodocyclus* type genus of the order; *-ales* suffix to denote order; M.L. fem. n. *Rhodocyclales* the *Rhodocyclus* order.

The order *Rhodocyclales* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the order contains the family *Rhodocyclaceae*.

Description is the same as for the family *Rhodocyclaceae*.

Type genus: **Rhodocyclus** Pfennig 1978, 285.

Family I. **Rhodocyclaceae** *fam. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Rho.do.cy.cla′ ce.ae. M.L. masc. n. *Rhodocyclus* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Rhodocyclaceae* the *Rhodocyclus* family.

The family *Rhodocyclaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Rhodocyclus* (type genus), *Azoarcus*, *Azonexus*, *Azospira*, *Azovibrio*, *Dechloromonas*, *Dechlorosoma*, *Ferribacterium*, *Propionibacter*, *Propionivibrio*, *Quadricoccus*, *Sterolibacterium*, *Thauera*, and *Zoogloea*. *Quadricoccus* and *Sterolibacterium* were proposed after the cut-off date for inclusion in this volume (June 30, 2001) and are not described here (see Maszenan et al., 2002, and Tarlera and Denner, 2003).

Family is phenotypically, metabolically, and ecologically diverse. Includes photoheterotrophs; aerobes, anaerobes, and facultative anaerobes utilizing a number of electron acceptors; fermentative organisms; and nitrogen-fixing organisms.

Type genus: **Rhodocyclus** Pfennig 1978, 285.

Genus I. **Rhodocyclus** *Pfennig 1978, 285[AL]*

JOHANNES F. IMHOFF

Rho.do.cy′ clus. Gr. n. *rhodon* the rose; Gr. n. *cyclos* a circle; M.L. masc. n. *Rhodocyclus* red circle.

Cells are slender, curved, or straight, thin rods. Motile by means of polar flagella or nonmotile. Multiply by binary fission. **Gram negative, belonging to class *Betaproteobacteria*.** Internal photosynthetic membranes may appear as small, single, finger-like intrusions of the cytoplasmic membrane or may be absent. **Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids. Contain ubiquinones and menaquinones with eight isoprene units (Q-8 and MK-8). Straight-chain $C_{16:1}$ and $C_{16:0}$ acids are the major components of cellular fatty acids. $C_{10:0\ 3OH}$ is present.**

Preferably grow photoheterotrophically under anoxic conditions in the light with different organic substrates as carbon and electron sources. **Photoautotrophic growth with molecular hydrogen** may be possible if growth factors are supplied. **Chemotrophic growth is also possible under microoxic to oxic conditions in the dark.** Reduced sulfur compounds are not used as photosynthetic electron donors. Assimilatory sulfate reduction is possible. Growth factors may be required. **Mesophilic and neutrophilic freshwater bacteria.** Habitat: freshwater ponds, sewage ditches, swine waste lagoon.

The mol% G + C of the DNA is: 64.1–65.1.

Type species: **Rhodocyclus purpureus** Pfennig 1978, 285.

FURTHER DESCRIPTIVE INFORMATION

Only a few carbon compounds can be assimilated by *Rhodocyclus purpureus*. Benzoate and cyclohexane carboxylate are both used, which may indicate that *Rhodocyclus purpureus* uses the same pathway for anaerobic benzoate degradation as *Rhodopseudomonas palustris* (Dutton and Evans, 1969; Pfennig, 1978). Neither of these carbon substrates is used by other *Rhodocyclus* species, and they are used only rarely by other purple nonsulfur bacteria.

Nitrogen metabolism of *R. purpureus* and *R. tenuis* has been studied in some detail (Masters and Madigan, 1983). Alanine dehydrogenase is absent in both species. Glutamate dehydrogenase (NADPH-dependent) is found in *R. purpureus* at unusually high activity levels under all growth conditions, and the glutamine synthetase inhibitor methionine sulfoximine exerts no growth inhibition. This may indicate that the major route of nitrogen assimilation in *R. purpureus* is via glutamate dehydrogenase (unlike that in all other investigated purple nonsulfur bacteria). *R. tenuis* employs the glutamine synthetase/glutamate synthase (NADPH-dependent) pathway for the assimilation of ammonia (Masters and Madigan, 1983).

As with other phototrophic *Betaproteobacteria*, the major phospholipid components of *Rhodocyclus* species are cardiolipin, phosphatidylethanolamine and phosphatidylglycerol (Imhoff and Bias-Imhoff, 1995). Straight-chain $C_{16:1}$ and $C_{16:0}$ acids are the main components of cellular fatty acids (see Table BXII.β.110).

ENRICHMENT AND ISOLATION PROCEDURES

R. purpureus was isolated from a swine waste lagoon in Ames, Iowa (USA), where it was the dominant phototrophic bacterium. It has not been observed in other localities and is probably a rare species. Media for enrichment, isolation and growth of *Rhodocyclus* species are the same as those generally employed for other purple nonsulfur bacteria. While suitable conditions for selective enrichment of *R. tenuis* are not available, the vitamin B_{12} requirement and its unusual carbon nutrition are properties that can be exploited for the selective enrichment and isolation of *R. purpureus*. From a suitable habitat, it should be possible to selectively enrich this species with benzoic acid as the carbon source, in the presence of vitamin B_{12}, and in the absence of reduced sulfur compounds.

TABLE BXII.β.110. Differential characteristics of the species of the genus *Rhodocyclus*[a]

Characteristic	*Rhodocyclus purpureus*	*Rhodocyclus tenuis*
Cell diameter (μm)	0.6–0.7	0.3–0.5
Cell shape	Half-circle to circle	Curved rods
Motility	−	+
Slime production	−	+
Color	Purple-violet to violet	Brownish-red or purple-violet
Major carotenoids	Rhodopin, rhodopinal	Rhodopin, rhodopinal, lycopene[b]
Growth factors	B_{12}, *p*-aminobenzoic acid, biotin	None[c]
Gelatin liquefaction	−	−
Fructose fermentation	−	−
Starch hydrolysis	nd	nd
Tween 80 lysis	nd	nd
Carbon sources:		
Benzoate	+	−
C_{10} to C_{18} fatty acids	−	+
Citrate	−	−
Mannitol	−	−
Sorbitol	−	−
N_2-fixation	−	+
Fumarate reductase activity:		
With reduced methylviologen	High	High
With $FMNH_2$	Low	Low
Major fatty acids:		
$C_{16:0}$	33–35	33-3-6
$C_{16:1}$	40–45	43–50
$C_{18:0}$	<1	<1
$C_{18:1}$	18	15–18
3-OH fatty acid	$C_{10:0}$	$C_{10:0}$
Major quinones	Q-8 + MK-8	Q-8 + MK-8
Mol% G + C of DNA		
by HPLC	65.1	64.1–64.8
by Bd	65.3	64.8
by T_m	67.7	64.4–67.2

[a]Symbols: +, positive in most strains; −, negative in most strains; Q–8, ubiquinone-8; MK-8, menaquinone-8.

[b]Some strains may contain carotenoids of the spirilloxanthin series and lack rhodopinal (Schmidt, 1978).

[c]Some strains may require vitamin B_{12} (Siefert and Koppenhagen, 1982).

Maintenance Procedures

Rhodocyclus species are easily maintained by standard procedures in liquid nitrogen or by storage at −80°C in a mechanical freezer.

Differentiation of the genus *Rhodocyclus* from other genera

Rhodocyclus species are distinguished from other phototrophic purple bacteria by their separate phylogenetic position within the class *Betaproteobacteria*. Physiological properties are, in general, not significantly different from those of other purple nonsulfur bacteria, although the utilization of benzoic acid by *R. purpureus* is not a common property among other purple nonsulfur bacteria. The requirement for vitamin B_{12} is also unusual among the purple nonsulfur bacteria, being more common among the green and purple sulfur bacteria. Besides *Rhodocyclus purpureus*, only single strains of *Rhodocyclus tenuis* and *Rhodopseudomonas palustris* have been reported to require vitamin B_{12} (Siefert and Koppenhagen, 1982). Properties that differentiate *Rhodocyclus* species from other phototrophic *Betaproteobacteria* are given in Tables 6 (p. 130) and 7 (p. 131) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A. The phylogenetic relationships among the phototrophic *Betaproteobacteria* are shown in Fig. 4 (p. 132) of that same chapter.

Taxonomic Comments

At present, this genus comprises two species, *Rhodocyclus purpureus* and *Rhodocyclus tenuis* (formerly *Rhodospirillum tenue*). Only a single strain of *R. purpureus* is known. A dichotomy has been observed in *R. tenuis* strains based on carotenoid composition (Schmidt, 1978), color of cell suspensions, and absorption spectra (Biebl, 1973). Some strains of *R. tenuis* have carotenoids of the rhodopinal series and others have carotenoids of the spirilloxanthin series. The type strain (DSM 109) belongs to those strains that transform rhodopin further to spirilloxanthin, whereas another group of strains (including strain DSM 110) does not form anhydrorhodovibrin and spirilloxanthin, but rather accumulates major amounts of rhodopinal, rhodopinol, and lycopenal (Schmidt, 1978). Both of these strains (DSM 109 and 110) show a reasonably close genetic relationship to each other (see Fig. 4 [p.132] of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A).

Differentiation of the species of the genus *Rhodocyclus*

While cells of *Rhodocyclus purpureus* are nonmotile and form a half or full circle, those of *Rhodocyclus tenuis* are slender, slightly curved, and rapidly motile under optimal growth conditions. *R. purpureus* and *R. tenuis* also differ significantly in their nitrogen

nutrition. Whereas the former species uses only ammonia and glutamine as nitrogen sources and is unable to fix dinitrogen (a property common to most species of the purple nonsulfur bacteria), the latter species utilizes a greater number of amino acids, urea, dinitrogen, yeast extract, peptone, and Casamino acids (Masters and Madigan, 1983). In addition, differences in carbon nutrition and vitamin requirements clearly differentiate the two species. Diagnostic properties of *Rhodocyclus* species are listed in Table BXII.β.110. Their carbon substrates are shown in Table BXII.β.111.

List of species of the genus Rhodocyclus

1. **Rhodocyclus purpureus** Pfennig 1978, 285[AL]
pur.pu′ re.us. L. adj. *purpureus* purple or red-violet.

Cells are half-ring-shaped to ring-shaped before cell division and are 0.6–0.7 μm wide. The diameter of a circle is 2.0–3.0 μm. Half-circle-shaped cells are about 2.7 μm long (Fig. BXII.β.104). Open or compact spirals or coils of variable length may be formed. In sulfide-containing media, closely wound spirals are united in compact cell aggregates. Cells are nonmotile under all growth conditions. The color of phototrophically grown cultures is purple-violet to violet. Aerobically grown cells are colorless to pale violet. Living cells have absorption maxima at 379, 408, 510, 535, 597, 813, and 866 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the rhodopinal series, with rhodopinal as the major component.

Photoheterotrophic growth occurs under anoxic conditions in the light with a relatively small number of organic substrates as carbon and electron sources. Cells grow photoautotrophically with hydrogen as the electron donor in the presence of growth factors. Chemotrophic growth is possible under microoxic to oxic conditions in the dark. Carbon sources utilized are listed in Table BXII.β.111. In addition, cyclohexane carboxylate is used, but propanol, yeast extract, and Casamino acids are not utilized as sole carbon sources. Photoheterotrophically grown cells use only ammonia and glutamine as nitrogen sources; dinitrogen is not assimilated. Sulfate can be used as the sole sulfur source. Vitamin B_{12}, *p*-aminobenzoic acid, and biotin are required as growth factors.

Mesophilic freshwater bacterium with optimal growth at 30°C and pH 7.2 (pH range with acetate: pH 6.5–7.5). Habitat: swine waste lagoon. Major quinone components are Q-8 and MK-8.

The mol% G + C of the DNA is: 65.3 (Bd), 65.1 (HPLC), 67.7 (T_m).

Type strain: Ames 6770, DSM 168.

GenBank accession number (16S rRNA): M34132.

2. **Rhodocyclus tenuis** (Pfennig 1969b) Imhoff, Trüper and Pfennig 1984, 341[VP] (*Rhodospirillum tenue* Pfennig 1969b, 619.)
te′ nu.is. L. masc. adj. *tenuis* slender, thin.

Cells are curved in spirals of one to two complete turns, 0.3–0.5 × 1.5–6.0 μm, sometimes even longer. One complete turn of a spiral is ~0.8–1.0 μm wide and 3 μm long (Fig. BXII.β.105). Photosynthetically grown cells are brownish-red or purple-violet, depending on the strain. Aerobically grown cells may be colorless or pigmented. Absorption maxima of brownish cells that have carotenoids of the spi-

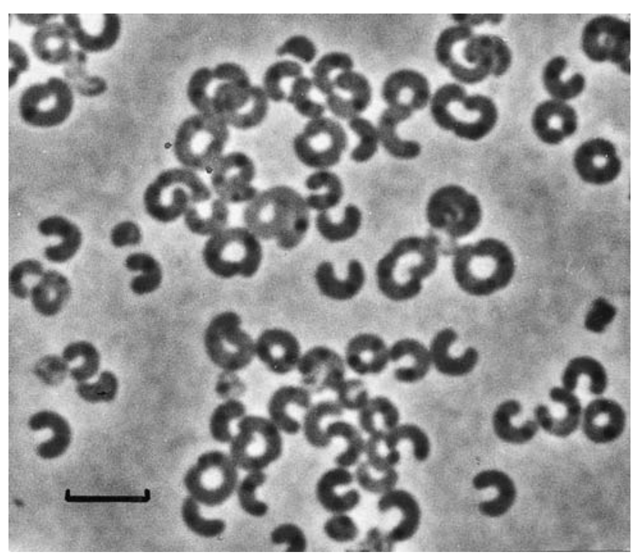

FIGURE BXII.β.104. *Rhodocyclus purpureus* DSM 168. Phase-contrast micrograph. Bar = 5 μm (Courtesy of N. Pfennig).

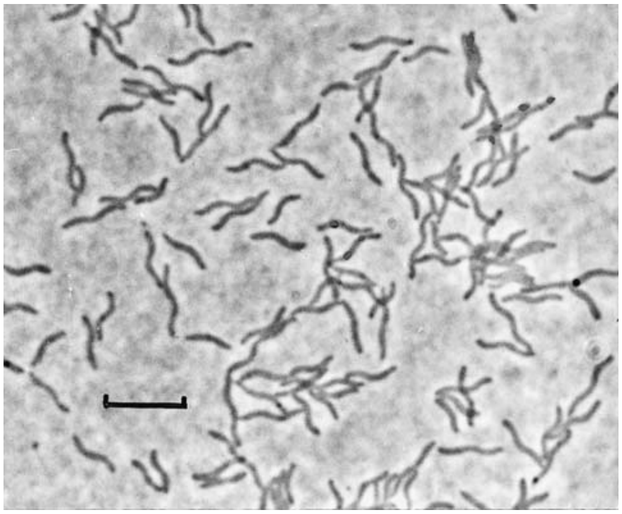

FIGURE BXII.β.105 *Rhodocyclus tenuis* DSM 109. Phase-contrast micrograph. Bar = 5 μm (Courtesy of N. Pfennig).

rilloxanthin series are at 378–380, 465, 492–495, 528, 592–594, 799–801, and 868–871 nm. Absorption maxima of purple cells that have carotenoids of the rhodopinal series are at 377–378, 469, 495–500, 529–533, 590–592, 798–801, and 856–858 nm. Both types of cells contain bacteriochlorophyll *a* esterified with phytol.

Growth occurs preferably under anoxic conditions in the light with numerous carbon substrates as carbon and electron sources. Photoautotrophic growth with molecular hydrogen is possible. Chemotrophic growth is possible under microoxic to oxic conditions in the dark. The organic substrates used are listed in Table BXII.β.111. In addition, Casamino acids and yeast extract are utilized, but cyclohexane carboxylate is not. Aspartate, glutamate, glutamine, ammonia, and dinitrogen are used as nitrogen sources; also utilized are Casamino acids, peptone, yeast extract, alanine, arginine, lysine, methionine, serine, threonine, and urea. Sulfate, sulfite, sulfide, thiosulfate, cysteine, and reduced glutathione can serve as assimilatory sulfur sources. Growth factors are not required. Growth is stimulated, however, in the presence of complex organic nutrients or yeast extract, and some strains may need vitamin B_{12}.

Mesophilic freshwater bacterium with optimal growth at 30°C and pH 6.6–7.4. Habitat: freshwater ponds, sewage ditches. Major quinone components are Q-8 and MK-8.

The mol% G + C of the DNA is: 64.1–64.8 (HPLC), 64.4–67.2 (T_m); type strain: 64.8 (Bd) and 66.1 (T_m).

Type strain: ATCC 25093, DSM 109.

GenBank accession number (16S rRNA): D16208.

Genus II. **Azoarcus** *Reinhold-Hurek, Hurek, Gillis, Hoste, Vancanneyt, Kersters and De Ley 1993b, 582*[VP]

Barbara Reinhold-Hurek, Zhiyuan Tan and Thomas Hurek

A.zo' ar.cus. Fr. n. *azote* nitrogen; L. masc. n. *arcus* arch, bow; M.L. masc. n. *Azoarcus* nitrogen (-fixing) bow.

Straight to slightly curved rods, 0.4–1.5 × 1.1–4.0 μm. Cell pairs often appear slightly S-shaped. In most species, some elongated cells (8–12 μm) occur in late-log or stationary-phase cultures on medium containing malic acid and N_2 or ammonium as nitrogen source. **Cells are highly motile by means of one polar flagellum. Accumulate poly-β-hydroxybutyrate granules.** Gram negative. **Some species are nitrogen fixers**; these require microaerobic conditions for growth on N_2. On semisolid nitrogen-free media, microaerophilic growth can be observed as veil-like pellicles developing several mm below the surface and moving to the medium surface during growth. In most species, colonies on VM agar[1] supplemented with ethanol develop **a nondiffusible yellowish pigment**. Optimal temperature for growth 30–40°C; no growth occurs at 45°C. **Chemoorganoheterotrophic. Bacteria have a strictly respiratory metabolism with O_2 as the terminal electron acceptor,** except one species. Alternatively, under anaerobic conditions, nitrate can be used for dissimilatory nitrate reduction. **Oxidase positive. Grow well on salts of organic acids** such as L-malate, succinate, fumarate, DL-lactate; also grow well on ethanol, on L-glutamate, but not on mono- or disaccharides except for species that are not plant-associated. These soil-borne species utilize a variety of **aromatic substrates as sole carbon sources under denitrifying conditions**. Nitrate can be used as a nitrogen source (assimilatory nitrate reduction). Growth factor requirements vary: some strains depend on *p*-aminobenzoic acid or on cobalamine. All investigated species have $C_{16:1}$ cellular fatty acids; all species except one have $C_{16:1\ \omega7c}$ and $C_{18:1}$ as the major cellular fatty acids.

The mol% G + C of the DNA is: 62–68 (T_m).

Type species: **Azoarcus indigens** Reinhold-Hurek, Hurek, Gillis, Hoste, Vancanneyt, Kersters and De Ley 1993b, 583.

Further descriptive information

The members of *Azoarcus* comprise two biogroups: (1) the soil-borne species *A. tolulyticus*, *A. toluclasticus*, *A. toluvorans*, *A. evansii*, and *A. anaerobius*, and (2) the plant-associated species *A. indigens*, *A. communis*, and an unnamed *Azoarcus* strain, strain BH72 (Fig. BXII.β.106).

Morphology Cells are straight to slightly curved rods that are highly motile by one, rarely two, polar flagella (Fig. BXII.β.107). All species have a cell width of ≤1 μm, with the exception of *Azoarcus anaerobius*, which has a cell width of 1.5 μm (Springer et al., 1998). The cell length ranges from 1.5–4.0 μm. Elongated cells of 8–12 μm length are rarely found in the plant-associated species (*A. communis*, *A. indigens*, and *Azoarcus* strain BH72) in stationary phase cultures grown in semisolid N-free malate medium.

Growth The optimal growth temperature for most species is 30°C or 37–40°C depending on species, but is lower (28°C) for *A. anaerobius*. The optimal pH is 7.

1. VM agar contains (g per liter): K_2HPO_4, 0.6; KH_2PO_4, 0.4; NH_4Cl, 0.5; $MgSO_4{\cdot}7H_2O$, 0.2; NaCl, 1.1; $CaCl_2{\cdot}2H_2O$, 0.026; $MnSO_4{\cdot}H_2O$, 0.01; $Na_2MoO_4{\cdot}2H_2O$, 0.002; Fe (III)-EDTA, 0.066; yeast extract, 1; Bacto-Tryptone, 3; pH 6.8; ethanol, 6 ml per l, sterilized by filtration.

Metabolism The optimal growth temperature for most species is 30°C or 37–40°C depending on species, but is lower (28°C) for *A. anaerobius*. The optimal pH is 7.

All species except *A. anaerobius* use oxygen as the terminal electron acceptor. In the original description of *Azoarcus*, standard procedures had failed to reveal an ability to denitrify (Reinhold-Hurek et al., 1993b). On closer examination, the ability to use nitrate as the terminal electron acceptor was demonstrated for the plant-associated strains (Hurek and Reinhold-Hurek, 1995), a feature that they share with all other species (Anders et al., 1995; Zhou et al., 1995; Springer et al., 1998; Song et al., 1999). Most strains belonging to *A. tolulyticus*, *A. evansii*, *A. toluclasticus*, *A. toluvorans*, and *A. anaerobius* were enriched or isolated anaerobically on nitrate, whereas the plant-associated species were enriched under nitrogen-fixing conditions.

In general, carbohydrates are not the preferred carbon sources of *Azoarcus* species. None of the plant-associated species is able to utilize any of the 50 mono- and disaccharides or sugar alcohols tested (Reinhold-Hurek et al., 1993b). Similarly, *A. anaerobius* shows no growth on common carbohydrates such as D(+)-glucose or D(−)-fructose (Springer et al., 1998). In contrast, all strains of soil-borne species tested so far are able to utilize at least some carbohydrates (see Table BXII.β.112). All strains grow well on organic acids and a few amino acids (Table BXII.β.112). The carbon sources listed in Table BXII.β.112 were tested with O_2 as the terminal electron acceptor (except in the case of *A. anaerobius*). For some strains, tests were also carried out under anaerobic conditions with nitrate as electron acceptor. For the majority of carbon sources, results were identical; however, for several carbon sources discrepancies were found between aerobic and anaerobic conditions as well as between strains (Song et al., 1999). Most soil-borne species grow on aromatic compounds such as toluene or phenol (Zhou et al., 1995; Song et al., 1999), benzoate (Anders et al., 1995), or resorcinol (Springer et al., 1998) under denitrifying conditions, in contrast to plant-associated species (Reinhold-Hurek et al., 1993b; Hurek and Reinhold-Hurek, 1995). Due to the anaerobic degradation of aromatic compounds, this bacterial group has received particular attention for its role in biodegradation and biotransformation. Whereas aerobic metabolism is characterized by the extensive use of molecular oxygen, which is essential for the hydroxylation and cleavage of the ring structures, anaerobic degradation uses other strategies that are currently being studied. Toluene, which can be decomposed anaerobically by three species, is activated by the addition of fumarate to form benzylsuccinate (Beller and Spormann, 1997). The reaction is catalyzed by benzylsuccinate synthase and involves a glycyl radical (Krieger et al., 2001). See the description of *A. evansii* for further details on degradation of aromatic compounds.

In the original description of the genus *Azoarcus*, the ability to fix nitrogen is listed as a genus character (Reinhold-Hurek et al., 1993b). Subsequently, nitrogen fixation or the occurrence of a nitrogenase gene *nifH* was also demonstrated for *A. tolulyticus* (Fries et al., 1994; Zhou et al., 1995; Hurek et al., 1997a). However, nitrogen fixation can no longer be considered a universal characteristic of the genus *Azoarcus*, due to the addition of new species that do not fix nitrogen. Nitrogen fixation was not detected in *A. anaerobius* (Springer et al., 1998). Although there are no physiological data available (Anders et al., 1995), *A. evansii* is unlikely to be diazotrophic since there is no evidence for occurrence of a PCR-amplifiable *nifH* fragment (Hurek and Reinhold-Hurek, unpublished observations). For most other isolates enriched under denitrifying conditions, this character was not tested at all.

In those species and strains that carry out nitrogen fixation (*A. indigens*, *A. communis*, *A. tolulyticus*, *Azoarcus* sp. strain BH72), nitrogenase activity occurs only under microaerobic conditions, probably due to a lack of efficient oxygen protection mechanisms. When cultured on N-free semisolid medium, the nitrogen-fixing strains develop a veil-like pellicle, which, due to aerotaxis, moves to the medium surface when the culture becomes denser. For strain BH72, nitrogen fixation is more tolerant to oxygen than in *Azospirillum* spp., reaching steady states in an oxygen-controlled chemostat up to 25 μM dissolved O_2 (Hurek et al., 1987). In accordance with these physiological data, the expression of nitrogenase genes is transcriptionally regulated in response to oxygen (fully repressed by 4% oxygen in the headspace) or combined nitrogen (repressed by 0.5 mM ammonium or nitrate) (Egener et al., 1999). In empirically optimized batch cultures, strain BH72 shows augmented rates and efficiency of nitrogen fixation, called hyperinduction, when shifting into extremely low oxygen concentrations (30 nM) (Hurek et al., 1994a). In the course of hyperinduction, novel intracytoplasmic membrane stacks are formed that might participate in efficient nitrogenase activity, since the iron protein of nitrogenase is mainly associated with these membranes (Hurek and Reinhold-Hurek, 1995). The formation of these so-called diazosomes is most abundant and reproducible in coculture of strain BH72 and an endophytic fungus isolated from Kallar grass (Hurek and Reinhold-Hurek, 1995) related to *Acremonium alternatum* (Hurek and Reinhold-Hurek, 1999). As in many *Proteobacteria*, the nitrogenase genes are organized in a *nifHDK* operon (Egener et al., 2001). Phylogenetically, the nitrogenase in the genus *Azoarcus* either follows the organismal phylogenetic tree or appears to have been acquired by lateral gene transfer, depending on the species. In *A. indigens*, *A. communis*, and *Azoarcus* spp. strain BH72, a fragment of the iron protein of nitrogenase encoded by the *nifH* gene is most closely related to nitrogenases that occur in diazotrophs of *Gammaproteobacteria*, whereas in *A. tolulyticus* it is located within a clade of nitrogenases that occur in species of *Alphaproteobacteria* (*Bradyrhizobium* and *Azospirillum*) (Hurek et al., 1997a).

Exoenzymes There are few studies of the exoenzymes of *Azoarcus* sp. In all three plant-associated species, an exoglucanase having β-glucosidase and cellobiohydrolase activity was detected, whereas an endoglucanase was found in strain BH72 and in *A. communis* only (Reinhold-Hurek et al., 1993a). Although these enzymes cannot be used for direct metabolic purposes because these strains do not grow on carbohydrates, they may be involved in plant infection.

Antigens Polyclonal antibodies have been raised against *Azoarcus* sp. strain BH72 and mainly bind to the cell surface. They cross-react weakly with *A. indigens* and *A. communis* cells. These antibodies have been used for histochemical detection of *Azoarcus* in grass roots (Hurek et al., 1994b).

Genetics DNA reassociation experiments with the three plant-associated species of *Azoarcus* have led to the estimation of a genome size from 4.5–5 Mb. Nothing is known about bacteriophages of the genus *Azoarcus*. Similarly, the plasmid content has not been well studied. In strain BH72, plasmids could not be detected in Eckhardt gels or by pulsed-field gel electrophoresis (Reinhold-Hurek and Hurek, unpublished observations). Several strains of *Azoarcus* species have been shown to be transformable.

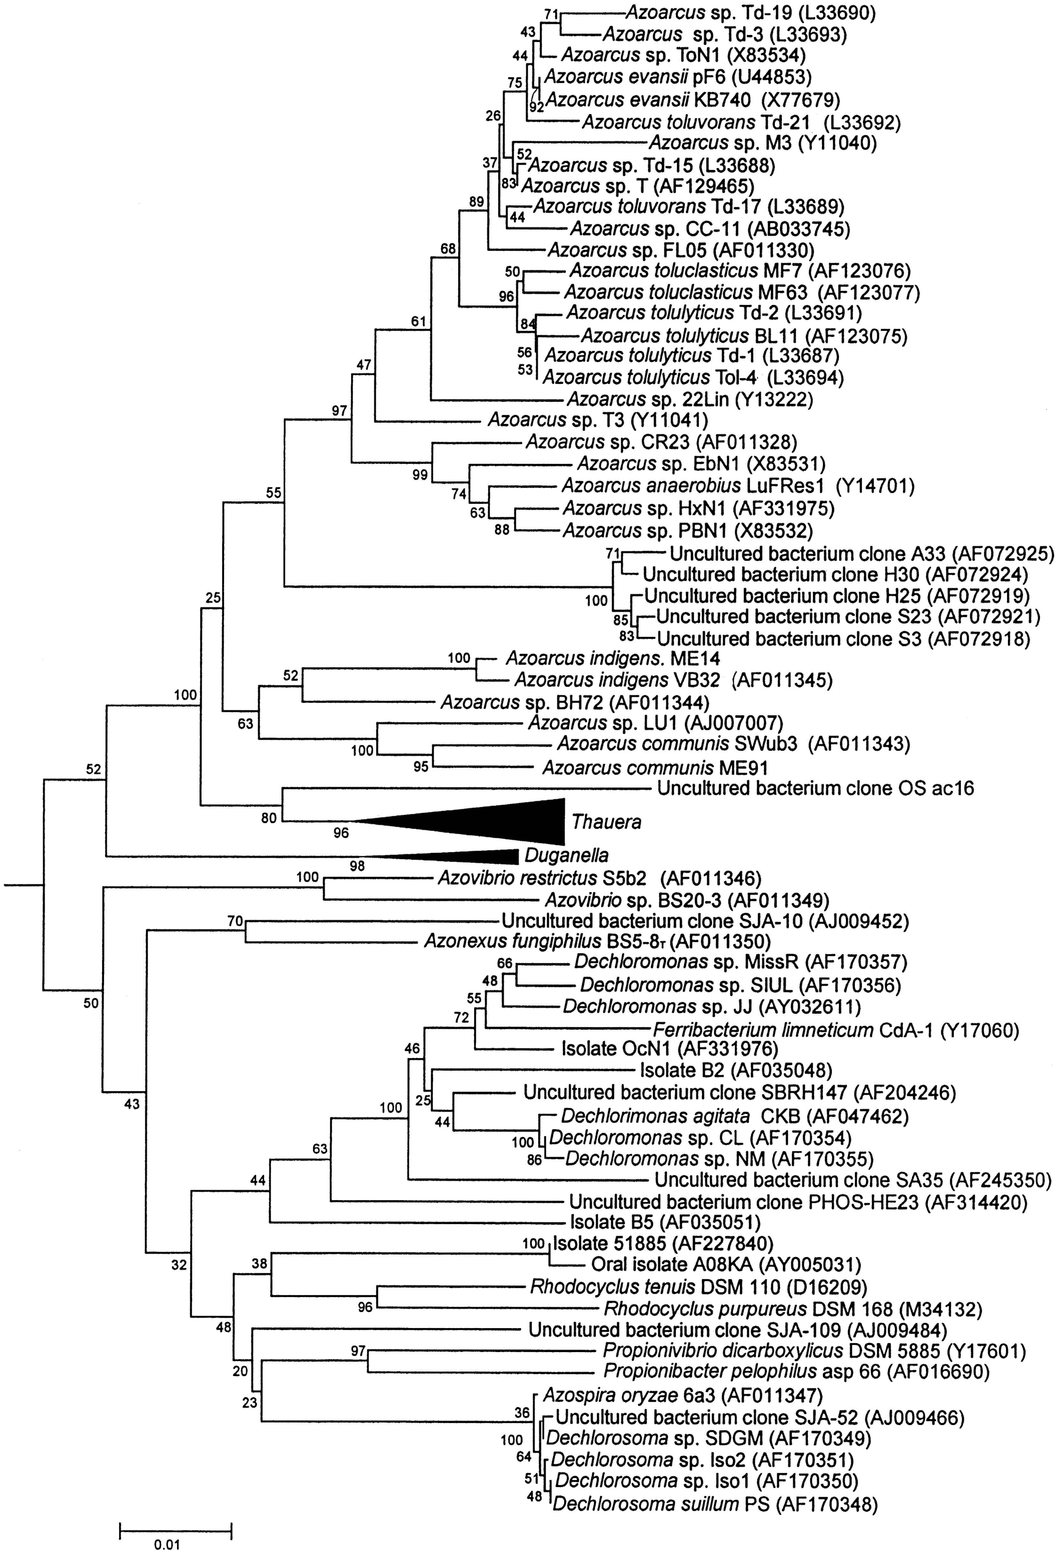

FIGURE BXII.β.106 Phylogenetic analysis of 16S rDNA sequences (1358 positions). Shown is a subtree of the *Rhodocyclus/Thauera/Azoarcus* group derived from an analysis of 158 sequences of the *Betaproteobacteria.* Tree inference was carried out using the neighbor-joining algorithm with a Jukes-Cantor correction with 125 bootstrap repetitions. Sequence accession numbers are given in parentheses.

[j]Negative for *A. evansii*.

[k]Negative for *A. toluclasticus*, d for *A. tolulyticus*.

[l]Negative for *A. tolulyticus*, ND for *A. toluvorans*, *A. toluclasticus*, *A. anaerobius*.

Broad host range plasmids based on RK2 such as pRK290 or pAFR3 can be transferred by triparental mating and are stably replicated in strain BH72 (Egener et al., 2001). Transformation can also be achieved by electroporation (Hurek et al., 1995), and mutagenesis by allelic exchange (Hurek et al., 1995) or transposon mutagenesis (Dörr et al., 1998) is possible.

Antibiotic resistance Resistance of *Azoarcus* species to antibiotics has not been extensively tested. *A. indigens*, *A. communis*, and strain BH72 are not resistant to ampicillin, kanamycin, streptomycin, spectinomycin, or tetracycline (Reinhold-Hurek and Hurek, unpublished observation).

Pathogenicity None of the strains has been reported to be pathogenic. Although the plant-associated species colonize the interior of grasses as endophytes, no symptoms of plant disease have been reported (Reinhold-Hurek and Hurek, 1998).

Ecology The two groups of *Azoarcus* species—plant-associated and soil-borne species—differ strongly in their ecology. Strains of *A. indigens*, *A. communis*, and *Azoarcus* sp. BH72 occur inside roots or on the root surface of Gramineae and have never been isolated from root-free soil (Reinhold-Hurek and Hurek, 1998), except for a strain of *A. communis* that originated not from plants but from French refinery oily sludge (Laguerre et al., 1987; Reinhold-Hurek et al., 1993b). In contrast, all isolates that belong to the clade of *A. tolulyticus*, *A. toluvorans*, *A. toluclasticus*, *A. evansii*, or *A. anaerobius* have not been isolated from living plants but instead from soil and sediments; therefore, their ecology will be treated separately. The plant-associated strains were originally detected in association with roots of Kallar grass (*Leptochloa fusca* (L.) Kunth), a flood-tolerant salt marsh grass grown as a pioneer species on salt-affected, flooded, low-fertility soils in the Punjab of Pakistan since the 1970s (Reinhold et al., 1986; Reinhold-Hurek et al., 1993b). These nitrogen-fixing *Azoarcus* strains were found in high numbers in surface-sterilized roots and only rarely on the root surface (*A. communis*). Isolates were later obtained from rice (*Oryza sativa*) from Nepal (Engelhard et al., 2000) or from resting stages (sclerotia) of a plant-associated basidiomycete found in rice field soil from Pakistan (Hurek et al., 1997b). More detailed studies on plant–microbe interactions of a strain originating from Kallar grass—strain BH72—showed that in gnotobiotic culture in the laboratory, these bacteria had a wider host range. They could also invade rice roots and stems (Hurek et al., 1994b), where they mainly colonize the cortex tissue intercellularly and, rarely, the stele including xylem cells (Hurek et al., 1994b). Despite a high density of colonization, the bacteria do not cause symptoms of plant disease and thus have an endophytic and not a pathogenic lifestyle. Unlike rhizobia, they do not form an endosymbiosis in living plant cells. Nevertheless, they show endophytic nitrogen fixation, expressing nitrogenase genes in the apoplast of aerenchymatic air spaces of flooded rice seedlings (Egener et al., 1999) or field-grown Kallar grass plants (Hurek et al., 1997a). They might even be distributed, based on molecular-ecological studies on root material or fungal spores. *Azoarcus* 16S rDNA genes (Hurek and Reinhold-Hurek, 1995) or *nifH* genes (Ueda et al., 1995; Engelhard et al., 2000) have been retrieved that did not correspond to the genes of cultivated strains or species. Because the corresponding bacteria could not be isolated from the same samples, they may occur in an as yet unculturable state and thus be overlooked by classical microbiological techniques. Interestingly, the sequences that have been retrieved so far from plant material have not clustered with genes from soil-borne species, confirming that they do not appear to be plant-associated.

The soil-borne species are very widespread. Strains belonging to the valid species have been isolated from uncontaminated soils (Song et al., 1999), from soils containing unknown contaminants in industrial areas (Song et al., 1999), and from soils containing known contaminants such as petroleum (Fries et al., 1994; Zhou et al., 1995). Many strains have also been cultured from sediments of uncontaminated or contaminated creeks (Anders et al., 1995), aquifers (Fries et al., 1994, 1997; Zhou et al., 1995), or activated sewage sludge (Springer et al., 1998). Soil-borne *Azoarcus* spp. are also widespread with respect to their geographical distribution. For example, they have been found in North America (USA and Canada), South America (Puerto Rico, Brazil), and Europe (Germany, Switzerland). Their occurrence in anoxic sediments or sewage sludge indicates that their lifestyle *in situ* might be anaerobic (using nitrate as terminal electron acceptor) rather than microaerobic (fixing nitrogen, and using O_2 as terminal electron acceptor) in contrast to the plant-associated strains. Further information on strains that do not belong to validly published species is given below (see Other Organisms).

Enrichment and Isolation Procedures

Plant-associated species and soil-borne species of *Azoarcus* will be treated separately. Plant-associated strains are best enriched on media free of combined nitrogen. Washed roots or roots that have been surface-sterilized in 5% NaOCl for 2 min and then thoroughly washed are macerated aseptically in the enrichment medium free of carbon source. To avoid overgrowth by faster growing diazotrophs, enrichment cultures should be inoculated with serial dilutions of this material. For enrichment of nitrogen-fixing bacteria, N-free semisolid synthetic malate medium (SM-N) is used.[2] The medium is solidified in screw-cap tubes and is inoculated with 10 µl of macerate or root pieces below the medium surface. The tubes are incubated without shaking at 30°C (37°C for tropical or subtropical strains) and checked for development of a subsurface pellicle. Samples for streaking should be taken before the pellicle has moved to the medium surface and become very dense. Isolation of single colonies is carried out on SM-N agar supplemented with 20 mg of yeast extract per liter and 10 g of agar per liter. Enrichment cultures or isolates are analyzed for nitrogenase activity in semisolid medium by the acetylene reduction method. Purity and colony color are checked on a complex medium, VM ethanol, which is based on SM-N medium but supplemented with the following ingredients (per liter): Lab Lemco Powder (Oxoid) or Bacto Peptone (Difco), 3.0 g; yeast extract, 1.0 g; NaCl, 1.0 g; NH_4Cl, 0.5 g; and agar, 15.0 g. Alternatively, for salt-affected habitats, the SSM medium of Reinhold et al. (1986) can be used instead of SM medium for enrichment and isolation.

---

2. N-free semisolid synthetic malate medium (SM-N) consist of (per liter of distilled water): $MgSO_4 \cdot 2H_2O$, 0.2 g; NaCl, 0.1 g; $CaCl_2$, 0.02 g; $MnSO_4 \cdot H_2O$, 0.01 g; $Na_2MoO_4 \cdot 2H_2O$, 0.002 g; Fe(III)-EDTA, 0.066 g; phosphate buffer consisting of KH_2PO_4, 0.6 g, and K_2HPO_4, 0.4 g, which is adjusted to pH 6.8; DL-malate solution consisting of DL-malic acid, 5 g; and KOH, 4.5 g, adjusted to pH 6.8; agar, 2 g; and vitamin solution, 1 ml. The vitamin solution contains (mg per liter of distilled water) myoinositol, 10,000; niacinamide, 100; pyridoxine-HCl, 100; thiamine-HCl,100; calcium pantothenate, 50; folic acid, 20; choline chloride, 50; riboflavin, 10; ascorbic acid, 100; *p*-aminobenzoic acid, 1.0; vitamin A, 0.5; vitamin D_3, 0.5; vitamin B_{12}, 0.5; and D-biotin, 0.5. Phosphate buffer and vitamin solution are sterilized separately and added to the autoclaved medium after autoclaving.

For soil-borne strains, enrichment is routinely done under strictly anaerobic conditions with nitrate as the terminal electron acceptor. A variety of aromatic carbon sources has been used, depending on the species or strain under study. The preparation of media and cultivation of bacteria are carried out under strictly anoxic conditions. A typical medium is that used for *A. evansii*.[3] Ascorbic acid (4 mM) can be used to reduce the medium. Potentially toxic carbon sources are added at low concentrations (toluene, 5 ppm; phenol, 1 mM; Na-benzoate, 5 mM), and cultures are spiked again with the carbon source after its degradation. Enrichment is carried out in anoxic sealed serum bottles. When rich sediments are used as an inoculum, they may have to be depleted of readily oxidizable carbon sources by repeated incubation in a medium free of these sources (Fries et al., 1994). The enriched samples are plated on agar media such as M-R2A medium[4] or used for an agar dilution series (Widdel and Bak, 1992). For cultivation on poorly water-soluble compounds such as alkylbenzenes, special procedures are required (see Rabus and Widdel, 1995).

Maintenance Procedures

Due to alkalinization of the medium in stationary phase, subculturing *Azoarcus* strains on the salts of malic acid should be avoided and VM ethanol medium should be used instead (soil-borne strains may also be subcultured on M-R2A medium).

Preservation can be done by lyophilization. Strains may also be stored in liquid nitrogen, with 5% DMSO as a cryoprotectant.

Procedures for Testing Special Characters

The genus *Azoarcus* can be specifically detected by 16S rDNA-targeted PCR. Primers TH3 (5′-GATTGGAGCGGCCGATGTC-3′) and TH5 (5′-CTGGTTCCCGAAGGCACCC-3′), which correspond to *E. coli* positions 222 to 240 and 1040 to 1022, respectively, yield a specific amplification product at an annealing temperature of 70°C for 30 cycles (Hurek et al., 1993).

Differentiation of the genus *Azoarcus* from other genera

Table BXII.β.112 gives the characteristics of *Azoarcus* that differentiate it from other morphologically or physiologically similar genera. The phylogenetically closely related genus *Thauera*, which is physiologically the most similar to the soil-borne species, is difficult to differentiate by classical tests.

Taxonomic Comments

Azoarcus spp. belong to the order *Rhodocyclales* of the class *Betaproteobacteria* according to phylogenetic analysis of almost complete 16S rRNA sequences. Within the genus *Azoarcus*, the 16S rDNA phylogenetic distances are as high as 6%; thus, the genus represents a rather heterogeneous group. Especially within the phylogenetic branch containing soil-borne strains, the 16S rDNA sequence analysis does not always resolve species well from each other (see *A. toluvorans*, Fig. BXII.β.106). *Thauera* is the most closely related genus with a 16S rDNA phylogenetic distance of 6–7%.

Several members of the genus *Azoarcus sensu lato* (Reinhold-Hurek et al., 1993b) were recently reclassified as separate genera; these are *Azovibrio*, *Azonexus*, and *Azospira*, which are closely related to the *Azoarcus/Thauera* clade (Fig. BXII.β.106) (Reinhold-Hurek and Hurek, 2000). Members of the residual genus *Azoarcus* are phylogenetically most closely related to the genus *Thauera*, with which they form the *Azoarcus/Thauera* branch, which is reasonably supported by statistical analysis (Fig. BXII.β.106). *Azoarcus* species are located in two different clades, which in part reflects their physiology and ecology.

The genus *Azoarcus* consists of the following validly described species based on polyphasic taxonomic approaches including DNA–DNA hybridization, protein profiles, fatty acid analysis, and nutritional profiles: *A. indigens* (type species), *A. communis*, *A. tolulyticus*, *A. toluclasticus*, *A. toluvorans*, *A. evansii*, and *A. anaerobius*. The unnamed strain BH72 differs from these at the species level according to DNA–DNA homology studies (≤ 25% DNA binding); however, a species name has not been given because there is only a single strain (Reinhold-Hurek et al., 1993b). Numerous additional soil-borne strains are localized in the *Azoarcus* clade according to 16S rDNA sequence analysis (examples given in Fig. BXII.β.106). Most have been isolated under conditions of denitrification with aromatic hydrocarbons as carbon sources, but the lack of nutritional/physiological data and DNA–DNA homology values do not allow a species assignment. Interestingly, a deeply branching clade of as yet uncultured bacteria is also localized within the *Azoarcus* cluster.

The analysis of phylogenetic relationships in the *Azoarcus/Thauera* 16S rDNA cluster is rendered difficult because the branching pattern between *Thauera*, the soil-borne *Azoarcus* species, and the plant-associated *Azoarcus* species is unstable when tested with different tree-building methods. This was also observed previously (Hurek et al., 1997a; Reinhold-Hurek and Hurek, 2000). Similarly, in other taxa closely related to each other, such as the rhizobia, the resolution of phylogenetic analysis is sometimes limited. Nevertheless, all named species in the genus *Thauera* cluster in one clade with a significant level of support by bootstrap analysis (Fig. BXII.β.106), allowing a reliable assignment to this genus. Likewise, most soil-borne species and strains of *Azoarcus* fall into one clade significantly supported by bootstrap analysis, and none of the species containing plant-associated strains are located on this branch. The phylogenetic distances within these three clades are similar; the consequence of this finding—that the clades might deserve the rank of different genera—is discussed below. All of the valid species of *Azoarcus* are well resolved except for the strains of *A. toluvorans*, which are interspersed among several strains of uncertain affiliation (Fig. BXII.β.106). Former strains of *A. tolulyticus*—Td-3 and Td-

---

3. *Azoarcus evansii* medium consists of (g per liter of distilled water): KH_2PO_4, 0.816 g; K_2HPO_4, 5.920 g; NH_4Cl, 0.53 g; $MgSO_4 \cdot 7H_2O$, 0.200 g; KNO_3, 0.5 g; and $CaCl_2 \cdot 2H_2O$, 0.025 g. The phosphate is dissolved separately from the other ingredients. Both solutions are adjusted to pH 7.8 for *A. evansii* or to pH 7 for other strains. The two solutions are autoclaved and combined after cooling. To this solution are added 10 ml of sterile trace elements SL-1 and 5 ml of vitamin solution. SL-1 solution contains (per liter of distilled water): HCl (25%; 7.7 M), 10 ml; $FeCl_2 \cdot 4H_2O$, 1.5 g; $ZnCl_2$, 70 mg; $MnCl_2 \cdot 4H_2O$, 100 mg; H_3BO_3, 6 mg; $CoCl_2 \cdot 6H_2O$, 190 mg; $CuCl_2 \cdot 2H_2O$, 2 mg; $NiCl_2 \cdot 6H_2O$, 24 mg; and $Na_2MoO_4 \cdot 2H_2O$, 36 mg. The $FeCl_2$ is dissolved in the HCl and then diluted in water. The other salts are then added and dissolved. The vitamin solution contains (mg per liter of distilled water): vitamin B_{12}, 50 mg; pantothenic acid, 50 mg; riboflavin, 50 mg; pyridoxamine-HCl, 10 mg; biotin, 20 mg; folic acid, 20 mg; nicotinic acid, 25 mg; nicotinamide, 25 mg; α-lipoic acid, 50 mg; *p*-aminobenzoic acid, 50 mg; and thiamine-HCl·$2H_2O$, 50 mg.

4. M-R2A medium (Fries et al., 1994) contains (per liter of distilled water): yeast extract, 0.5 g; peptone, 0.5 g; Casamino acids, 0.5 g; dextrose, 0.5 g; soluble starch, 0.5 g; sodium pyruvate, 0.3 g; K_2HPO_4, 0.4 g; KH_2PO_4, 0.25 g; KNO_3, 0.505 g; $CaCl_2 \cdot 2H_2O$, 0.015 g; $MgCl_2 \cdot 2H_2O$, 0.02 g; $FeSO_4 \cdot 7H_2O$, 0.007 g; Na_2SO_4, 0.005 g; NH_4Cl, 0.8 g; $MnCl_2 \cdot 4H_2O$, 5 mg; H_3BO_3, 0.5 mg; $ZnCl_2$, 0.5 mg; $CoCl_2 \cdot 6H_2O$, 0.5 mg; $NiSO_4 \cdot 6H_2O$, 0.5 mg; $CuCl_2 \cdot 2H_2O$, 0.3 mg; $NaMoO_4 \cdot 2H_2O$, 0.01 mg; agar, 15 g. The pH is adjusted to 7.0 before autoclaving.

19—have recently been removed from this species due to low DNA–DNA hybridization values (<40%), which are also reflected in the 16S rDNA sequence analysis (Fig. BXII.β.106).

In the original description of the genus *Azoarcus*, two groups of bacteria that were distinct at the species level and located on the *Azoarcus* rRNA branch—albeit at low $T_{m(e)}$ values—were classified as *Azoarcus sensu lato* (Reinhold-Hurek et al., 1993b). Availability of additional strains and 16S rDNA sequences allowed the reassessment of the taxonomic structure of *Azoarcus sensu lato*. The unnamed groups C and D (Reinhold-Hurek et al., 1993b) were classified as the genera *Azovibrio* and *Azospira*, respectively (Reinhold-Hurek and Hurek, 2000), and *Azoarcus sensu lato* group E, which had been described later (Hurek et al., 1997b), was proposed as *Azonexus* (Reinhold-Hurek and Hurek, 2000). These bacteria are very similar in physiology and ecology to the plant-associated *Azoarcus* species.

The definition of the genus *Azoarcus* is complex. It includes strains with a variety of physiological and ecological attributes, which place them into at least two groups—the plant-associated species and the soil-borne species. In addition to their ecological differences, the species containing plant-associated strains differ from the soil-borne species in some nutritional features, e.g., the inability to use carbohydrates or, under conditions of denitrification, certain aromatic compounds, as sole carbon source. Moreover, the phylogenetic analysis of 16S rDNA sequences also points to a separation of these two groups. Since the phylogenetic distances within the three clades in the *Azoarcus/Thauera* group are similar, both subgroups of *Azoarcus* might also deserve the rank of different genera in future. However, this will require a rigid polyphasic taxonomic analysis, which subjects the strains to the same tests. As can be seen from Tables BXII.β.113 and BXII.β.114, many features have not been tested for all species or strains. For instance, nitrogen fixation and aerobic nutritional profiles are not tested in all soil-borne strains, whereas nutritional profiles under conditions of denitrification are lacking for plant-associated species. These studies should also include the numerous soil-borne isolates that have not yet been assigned to any species. Because some strains are deeply branching in the phylogenetic analysis (e.g., strains 22Lin, T3, and M3; Fig. BXII.β.106) the description of new species might be expected.

Differentiation of the species of the genus *Azoarcus*

The differential characteristics of the species of *Azoarcus* are indicated in Table BXII.β.113. Other characteristics of the species are presented in Table BXII.β.114.

List of species of the genus Azoarcus

1. **Azoarcus indigens** Reinhold-Hurek, Hurek, Gillis, Hoste, Vancanneyt, Kersters and De Ley 1993b, 583[VP]
in'di.gens. L. v. *indigere* to be in need of; M.L. pres. part. *indigens* being in need of, referring to the vitamin requirements.

This species can be differentiated from the other species by its requirement for *p*-aminobenzoic acid, by its ability to grow on itaconate, and by a combination of characteristics given in Table BXII.β.113. Additional characteristics are given in Table BXII.β.114. Cells are thin (0.5–0.7 μm wide) and curved; cell pairs appear slightly S-shaped. Colonies are very compact and difficult to disperse. Growth in liquid media is clumpy; aggregation is very strong on peptone media. Optimal temperature, 40°C. Diazotrophic. The major fatty acids are $C_{10:0\ 3OH}$, $C_{12:0}$, $C_{16:1\ \omega7c}$, $C_{17:0\ cyclo}$, and $C_{18:1}$. Isolated from roots and stem bases of *Leptochloa fusca* (L.) Kunth from Punjab of Pakistan (Reinhold-Hurek et al., 1993b), black sclerotia of an *Ustilago*-related basidiomycete from rice soil in the Punjab of Pakistan (Hurek et al., 1997b), and from rice roots (*Oryza sativa*) from Nepal (Engelhard et al., 2000).

The mol% G + C of the DNA is: 62.4 (T_m).
Type strain: VB32, DSM 12121, LMG 9092.
GenBank accession number (16S rRNA): AF011345.

2. **Azoarcus anaerobius** Springer, Ludwig, Philipp and Schink 1998, 954[VP]
an.a.e.ro'bi.us. Gr. pref. *an* not; Gr. n. *aer* air; Gr. n. *bios* life; N.L. adj. *anaerobius* not living in air, anaerobic.

This species can be differentiated from the others by its strictly anaerobic lifestyle with nitrate as the only electron acceptor. Nitrate is quantitatively reduced to N_2 gas, nitrite is accumulated as an intermediate, and N_2O is not detected. Oxygen is not reduced, even at low partial pressures. Sulfate, thiosulfate, sulfite, sulfur, trimethylamine *N*-oxide, DMSO, $Fe(OH)_3$, $K_3[Fe(CN)_6]$, and fumarate are not reduced. Superoxide dismutase-positive. Additional characteristics are given in Tables BXII.β.113 and BXII.β.114. Optimal temperature, 28°C. pH range, 6.5–8.2; optimal pH, 7.2. Enhanced salt concentration impairs growth. Not diazotrophic. Sole carbon sources for growth include propanol, valerate, pyruvate, cyclohexanecarboxylate, phenol, resorcinol, and *p*-cresol. No growth occurs with L-malate, formate, 5-oxocaproate, pimelate, catechol, hydroquinone, 2-hydroxybenzoate, *o*-cresol, and *m*-cresol. No autotrophic growth occurs with hydrogen or thiosulfate. Isolated from sewage sludge.

The mol% G + C of the DNA is: 65.5 ± 0.5 (T_m).
Type strain: LuFRes1, DSM 12081.
GenBank accession number (16S rRNA): Y14701.

3. **Azoarcus communis** Reinhold-Hurek, Hurek, Gillis, Hoste, Vancanneyt, Kersters and De Ley 1993b, 583[VP]
com'mu.nis. L. masc. adj. *communis* common, referring to diverse habitats.

[a]Symbols: see standard definitions. Blank space, not determined. ±, weakly positive.

This species can be differentiated from the others by its cell width (0.8–1.0 μm), by its growth on D-mandelate and on citrate, and by a combination of characteristics given in Table BXII.β.113. Additional characteristics are given in Table BXII.β.114. Cells are plump and only slightly curved. Optimal temperature, 37°C. Diazotrophic. Some strains grow well at 2% NaCl. The major fatty acids are $C_{10:0\ 3OH}$, $C_{14:0}$, $C_{16:1\ \omega7c}$, $C_{16:0}$, and $C_{18:1}$. Isolated from roots of *L. fusca* (L.) Kunth from Punjab of Pakistan (SWub3) (Reinhold-Hurek et al., 1993b; Engelhard et al., 2000) and from refinery oily sludge in France (Laguerre et al., 1987).

The mol% G + C of the DNA is: 62.4 (T_m).

Type strain: SWub3.

GenBank accession number (16S rRNA): AF011343.

Additional Remarks: The species affiliation of strain LU1, which was isolated from a compost biofilter in Canada (Juteau et al., 1999), is not clear; it has a phylogenetic distance of 2.9% with the type strain.

4. **Azoarcus evansii** Anders, Kaetzke, Kämpfer, Ludwig and Fuchs 1995, 331[VP]

e' van.si.i. L. gen. n. *evansii* of Evans, in honor of the late W.C. Evans, a pioneer in studies of anaerobic aromatic metabolism.

This species can be differentiated from other species by a combination of characters given in Table BXII.β.113. Cells are rods with rounded ends, motile by means of a subpolar flagellum. Yeast extract (0.1%) inhibits growth. Optimal temperature 35–37°C. Optimal pH, 7.8. Does not fix nitrogen. During denitrifying growth on aromatic compounds, nitrite is an intermediate and is reduced mainly to N_2O (strain KB740). Characteristics in addition to those listed in Table BXII.β.114 are as follows. Under anaerobic conditions, the type strain KB740 uses benzoate, phenylacetate, phenylglyoxylate, 3-and 4-hydroxybenzoate, 2-aminobenzoate, 4-hydroxyphenylacetate, phenylalanine, *p*-cresol, 2-fluorobenzoate, benzaldehyde, benzyl alcohol, indolylacetate, *o*-phthalate, adipate, pimelate, cyclohexanecarboxylate, succinate, fumarate, L-malate, acetate, acetone, D-fructose, and D-maltose. Slow growth occurs on glutarate and D-glucose but not on toluene, phenol, 2-hydroxybenzoate, protocatechuate, *o*-and *m*-cresol, indole, ethanol, D-ribose, and D-lactose. Pyridine is used by reference strain pF6 under aerobic and anaerobic conditions. The aerobic metabolism of benzoate is unusual in the type strain KB740, since none of the known pathways—i.e., the conversion of benzoate to catechol (1,2-dihydroxybenzoene) or protocatechuate (3,4-dihydroxybenzoate)—appear to operate in this species (Mohamed et al., 2001). The first step is the activation of benzoate to benzoyl-CoA by a benzoate-CoA ligase, and the second step involves the hydroxylation of benzoyl-CoA by a novel benzoyl-CoA oxygenase (Mohamed et al., 2001). The first step of phenylacetate degradation is catalyzed by two different phenylacetate-CoA-ligases under aerobic and anaerobic conditions, respectively (Mohamed, 2000). Reference strain PF6 degrades pyridine aerobically and anaerobically when growing on nitrate (Rhee et al., 1997). Benzoyl-CoA is also a central intermediate in the anaerobic degradation of aromatic compounds (Harwood et al., 1998). In the type strain KB740, the nucleotide sequence analysis of the gene cluster—including a gene for benzoate-CoA ligase—indicates that the degradation of benzoate is probably similar to the benzoate-CoA pathway in *Thauera aromatica* (Harwood et al., 1998). The major cellular fatty acids are $C_{16:1\ \omega7c}$, $C_{16:0}$, $C_{12:0}$, $C_{10:0\ 3OH}$, and $C_{18:1\ \omega7,\ 9c}$. The major quinone is ubiquinone 8. The species was described with one strain isolated from creek sediment in the United States (Braun and Gibson, 1984). However, a second strain,

[a]Data from Reinhold-Hurek et al. (1993b); Anders et al. (1995); Hurek and Reinhold-Hurek (1995); Zhou et al. (1995); Hurek et al. (1997a); Rhee et al. (1997); Springer et al. (1998); Song et al. (1999); Engelhard et al. (2000); Reinhold-Hurek and Hurek (2000). For all characteristics: ±, intermediate reaction; r, rare; ND, not determined. All strains have the following features: cells are straight to curved rods; oxidase positive; no growth in the presence of 5% NaCl and no growth-rate increase when NaCl is added to medium (ND for *A. toluvorans*, *A. toluclasticus*, *A. anaerobius*); denitrification (ND for *Azonexus* sp.); no spore formation; no starch hydrolysis (ND for *A. evansii* and *A. anaerobius*).

[b]Marked characters were determined for *A. tolulyticus* strain Td-1 or *A. evansii* strain KB740 (Reinhold-Hurek and Hurek, 2000).

[c]Growth on VM ethanol agar (VM) or Congo red agar (CR) at 37°C for 4 d.

[d]Not tested for strain pF6

[e]All strains grow on DL-lactate, succinate, acetate, L-glutamate, butyrate, ethanol (ND for *A. toluvorans* and *A. toluclasticus*) (no substrate but L-malate tested for *A. evansii* pF6); no growth on D(+)-mannose, maltitol, *N*-acetyl-D-glucosamine, D-gluconate, caprate; no growth on[b] (ND for *A. toluclasticus*, *A. toluvorans*, *A. anaerobius*) D(+)-trehalose, L(+)-sorbose, α-D(+)-melibiose, D(+)-raffinose, lactulose, 1-*O*-methyl-β-galactopyranoside, 1-*O*-methyl-α-galactopyranoside, D(+) cellobiose, β-gentiobiose, 1-*O*-methyl-β-D-glucopyranoside, α-L-rhamnose, α-L-fucose, D(+)-arabitol, L(−)-arabitol, xylitol, dulcitol, D-tagatose, *myo*-inositol, D-sorbitol, adonitol, hydroxyquinoline-β-glucuronide, D-lyxose, erythritol, 1-*O*-methyl-α-D-glucopyranosid, 3-*O*-methyl-glucopyranose, D-saccharate, mucate, D-glucuronate, D-galacturonate, 2-keto-D-gluconate, 5-keto-D-gluconate, 3-phenylpropionate, caprylate, 4-aminobutyrate, DL-α-amino-*n*-valerate, trigonelline, putrescine, ethanolamine, D-glucosamine.

[f]Under denitrifying conditions.

pF6, sharing 100% 16S rDNA sequence identity with the type strain, was isolated on pyridine from industrial wastewater in Korea (Rhee et al., 1997).

The mol% G + C of the DNA is: 67.5.

Type strain: DSM 6898, KB740.

GenBank accession number (16S rRNA): X77679.

5. **Azoarcus toluclasticus** Song, Häggblom, Zhou, Tiedje and Palleroni 1999, 1139[VP]
to.lu.clas' ti.cus. N.L. n. Fr. Sp. *tolu* balsam from Santiago de Tolu, toluene; Gr. adj. *clasticus* breaking; M.L. adj. *toluclasticus* toluene-breaking.

This species can be differentiated from the other species by the lack of catalase activity despite its aerobic growth, and also by a combination of characters given in Table BXII.β.113. Additional characteristics are given in Table BXII.β.114. Cells are short motile rods. Optimal temperature, 30°C. Under denitrifying conditions, growth occurs on acetate, benzoate, pyruvate, succinate, D-xylose, L-arabinose, D-ribose, D-galactose, sucrose, lactose, maltose, adipate, lactate, mannitol, aspartate, proline, and arginine. All strains except strain MF23 can use toluene as a growth substrate; strains MF58 and MF63T can also grow on phenol under denitrifying conditions. The strains grow on brain-heart infusion, nutrient and trypticase soy agar, except for strain MF63T, which does not grow on nutrient agar. The predominant fatty acids are $C_{16:0}$ and $C_{16:1\ \omega7c}$. DNA–DNA hybridizations show intermediate similarities (47–55%) among genomovar I (strains MF7 and MF23) and genomovar II (strains MF58, MF63T, and MF441). Isolated from aquifer sediments in the United States.

The mol% G + C of the DNA is: 67.3 (HPLC).

Type strain: MF63, ATCC 700605.

GenBank accession number (16S rRNA): AF123077.

6. **Azoarcus tolulyticus** Zhou, Fries, Chee-Sanford and Tiedje 1995, 505[VP]
to.lu.ly' ti.cus. N.L. n. Fr. Sp. *tolu* balsam from Santiago de Tolu, toluene; Gr. adj. *lyticus* dissolving; N.L. masc. adj. *tolulyticus* toluene dissolving.

This species can be differentiated from the other species by a combination of characters given in Table BXII.β.113. Additional characteristics are given in Table BXII.β.114. Cells are short motile rods that are slightly elongated (to 2.8 μm) when grown on M-R2A agar. Diazotrophic. Optimal temperature, 30°C; growth can occur at 37°C. Under denitrifying conditions, growth occurs on acetate, adipate, arginine, L-arabinose, aspartate, benzoate, fumarate, D-galactose, D-glucose, lactate, lactose, maltose, mannitol, proline, pyruvate, D-ribose, succinate, sucrose, toluene, D-xylose, and 4-hydroxybenzoate. Growth occurs on brain-heart infusion agar but either not at all or only poorly on nutrient and trypticase soy agar. The predominant fatty acids are $C_{16:0}$ and $C_{16:1\ \omega7c}$. Isolated from aquifer sediments and petroleum-contaminated soils in the United States (Fries et al., 1994, 1997; Chee-Sanford et al., 1996).

The mol% G + C of the DNA is: 66.9 (HPLC).

Type strain: Tol-4, CC 51758.

GenBank accession number (16S rRNA): L33694.

Additional Remarks: Strains Td-19 and Td-3 (Zhou et al., 1995) have been removed from the species due to low DNA–DNA hybridization values with the type strain (Song et al., 1999). Other strains of *A. tolulyticus* include strains MF66, 2a1, 3a1, 7a1, BL2, and BL11. The cells of strain MF66 are short motile rods with monopolar flagellation. This strain can grow under aerobic and denitrifying conditions with acetate, benzoate, butyrate, D-fructose, fumarate, D-glucose, phenol, pyruvate, succinate, toluene, D-xylose, L-arabinose, D-ribose, D-galactose, sucrose, lactose, maltose, adipate, lactate, mannitol, aspartate, proline, phenylalanine, or arginine. Under denitrifying conditions, 4-hydroxybenzoate is used as a growth substrate. The cells are oxidase-positive and catalase-negative and grow on brain-heart infusion plates, but do not grow on nutrient and trypticase soy agar plates. The predominant fatty acids are $C_{16:0}$ and $C_{16:1\ \omega7c}$, similar to those of other members of *A. tolulyticus.* It belongs to the species *A. tolulyticus* based on 16S rRNA gene sequence analysis, DNA–DNA hybridization, similar patterns of whole-cell proteins, and genomic DNA analysis. Strains 2a1, 3a1, 7a1, BL2, and BL11 were isolated from northern Michigan, USA, and are short motile rods with monopolar flagellation. They can grow on acetate, benzoate, butyrate, D-fructose, fumarate, D-glucose, pyruvate, succinate, D-xylose, L-arabinose, D-ribose, D-galactose, sucrose, lactose, maltose, adipate, lactate, mannitol, aspartate, proline, or arginine under aerobic and denitrifying conditions and use 4-hydroxy-benzoate and toluene for growth under denitrifying conditions. They grow on brain-heart infusion, nutrient, and trypticase soy agar plates, and give positive reactions in the catalase and oxidase tests. A different colony morphology of these strains on half-strength trypticase soy agar plus nitrate at 30°C for 48 h has been reported (Chee-Sanford et al., 1996). The predominant fatty acids are $C_{16:0}$ and $C_{16:1\ \omega7c}$. Whole cell protein and genomic DNA fragmentation analyses show identical patterns to the other members of *A. tolulyticus*, and 16S rRNA sequence analysis of one strain (BL11) shows a close relationship with the members of *A. tolulyticus.* Thus, they belong to the species *A. tolulyticus.* Because the DNA hybridization values between these isolates and the strains of *A. tolulyticus* are approximately 55%, they constitute a genomovar of this species.

7. **Azoarcus toluvorans** Song, Häggblom, Zhou, Tiedje and Palleroni 1999, 1139[VP]
to.lu.vo' rans. N.L. n. Fr. Sp. *tolu* balsam from Santiago de Tolu, toluene; L. part. adj. *vorans* devouring; M.L. part. adj. *toluvorans* toluene-devouring.

This species can be differentiated from the other species by a combination of characters given in Table BXII.β.113. Additional characteristics are given in Table BXII.β.114. Optimal temperature, 30°C. Growth occurs on brain-heart infusion, nutrient, and trypticase soy agar. Under denitrifying conditions, growth occurs on acetate, benzoate, butyrate, fumarate, phenylacetate, pyruvate, succinate, toluene, D-xylose, L-arabinose, D-ribose, D-galactose, sucrose, maltose, adipate, lactate, mannitol, aspartate, proline, phenylalanine, arginine, 4-hydroxybenzoate, and phenol, and under aerobic conditions on benzene or ethylbenzene. Isolated from soil from industrial area in Brazil (Td17) and uncontaminated organic soil in the United States (Td21) (Fries et al., 1994).

The mol% G + C of the DNA is: 67.8 (HPLC).

Type strain: Td21, ATCC 700604.

GenBank accession number (16S rRNA): L33692.

Other Organisms

1. *Azoarcus* sp. strain BH72 Reinhold-Hurek, Hurek, Gillis, Hoste, Vancanneyt, Kersters and De Ley 1993b, 582.

   This unnamed strain differs at the species level by having a DNA–DNA hybridization value of ≤25% with other species. It can be differentiated from the other species by its lack of growth on L-phenylalanine and a combination of characteristics given in Table BXII.β.113. Additional characteristics are given in Table BXII.β.114. Cells are long, thin (0.6–0.8 μm wide) and slightly curved, elongated (8–12 μm) cells occurring in late log or in stationary phase culture on N-free or ammonium-supplemented SM medium. The optimal temperature for growth is 40°C. Diazotrophic. The major fatty acids are$C_{16:0}$, $C_{16:1\,\omega7c}$, $C_{18:1}$, $C_{18:1}$, and $C_{14:0}$. Isolated from the root interior of *Leptochloa fusca* (L.) Kunth from Punjab of Pakistan (Reinhold et al., 1986).

   The mol% G + C of the DNA is: 67.6 (T_m).

   GenBank accession number (16S rRNA): AF011344.

Additional Remarks: A wide range of strains have been isolated under conditions of denitrification, mostly on aromatic carbon sources, which cluster within the clade of soil-borne *Azoarcus* species according to phylogenetic analysis of 16S rDNA sequences (Fig. BXII.β.106); however, data are not sufficient for the assignment to given species. As described above, some are only distantly related and may thus deserve the rank of separate species in future. Examples of strains and habitats are: EbN1, PbN1, isolated on ethylbenzene from freshwater mud, Germany (Rabus and Widdel, 1995); Lin22, isolated on cyclohexane-1,2-diol from activated sludge, Germany (Harder, 1997); pCyN1, isolated on *p*-cymene from freshwater mud, Germany (Harms et al., 1999a); CC-11, isolated from a 3-year-enrichment culture on phenol, Japan (Shinoda et al., 2000); M3, isolated on toluene from a diesel-fuel contaminated aquifer, Switzerland (Hess et al., 1997); CR23, isolated on phenol from creek in Costa Rica (van Schie and Young, 1998).

Genus III. **Azonexus** *Reinhold-Hurek and Hurek 2000, 658[VP]*

THE EDITORIAL BOARD

A.zo' nex.us. Fr. n. *azote* nitrogen; L. masc. n. *nexus* coil; M.L. masc. n. *Azonexus* nitrogen-fixing coil.

Gram-negative somewhat curved motile rods (0.6–0.8 × 1.5–4.0 μm). **Cells elongated and coiled in stationary phase.** One polar flagellum. Chemoorganoheterotrophic and aerobic; microaerophilic when fixing nitrogen. Strictly respiratory; O_2 is the electron acceptor. Oxidase and catalase positive. **Fix N_2.** Require cobalamine. Grow on acetate, ethanol, fumarate, DL-lactate, L-malate, 2-oxoglutarate, L-proline, and succinate.

The mol% G + C of the DNA is: not known.

Type species: **Azonexus fungiphilus** Reinhold-Hurek and Hurek 2000, 658.

FURTHER DESCRIPTIVE INFORMATION

Azonexus fungiphilus is notable for its tendency to produce elongated (up to 50 μm) cells in early stationary phase cultures (Reinhold-Hurek and Hurek, 2000). These elongated cells appear to break up into curved segments later in stationary phase.

Azonexus fungiphilus strains were recovered from fungal resting stages obtained from the rhizosphere of rice plants in Pakistan (Hurek et al., 1997b).

Analysis of 16S rDNA sequences placed *Azonexus* in the *Betaproteobacteria*; in these analyses, *Azonexus* was most closely related to members of the genera *Thauera* and *Rhodocyclus*. *Azonexus* strains could be separated from *Azoarcus*, *Azospira*, and *Azovibrio* strains by comparisons of fatty acid composition, SDS-soluble protein electrophoretic patterns, and BOX-PCR genomic fingerprinting. DNA–DNA hybridization results supported these divisions (Hurek et al., 1997b; Reinhold-Hurek and Hurek, 2000).

ENRICHMENT AND ISOLATION PROCEDURES

Enrichment and isolation procedures are described in Reinhold et al. (1986).

MAINTENANCE PROCEDURES

Maintenance and long-term storage procedures are described in Reinhold-Hurek et al. (1993b).

DIFFERENTIATION OF THE GENUS *AZONEXUS* FROM OTHER GENERA

Reinhold-Hurek and Hurek (2000) provide tables of characteristics that differentiate the genera *Azoarcus*, *Azonexus*, *Azospira*, and *Azovibrio* from each other and from *Acetobacter diazotrophicus*, *Burkholderia vietnamensis*, the genus *Azospirillum*, and the genus *Herbaspirillum* (see also Table BXII.β.112 in the chapter on *Azoarcus*).

TAXONOMIC COMMENTS

This genus was first described as *Azoarcus* sp. group E (Hurek et al., 1997b; Reinhold-Hurek and Hurek, 2000).

List of species of the genus Azonexus

1. **Azonexus fungiphilus** Reinhold-Hurek and Hurek 2000, 658[VP]

   fun.gi' phil.us. M.L. masc. n. *fungi* mushrooms, fungi; Gr. adj. *philos* loving; M.L. masc. adj. *fungiphilus* loves mushrooms or fungi, referring to its source of isolation.

   Description as for the genus with the following additional characteristic: grows on L-aspartate, L-glutamate, and 3-hydroxybutyrate.

   The mol% G + C of the DNA is: unknown.

   Type strain: BS5-8.

   GenBank accession number (16S rRNA): AF011350.

Genus IV. **Azospira** *Reinhold-Hurek and Hurek 2000, 658*[VP]

THE EDITORIAL BOARD

A.zo' spi.ra. Fr. n. *azote* nitrogen; L. fem. n. *spira* winding, turn; M.L. fem. n. *Azospira* nitrogen-fixing spiral.

Gram-negative curved motile rods (0.4–0.6 × 1.1–2.5 μm). One polar flagellum. **Cells elongated in stationary cultures.** Chemoorganoheterotrophic and aerobic; microaerophilic when fixing N_2. Strictly respiratory; O_2 and nitrate are electron acceptors. Oxidase and catalase positive. **Fix N_2.** Grow on acetate, *n*-caproate, ethanol, fumarate, L-glutamate, DL-lactate, L-malate, 2-oxoglutarate, propionate, and succinate.

The mol% G + C of the DNA is: 65–66.

Type species: **Azospira oryzae** Reinhold-Hurek and Hurek 2000, 658.

FURTHER DESCRIPTIVE INFORMATION

Azospira oryzae cells become elongated (up to 8 μm) in stationary phase cultures and acquire at least one helical turn (Reinhold-Hurek and Hurek, 2000).

Azospira oryzae 6a3 was isolated from the roots of Kallar grass collected in Pakistan (Reinhold-Hurek et al., 1993b). Other strains have been isolated from roots of *Oryza officinalis*, *O. minuta*, and *O. sativa*.

Analysis of 16S rDNA sequences placed *Azospira* in the *Betaproteobacteria*; in these analyses, *Azospira* was most closely related to members of the genera *Thauera* and *Rhodocyclus*. *Azospira* strains could be separated from *Azoarcus*, *Azonexus*, and *Azovibrio* strains by comparisons of fatty acid composition, SDS-soluble protein electrophoretic patterns, and BOX-PCR genomic fingerprinting. DNA–DNA hybridization results supported these divisions (Hurek et al., 1997b; Reinhold-Hurek and Hurek, 2000).

ENRICHMENT AND ISOLATION PROCEDURES

Enrichment and isolation procedures are described in Reinhold et al. (1986).

MAINTENANCE PROCEDURES

Maintenance and long-term storage procedures are described in Reinhold-Hurek et al. (1993b).

DIFFERENTIATION OF THE GENUS *AZOSPIRA* FROM OTHER GENERA

Reinhold-Hurek and Hurek (2000) provide tables of characteristics that differentiate the genera *Azoarcus*, *Azonexus*, *Azospira*, and *Azovibrio* from each other and from *Acetobacter diazotrophicus*, *Burkholderia vietnamensis*, the genus *Azospirillum*, and the genus *Herbaspirillum* (see also Table BXII.β.112 in the chapter on *Azoarcus*).

TAXONOMIC COMMENTS

This genus was first described as *Azoarcus* sp. group D (Reinhold-Hurek et al., 1993b; Hurek et al., 1997b; Reinhold-Hurek and Hurek, 2000).

List of species of the genus Azospira

1. **Azospira oryzae** Reinhold-Hurek and Hurek 2000, 658[VP]
o' ry.zae. L. fem. *Oryza* genus name of rice; L. gen. n. *oryzae* from rice, referring to its frequent occurrence in association with rice roots.

Description as for the genus with the following additional characteristics. Optimal growth at 40°C. Utilizes L-aspartate, L-glutamate, 3-hydroxybutyrate, isovalerate, and D-tartrate.

The mol% G + C of the DNA is: 65.2.

Type strain: 6a3, LMG9096.

GenBank accession number (16S rRNA): AF011347.

Genus V. **Azovibrio** *Reinhold-Hurek and Hurek 2000, 657*[VP]

THE EDITORIAL BOARD

A.zo' vi.bri.o. Fr. n. *azote* nitrogen; L. v. *vibrare* move rapidly to and fro, vibrate; M.L. masc. n. *Azovibrio* nitrogen-fixing organism which vibrates.

Gram-negative somewhat curved motile rods (0.6–0.8 × 1.5–3.6 μm). One polar flagellum. Chemoorganoheterotrophic and microaerophilic. Strictly respiratory; O_2 and nitrate are electron acceptors. Oxidase positive. **Fix N_2.** Grow on acetate, ethanol, fumarate, L-glutamate, DL-lactate, L-malate, propionate, and succinate.

The mol% G + C of the DNA is: 64–65.

Type species: **Azovibrio restrictus** Reinhold-Hurek and Hurek 2000, 657.

FURTHER DESCRIPTIVE INFORMATION

Azovibrio restrictus does not form the elongated cells seen in stationary cultures of *Azospira oryzae* and *Azonexus fungiphilus* (Reinhold-Hurek and Hurek, 2000).

Azovibrio restrictus S5b2 was isolated from the roots of Kallar grass collected in Pakistan (Reinhold-Hurek et al.,1993b). Other strains were isolated from roots of *Oryza sativa* and from fungal sclerotia found in soil on which rice was grown.

Analysis of 16S rDNA sequences placed *Azovibrio* in the *Betaproteobacteria*; in these analyses, *Azovibrio* was most closely related to members of the genera *Thaurea* and *Rhodocyclus*. *Azovibrio* strains could be separated from *Azoarcus*, *Azospira*, and *Azonexus* strains by comparisons of fatty acid composition, SDS-soluble protein electrophoretic patterns, and BOX-PCR genomic fingerprinting. DNA–DNA hybridization results supported these divisions (Hurek et al., 1997b; Reinhold-Hurek and Hurek, 2000).

ENRICHMENT AND ISOLATION PROCEDURES

Enrichment and isolation procedures are described in Reinhold et al. (1986).

Maintenance Procedures

Maintenance and long-term storage procedures are described in Reinhold-Hurek et al. (1993b).

Differentiation of the genus *Azovibrio* from other genera

Reinhold-Hurek and Hurek (2000) provide tables of characteristics that differentiate the genera *Azoarcus*, *Azonexus*, *Azospira*, and *Azovibrio* from each other and from *Acetobacter diazotrophicus*, *Burkholderia vietnamensis*, the genus *Azospirillum*, and the genus *Herbaspirillum*.

Taxonomic Comments

This genus was first described as *Azoarcus* sp. group C (Reinhold-Hurek et al., 1993b; Hurek et al., 1997b; Reinhold-Hurek and Hurek, 2000).

List of species of the genus Azovibrio

1. **Azovibrio restrictus** Reinhold-Hurek and Hurek 2000, 657[VP]
re′stric.tus. L. adv. *restrictus* limited, restricted, referring to the restricted spectrum of carbon sources used for growth.

Description as for the genus with the following additional characteristic: grows on L-aspartate.

The mol% G + C of the DNA is: 64.8 (T_m).

Type strain: S5b2.

GenBank accession number (16S rRNA): AF011346.

Genus VI. **Dechloromonas** *Achenbach, Michaelidou, Bruce, Fryman and Coates 2001, 531*[VP]

The Editorial Board

De.chlo.ro.mo′nas. L. pref. *de* from; Gr. adj. *chloros* green (chlorine); Gr. fem. n. *monas* unit, monad; N.L. fem. n. *Dechloromonas* a dechlorinating monad.

Gram-negative, nonsporeforming, facultatively anaerobic, motile rods (0.5 × 2 μm). Strictly respiratory metabolism. **Chlorate and perchlorate reduced to chloride**; organic electron donors. O_2 also serves as an electron acceptor; some strains use nitrate as an electron acceptor.

The mol% G + C of the DNA is: 63.5.

Type species: **Dechloromonas agitata** Achenbach, Michaelidou, Bruce, Fryman and Coates 2001, 531.

Further descriptive information

Dechloromonas agitata was isolated from paper plant pulp sludge (Achenbach et al., 2001).

Dechloromonas agitata can use acetate, butyrate, fumarate, malate, propionate, succinate, yeast extract, Fe(II), sulfide, and reduced 2,6-anthrahydroquinone as electron donors; it does not use benzene, benzoate, citrate, Casamino acids, citrate, ethanol, formate, glucose, hexadecane, hydrogen, methanol, *N*-octane, palmitate, phenol, or toluene. Electron acceptors include chlorate, perchlorate, and oxygen (Bruce et al., 1999).

Analysis of 16S rDNA sequences of *Dechloromonas agitata* and ten other isolates placed them in the *Betaproteobacteria* and showed that they are allied to the genera *Rhodocyclus* and *Azoarcus* (Achenbach et al., 2001).

Enrichment and Isolation Procedures

Enrichment cultures were prepared using environmental samples suspended and incubated in anaerobic liquid medium that contains 10 mM acetate as electron donor and 10 mM chlorate as electron acceptor (Bruce et al., 1999; Coates et al., 1999). Pure cultures can be achieved using the same medium and the agar-shake serial dilution method described by Pfennig and Biebl (1981).

Differentiation of the genus *Dechloromonas* from other genera

Dechloromonas agitata can be distinguished from *Dechlorosoma suillum* by the ability of the former to use Fe(II), sulfide, and reduced 2,6-anthrahydroquinone sulfonate as electron donors for chlorate reduction (Achenbach et al., 2001).

List of species of the genus Dechloromonas

1. **Dechloromonas agitata** Achenbach, Michaelidou, Bruce, Fryman and Coates 2001, 531[VP]
a.gi.ta′ta. L. fem. part. adj. *agitata* agitated, highly active.

Description as for the genus with the following additional characteristics. Electron donors include acetate, butyrate, fumarate, malate, propionate, succinate, yeast extract, Fe(II), sulfide, and reduced 2,6-anthrahydroquinone. Electron acceptors include chlorate, perchlorate, and oxygen. Growth optima at 1% NaCl, pH 7.5, and 35°C.

The mol% G + C of the DNA is: 63.5 (HPLC).

Type strain: CKB, ATCC 700666, DSM 13637.

GenBank accession number (16S rRNA): AF 047462.

Genus VII. **Dechlorosoma** *Achenbach, Michaelidou, Bruce, Fryman and Coates 2001, 531*[VP]

THE EDITORIAL BOARD

De.chlo.ro.so′ma. L. pref. *de* from; Gr. adj. *chloros* green (chlorine); Gr. neut. n. *soma* body; N.L. neut. n. *Dechlorosoma* dechlorinating body.

Gram-negative, nonsporeforming motile rods (0.3 × 1.0 μm). **Nonfermentative facultative anaerobes. Chlorate and perchlorate reduced to chloride; organic electron donors.** O_2 and nitrate also serve as electron acceptors.

The mol% G + C of the DNA is: 65.8.

Type species: **Dechlorosoma suillum** Achenbach, Michaelidou, Bruce, Fryman and Coates 2001, 532.

FURTHER DESCRIPTIVE INFORMATION

Dechlorosoma suillum strains were isolated from samples from a swine waste treatment lagoon (Coates et al., 1999).

Dechlorosoma suillum PS is able to grow with acetate, butyrate, ethanol, fumarate, isobutyrate, lactate, malate, pyruvate, succinate, valerate, and Casamino acids as electron donors; it does not use benzoate, catechol, citrate, formate, glucose, glycerol, methanol, or hydrogen as electron donors. Chlorate, nitrate, and oxygen can serve as electron acceptors for growth on acetate; 2,6-anthraquinone disulfonate, fumarate, malate, selenate, sulfate, Fe(III), and Mn(IV) cannot (Coates et al., 1999).

Analysis of 16S rDNA sequences of *Dechlorosoma suillum* PS and three other isolates placed them in the *Betaproteobacteria* and showed that they are allied to the genera *Rhodocyclus* and *Azoarcus* (Achenbach et al., 2001).

ENRICHMENT AND ISOLATION PROCEDURES

Enrichment cultures can be prepared using environmental samples suspended and incubated in anaerobic liquid medium that was 10 mM in both acetate and chlorate as electron donor and acceptor, respectively (Bruce et al., 1999; Coates et al., 1999). Pure cultures can be achieved using the same medium and the agar-shake serial dilution method described by Pfennig and Biebl (1981).

DIFFERENTIATION OF THE GENUS *DECHLOROSOMA* FROM OTHER GENERA

Dechlorosoma suillum can be distinguished from *Dechloromonas agitata* by the ability of the latter to use 2,6-anthrahydroquinone sulfonate, Fe(II), and sulfide as electron donors for chlorate reduction (Achenbach et al., 2001).

1. **Dechlorosoma suillum** Achenbach, Michaelidou, Bruce, Fryman and Coates 2001, 532[VP]
su.il′lum. L. neut. adj. *suillum* pertaining to swine.

Description as for the genus with the following additional characteristics. Electron donors include acetate, butyrate, Casamino acids, ethanol, lactate, and propionate. Electron acceptors include chlorate, nitrate, oxygen, and percholorate. Reduce nitrate to N_2. Growth optima at 0% NaCl, pH 6.5, and 37°C.

The mol% G + C of the DNA is: 75.8 (HPLC).

Type strain: PS, ATCC BAA-33, DSM 13638.

GenBank accession number (16S rRNA): AF 170348.

Genus VIII. **Ferribacterium** *Cummings, Caccavo, Spring and Rosenzweig 2000, 1953*[VP]*(Effective publication: Cummings, Caccavo, Spring and Rosenzweig 1999, 187)*

THE EDITORIAL BOARD

Fer′ri.bac.te′ri.um. L. neut. n. *ferrum* iron; Gr. neut. n. *bacterion* a small rod; M.L. neut. n. *Ferribacterium* rod-shaped iron bacterium.

Strictly anaerobic straight or curved rods (0.3–0.5 × 1.4–2.0 μm); contain poly-β-hydroxybutyrate granules. Nonsporeforming. **Oxidizes acetate, benzoate, formate, and lactate using Fe(III) as the electron acceptor**; also oxidizes acetate using fumarate, or nitrate as electron acceptors.

The mol% G + C of the DNA is: unknown.

Type species: **Ferribacterium limneticum** Cummings, Caccavo, Spring and Rosenzweig 2000, 1953 (Effective publication: Cummings, Caccavo, Spring and Rosenzweig 1999, 187.)

FURTHER DESCRIPTIVE INFORMATION

Ferribacterium limneticum CdA-1 was isolated from a sediment core taken in Lake Coeur d'Alene, Idaho, USA (Cummings et al., 1999).

Ferribacterium limneticum CdA-1 is a strict anaerobe that grows only when Fe (III) is present in the medium; it does not grow in a complex organic medium. Electron donors are acetate, benzoate, formate, and lactate. Citrate, ethanol, glucose, isopropanol, methanol, propionate, and succinate are not used as electron donors. As (V), Mn (IV), Se (VI), nitrite, sulfate, sulfite, thiosulfate, and trimethylamine are not used as electron acceptors when acetate is the electron donor (Cummings et al., 1999).

An analysis of 16S rDNA sequences showed that *Ferribacterium limneticum* CdA-1 belongs to the class *Betaproteobacteria* (Cummings et al., 1999).

ENRICHMENT AND ISOLATION PROCEDURES

Enrichment in liquid medium was carried out under anaerobic conditions using acetate as the electron donor and amorphous ferric oxyhydroxide as the electron acceptor (Cummings et al., 1999). Incubation for four months resulted in blackening of the culture; the organism was recovered by streaking onto solid medium containing Fe (III) pyrophosphate as electron acceptor.

List of species of the genus Ferribacterium

1. **Ferribacterium limneticum** Cummings, Caccavo, Spring and Rosenzweig 2000, 1953[VP] (Effective publication: Cummings, Caccavo, Spring and Rosenzweig 1999, 187.)
lim.ne′ ti.cum. L. neut. n. *limne* lake; N.L. adj. *limneticum* from a lake.
The description is the same as that of the genus.
The mol% G + C of the DNA is: unknown.
Type strain: CdA-1.
GenBank accession number (16S rRNA): Y17060.

Genus IX. **Propionibacter** *Meijer, Nienhuis-Kuiper and Hansen 1999, 1042*[VP]

THEO A. HANSEN

Pro.pioni.bac′ ter. M.L. n. *acidum propionicum* propionic acid; M.L. masc. n. *bacter* equivalent of Gr. neut. n. *bakterion* small rod; M.L. masc. n. *Propionibacter* propionic acid rod.

Rods 0.9–1.1 × 0.5–0.6 μm. Motile by means of a single polar flagellum. Multiply by binary fission. Gram negative. Do not form spores. **Anaerobic.** Can grow in stationary cultures under an air atmosphere, but not in well-aerated cultures. In the absence of nitrate, **substrates are fermented to propionate and acetate**. Growth occurs on simple organic compounds (sugars, dicarboxylic acids, sugar alcohols, and aspartate). Nitrate is reduced to nitrite. **Utilize N_2 as nitrogen source.** Isolated from estuary mud.

The mol% G + C of the DNA is: 61.

Type species: **Propionibacter pelophilus** Meijer, Nienhuis-Kuiper and Hansen 1999, 1043.

ENRICHMENT AND ISOLATION PROCEDURES

Propionibacter has been obtained by direct anaerobic isolation from black surface mud of the Ems-Dollard estuary at the border between the Netherlands and Germany. Roll tubes with aspartate medium are used (Hansen et al., 1990). Strain asp 66, the type strain of *Propionibacter pelophilus*, is the most numerous aspartate-fermenting bacterium.

MAINTENANCE PROCEDURES

DSM Medium 503 (FWM medium; Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH, Braunschweig, Germany) supplemented with 0.2 g/l yeast extract and 20 mM aspartate or another suitable energy substrate can be used for routine cultivation. For long-term preservation, the organism can be stored in ampules in medium supplemented with 8% glycerol under liquid nitrogen or at −80°C.

DIFFERENTIATION OF THE GENUS *PROPIONIBACTER* FROM OTHER GENERA

Propionibacter is most closely related to *Propionivibrio* (Tanaka et al., 1990; Hippe et al., 1999) based on the 16S rDNA sequences (approximately 3% difference between the type species). Both genera have a (mainly) fermentative metabolism with propionate and acetate as characteristic products. *Propionibacter* cells are straight rods, whereas *Propionivibrio* consists of curved rods. *Propionibacter* uses a wider range of substrates than does *Propionivibrio*; the latter is restricted to C_4-dicarboxylic acids.

Characteristics that differentiate *Propionibacter* from other genera and species of bacteria that carry out propionic fermentation are listed in Table BXII.β.115.

TAXONOMIC COMMENTS

In this edition of the *Manual*, the genus *Propionibacter* is placed in the class *Betaproteobacteria*, the order *Rhodocyclales*, and the family *Rhodocyclaceae*. Other genera included in this family are *Rhodocyclus*, *Azoarcus*, *Azonexus*, *Azospira*, *Azovibrio*, *Ferribacterium*, *Propionivibrio*, *Thauera*, and *Zoogloea*.

The phylogenetic positions of *Propionibacter* and *Propionivibrio* have become clear only recently (Hippe et al., 1999; Meijer et al., 1999). The small difference in 16S rRNA gene sequence (approximately 3%) and the similarity in fermentative patterns would support a possible inclusion of *Propionibacter* in *Propionivibrio*; this, however, would require an emendation of the genus *Propionivibrio* as described by Tanaka et al. (1990).*

List of species of the genus Propionibacter

1. **Propionibacter pelophilus** Meijer, Nienhuis-Kuiper and Hansen 1999, 1043[VP]
pe.lo′ phi.lus. Gr. n. *pelos* mud; Gr. adj. *philus* loving; M.L. adj. *pelophilus* mud-loving.

Characteristics are as described for the genus, with the following additional features. Gram-negative cell envelope ultrastructure with an outer membrane. Colonies on anaerobic plates with aspartate are slimy white. Best growth occurs under anoxic conditions in sulfide-reduced media. Growth occurs in mineral media with a single fermentable substrate.

The following are utilized as energy sources: L-aspartate, fumarate, L-malate, pyruvate, oxaloacetate, citrate, fructose, glucose, xylose, gluconate, arabitol, xylitol, mannitol, arabinose, and mannose. The following substrates are not used: L-alanine, L-serine, L-threonine, L-methionine, L-glutamate, L-histidine, L-arginine, L-lysine, lactate, α-ketoglutarate, glycolate, succinate, propionate, butyrate, glycerol, ethanol, propanol, 2,3-butanediol, acetoin, cellulose, cellobiose, lactose, sucrose, maltose, melibiose, starch, sorbose, rhamnose, galactose, sorbitol, pectin, peptone, xylan, and inulin.

Indole and urease negative. Gelatin is not liquefied. Growth occurs on glucose and aspartate at pH 6.5–8.5 (optimal pH 7.5–8.0). The final pH of glucose-fermenting cul-

**Editorial Note:* While this volume of the *Manual* was in preparation, Brune et al. (2002) published a valid proposal to transfer the type species of the genus *Propionibacter*, *Propionibacter pelophilus*, to the genus *Propionivibrio*. Since the genus *Propionibacter* was monospecific, bacteriologists adhering to the proposal recognize that the genus *Propionibacter* thereby ceased to exist.

TABLE BXII.β.115. Characteristics that differentiate the genus *Propionibacter* from other genera and species of anaerobic bacteria that carry out a propionate fermentation[a]

Propionate and acetate formed as end products of fermentation. Succinate decarboxylated to propionate. Mesophilic. Member of the class *Betaproteobacteria.*

The mol% G + C of the DNA is: 60.8–61.6.

Type species: **Propionivibrio dicarboxylicus** Tanaka, Nakamura and Mikami 1991b, 331 (Effective publication: Tanaka, Nakamura and Mikami 1990, 327.)

List of species of the genus Propionivibrio

1. **Propionivibrio dicarboxylicus** Tanaka, Nakamura and Mikami 1991b, 331[VP] (Effective publication: Tanaka, Nakamura and Mikami 1990, 327.)
di.car.bo.xy' li.cus. M.L. adj. *dicarboxylicus* pertaining to dicarboxylic acid.

Gram-negative, curved to helical rods with tapered and rounded ends, 0.5–0.6 × 1.0–2.0 μm. Chains are helical. Motile in an active tumbling motion by means of a single polar flagellum. Catalase negative. Do not reduce nitrate, sulfate, sulfite, thiosulfate, or S^0. Utilize maleate, fumarate, and L-malate as carbon and energy sources, forming propionate and acetate as end products. Succinate decarboxylated to propionate. Do not utilize acetoin, acrylate, corn oil, crotonate, formate, glycerol, H_2/CO_2/acetate, lactate, peptone, pyruvate, yeast extract, monosaccharides, disaccharides, or trisaccharides. Optimal temperature 30°C (range 26–34°C); no growth at 20°C or 40°C. Optimal pH 6.7 (range 6.2–7.1). Habitat: anaerobic mud of freshwater sediments.

The mol% G + C of the DNA is: 61.
Type strain: CreMal1, DSM 5885, JCM 7784.
GenBank accession number (16S rRNA): Y17601.

2. **Propionivibrio limicola** Brune, Ludwig and Schink 2002, 443[VP]
li.mi' co.la. L. n. *limus* mud; L. v. *colere* to inhabit; N.L. n. *limicola* living in mud.

Gram-negative; straight, slender rods, 0.6–0.7 × 1.5–2.5 μm. Motile by single polar flagella. Oxidase and catalase negative; superoxide dismutase positive. Do not form spores. Chemoorganotrophic. Fermentative metabolism, utilizing quinic acid and shikimic acid and producing acetate, propionate, and CO_2. No external electron acceptors utilized. Does not utilize sugars, alcohols, carboxylic acids, amino acids, or aromatic compounds. Aerotolerant; grows in unreduced media when incubated under air without agitation. Optimal temperature: 37°C; no growth at 45°C. pH range: 6.0–8.0; optimal pH: 7.0–7.5. Optimal growth in freshwater media. Growth inhibited in brackish media with 10 g/l NaCl and 1.0 g/l $MgCl_2$. Habitat: anoxic freshwater sediments.

The mol% G + C of the DNA is: 61.6 ± 2.
Type strain: GolChi1, ATCC BAA-290, DSM 6832.
GenBank accession number (16S rRNA): AJ307983.

3. **Propionivibrio pelophilus** (Meijer, Nienjuis-Kuiper and Hansen 1999) Brune, Ludwig and Schink 2002, 444^{VP} (*Propionibacter pelophilus* Meijer, Nienhuis-Kuiper and Hansen 1999, 1043.)*

pe.lo′ phi.lus. Gr. n. *pelos* mud; Gr. adj. *pelophilus* mud-loving.

Growth occurs in mineral media with a single fermentable substrate. The following are utilized as energy sources: L-aspartate, fumarate, L-malate, pyruvate, oxaloacetate, citrate, fructose, glucose, xylose, gluconate, arabitol, xylitol, mannitol, arabinose, and mannose. The following substrates are not used: L-alanine, L-serine, L-threonine, L-methionine, L-glutamate, L-histidine, L-arginine, L-lysine, lactate, α-ketoglutarate, glycolate, succinate, propionate, butyrate, glycerol, ethanol, propanol, 2,3-butanediol, acetoin, cellulose, cellobiose, lactose, sucrose, maltose, melibiose, starch, sorbose, rhamnose, galactose, sorbitol, pectin, peptone, xylan, and inulin. Indole and urease negative. Gelatin is not liquefied. Growth occurs on glucose and aspartate at pH 6.5–8.5 (optimal pH 7.5–8.0). The final pH of glucose-fermenting cultures is pH 5.5. Sulfate can be used as a sulfur source; growth in the absence of sulfide leads to cell clumps. Nitrate reduced to nitrite. N_2 utilized as nitrogen source. Optimal temperature 27–30°C; no growth at 35°C. Habitat: anoxic freshwater and estuarine sediments.

The mol% G + C of the DNA is: 60.8.

Type strain: asp 66, CIP 106101, DSM 12018.

GenBank accession number (16S rRNA): AF016690.

**Editorial Note:* This description of *Propionivibrio pelophilus* is that of *Propionibacter pelophilus* and has been reproduced here from the preceding chapter because of a proposal to transfer *Propionibacter pelophilus* to the genus *Propionivibrio.*

Genus XI. **Thauera** *Macy, Rech, Auling, Dorsch, Stackebrandt and Sly 1993, 139^{VP} emend. Song, Young and Palleroni 1998, 893*

JOHANN HEIDER AND GEORG FUCHS

Thau′ e.ra. M.L. fem. n. *Thauera* named after R.K. Thauer, a German microbiologist.

Rods 0.5–1.4 × 1.4–3.7 μm, usually occurring singly. Some species exhibit great variability of cell form, from rods to coccoid forms of different sizes. Gram negative. **Most species are motile.** No resting stages known. **Oxidase positive.** Catalase positive. Colonies on minimal medium are nonpigmented. **Aerobic,** having a strictly respiratory type of metabolism; never fermentative. **Molecular oxygen, nitrate, nitrite, and nitrous oxide are used as terminal electron acceptors,** and the nitrogen oxides are reduced to N_2O or N_2; one species also uses selenate, which is reduced to elemental Se. Optimal temperature 28–40°C. All species grow at pH 7.5; pH optima of different species range from 7.2 to 8.4. **Chemoorganotrophic, using various organic acids, amino acids, and aromatic and aliphatic compounds** as sole substrates. Only a **few carbohydrates are utilized**. Ammonium and nitrate salts can be used as sole nitrogen sources. **No N_2 fixation** known. Not proteolytic on casein or gelatin. Starch, cellulose, chitin, and agar are not hydrolyzed. Occur in polluted freshwater and wet soil environments and wastewater treatment plants.

The mol% G + C of the DNA is: 64–69.

Type species: **Thauera selenatis** Macy, Rech, Auling, Dorsch, Stackebrandt and Sly 1993, 140.

FURTHER DESCRIPTIVE INFORMATION

Cell morphology and fine structure Cells of *Thauera* spp. are usually rods 0.5–1.0 μm in width and 1.4–3.4 μm in length. Variation in cell size is commonly observed in liquid cultures. Most strains have been found to accumulate poly-β-hydroxybutyrate granules in the late growth phase. Flagella are usually present; flagellar insertion in the described species is either polar monotrichous or peritrichous with up to eight flagella; cells of some strains have either no flagella or a single flagellum inserted at any point, which has been termed "degenerately peritrichous" (Song et al., 1998). No sheaths, capsules, or other extracellular features are known.

Colonial and cultural characteristics A red-brown pigmentation is observed in densely packed cells or in colonies on solid medium, which is due to normal cell constituents, e.g., ferredoxins or cytochromes. Therefore, *Thauera* spp. can be classified as nonpigmented. Exceptions are the production of large amounts of insoluble red elemental selenium by *T. selenatis* growing under selenate-reducing conditions and the production of an as yet uncharacterized red pigment (metabolic intermediate or side product) by *T. aromatica* strain AR-1 growing anaerobically on α-resorcylate in the presence of nitrate (Gallus et al., 1997).

Lipid composition Major fatty acids contained in membrane lipids are *cis*-9-hexadecenoate ($C_{16:1\ \omega 7c}$), hexadecanoate ($C_{16:0}$), and *cis*-11-octadecenoate ($C_{18:1\ \omega 7c}$). Relative amounts of these fatty acids in different species are 41–58%, 19–32%, and 10–16%, respectively. Less abundant fatty acids found in amounts of <8% in all species are dodecanoate ($C_{12:0}$) and 3-hydroxydecanoate ($C_{10:0\ 3OH}$). Small amounts (0.7–2.1%) of a cyclic fatty acid ($C_{17:0\ cyclo}$) produced in the stationary growth phase have been reported as a characteristic property of *T. aromatica* and *T. chlorobenzoica* strains, whereas they are lacking in *T. selenatis*, *T. linaloolentis*, *T. terpenica*, and *Azoarcus* spp. (Song et al., 2000a, 2001).

Nutrition and growth conditions *Thauera* species grow in mineral medium with ammonium ions or nitrate as the nitrogen source and simple organic compounds as sole carbon and energy sources. Only a few species require organic growth factors. All species are chemoorganotrophic and obligately respiratory, requiring either oxygen or an alternative final electron acceptor, such as nitrate, nitrite, nitrous oxide, or selenate. The optimal growth temperature for most species is around 30°C, but one species has an optimal of 40°C.

Metabolism and metabolic pathways All species are obligately respiratory, but can shift between aerobic respiration and denitrification (dissimilatory nitrate reduction to N_2O or N_2). One species is capable of anaerobic respiration on selenate. The first step, reduction of selenate to selenite, is catalyzed by a unique periplasmic selenate reductase, an enzyme containing a molybdenum cofactor, iron–sulfur clusters, and a cytochrome *b*

(Schröder et al., 1997; Krafft et al., 2000). Three of the known species catabolize various aromatic compounds anaerobically under denitrifying conditions. Two other species catabolize terpenoids, but not aromatic compounds, in the absence of oxygen. Whereas not much is known about the biochemistry involved in terpenoid metabolism, the anaerobic metabolism of aromatic substrates has been well studied. All tested species can catabolize some aromatic compounds under aerobic conditions. The aromatic substrates utilized aerobically and under denitrifying conditions are not necessarily the same, and the presence of completely different pathways for the same substrates has been demonstrated for *T. aromatica* and the physiologically similar *Azoarcus evansii* (Ziegler et al., 1989; Altenschmidt et al., 1993; Heider et al., 1998; Mohamed, 2000). Many organic acids and several amino acids serve as sole substrates aerobically and anaerobically for all species, whereas most species are very limited in their capacities to catabolize sugars.

Metabolism of aromatic compounds Aromatic substrates that are utilized under anaerobic conditions by strains of *T. aromatica* include benzoate, 3- and 4-hydroxybenzoate, phenol, toluene, phenylacetate, 4-hydroxyphenylacetate, and halogenated benzoates. Most of these substrates are first converted via diverse peripheral metabolic pathways to a common intermediate, benzoyl-CoA (Heider and Fuchs, 1997a, b). Benzoyl-CoA is then further catabolized by a conserved metabolic pathway, as shown in Fig. BXII.β.108. The first step is a two-electron reduction to a non-aromatic derivative, cyclohexa-1,5-diene-1-carboxy-CoA, by the key enzyme benzoyl-CoA reductase. This enzyme catalyzes benzoyl-CoA reduction, coupling this reaction to the hydrolysis of two moles of ATP (Boll et al., 1997). Further metabolic steps proceed via a beta-oxidation-like pathway, which leads to the first open-chain intermediate 3-hydroxypimelyl-CoA (Fig. BXII.β.108), generated by hydrolytic ring opening (Laempe et al., 1998, 1999). The benzoyl-CoA reductase of several analyzed *T. aromatica* strains appears to be immunologically distinct from the enzyme of closely related *Azoarcus* strains (Mechichi et al., 2002). The intermediate 3-hydroxypimelyl-CoA is degraded to three acetyl-CoA units and one CO_2, and acetyl-CoA is finally oxidized to CO_2 via the tricarboxylic acid cycle. Anaerobic catabolism of some aromatic compounds, such as α-resorcylate, apparently does not occur via the benzoyl-CoA intermediate. The first steps of a completely different pathway have recently been described for *T. aromatica* strain AR-1 that leads to oxidation of α-resorcylate to the intermediate hydroxyhydroquinol (Gallus and Schink, 1998). Catabolism of other aromatic substrates by strain AR-1 appears to proceed via the benzoyl-CoA pathway (Philipp and Schink, 2000). All tested *Thauera* species catabolize aromatic compounds aerobically. Aromatic substrates used under aerobic conditions include benzoate, phenylacetate, and 2-aminobenzoate. The catabolic pathways used for aerobic catabolism of aromatic compounds differ from those used under denitrifying growth conditions and involve the participation of oxygenases in all known instances.

Habitats Members of the genus *Thauera* are common saprophytic inhabitants of polluted freshwater and wet soil environments. They occur in wastewater treatment plants and are apparently naturally enriched in groundwater aquifers, river, lake, and pond sediments that are contaminated with aromatic or aliphatic organic compounds or toxic inorganic compounds such as selenate. They seem to be involved in mineralization and detoxification of xenobiotic contaminants in these habitats.

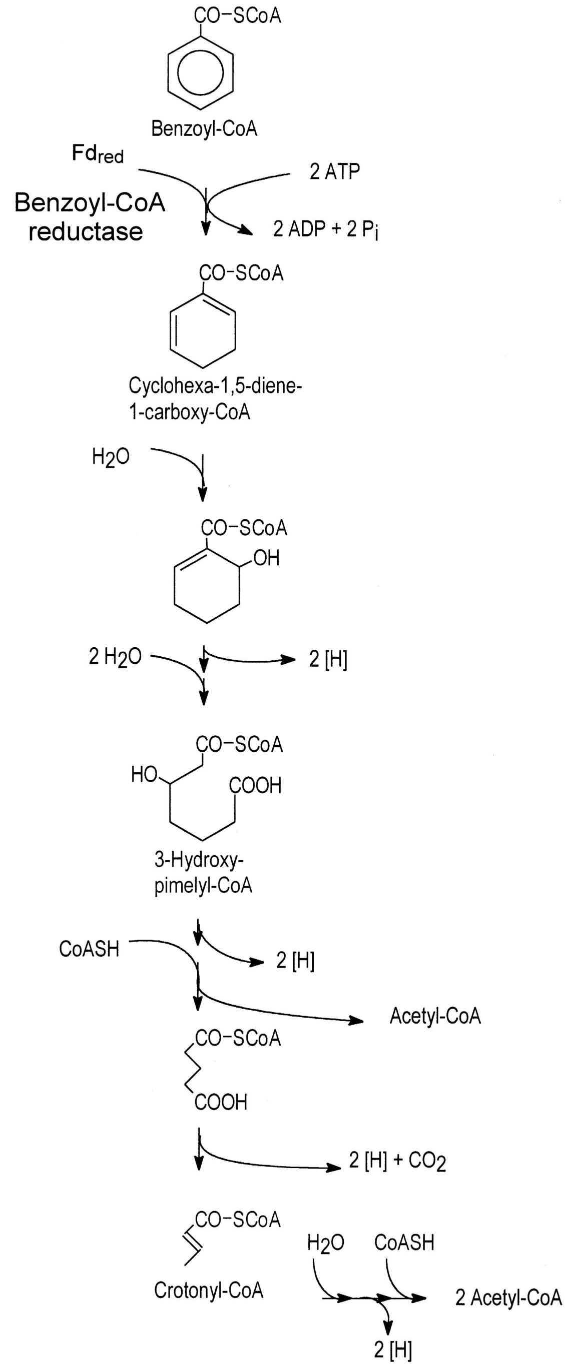

FIGURE BXII.β.108. Anaerobic benzoyl-CoA catabolic pathway of *T. aromatica*. Benzoate is converted to benzoyl-CoA by a coenzyme A ligase (AMP forming). For other substrates converted to this intermediate, see Heider and Fuchs (1997a, b).

Pathogenicity No pathogenic or symbiotic associations are known with plants or animals.

Enrichment and Isolation Procedures

There is no selective isolation procedure for *Thauera* strains. The known species have been obtained from enrichments designed for special physiological properties that are shared by strains of various other taxa. For example, anaerobic catabolism of aromatic compounds is also found in the related genus *Azoarcus* and

even in some less related recent isolates of denitrifying *Alphaproteobacteria*, *Betaproteobacteria*, and *Gammaproteobacteria* (Spormann and Widdel, 2000), and the anaerobic catabolism of terpenoids has also been reported for an *Alcaligenes* species (Foss et al., 1998a). *Thauera* strains are commonly isolated from wastewater treatment plants or contaminated soil or freshwater habitats after enrichment under anaerobic respiratory conditions. The enrichments are performed under mesophilic conditions at pH values of 7–8 in a buffered mineral salt medium containing either nitrate or selenate as the electron acceptor. Organic acids, aromatic compounds, or terpenoids may be used as sole substrates. Growth on some phenolic compounds or on acetone requires CO_2 or bicarbonate in the medium. Pure cultures are obtained after serial dilution in agar shakes under denitrifying conditions. However, highly purified agar (e.g., Oxoid purified agar) should be used for growth on solid media, because several strains are known to be sensitive to impurities in the agar. Alternative solidifying agents such as Gelrite should be tested to improve growth of some strains.

Maintenance Procedures

Stock cultures of *Thauera* strains grown under denitrifying conditions can be maintained in liquid cultures at 4°C for up to 3 months. Cultures of *Thauera* strains can be preserved for years in liquid nitrogen if they are supplemented with 5% (v/v) dimethylsulfoxide.

Procedures for Testing Special Characters

No specific 16S rRNA targeted probes have yet been derived for members of the genus *Thauera*. However, such oligonucleotide probes have been designed for *in situ* detection of strains of the closely related genus *Azoarcus* (Hess et al., 1997). Since no cross-reaction with *T. aromatica* has been recorded with these probes, it should be possible to design analogous probes for *Thauera* species. Another potentially useful procedure for characterizing the *Thauera* species that are capable of anaerobic catabolism of aromatic compounds is the immunological detection of benzoyl-CoA reductase. Antibodies raised against purified benzoyl-CoA reductase from the type strain of *T. aromatica* specifically react with extracts of several different strains of *Thauera* sp., but do not react with any of several tested *Azoarcus* spp. grown anaerobically on benzoate (Mechichi et al., 2002).

Differentiation of the genus *Thauera* from other genera

The most distinctive characteristics of *Thauera* are the ability to grow on unusual organic substrates and the limited ability to catabolize carbohydrates. These properties are shared with *Achromobacter*, *Acidovorax*, *Alcaligenes*, *Bordetella*, *Burkholderia*, *Comamonas*, *Pseudomonas*, *Ralstonia*, and *Zoogloea* species, as well as with the closely related genus *Azoarcus*. Useful phenotypic properties to discriminate these species are listed in Table BXII.β.116. The currently described species of the above-mentioned genera, except *Azoarcus*, are differentiated by their inability to degrade aromatic compounds such as benzoic acid in the absence of oxygen, but it can be expected that new isolates capable of anaerobic degradation of aromatic compounds will also be affiliated with some of these genera. *Azoarcus* strains are distinguished from *Thauera* sp. by their ability to fix dinitrogen and to use various sugars. Most above-mentioned genera belong to the class *Betaproteobacteria*, as does *Thauera*.

Taxonomic Comments

The genus *Thauera* is defined mainly based on 16S rDNA phylogeny. The few criteria listed in Table BXII.β.116 to differentiate most species of the genus from physiologically similar genera (e.g., absence of N_2 fixation) are not tested for all known species, and it may be expected that *Thauera* species will be isolated that deviate from some of these criteria. The six validly described species have been obtained following very different enrichment procedures and vary considerably in their physiological properties.

Phylogeny within the genus is currently based on 16S rDNA and DNA–DNA reassociation data. As shown in Fig. BXII.β.109, a phylogenetic tree of all known 16S rRNA sequences of *Thauera* strains currently in the database shows that the genus is monophyletic and well separated from *Azoarcus* spp., the closest known relatives. The positions of the *T. terpenica* and *T. linaloolentis* strains justify their treatment as separate species. The 16S rDNA sequences of the other four described species, *T. selenatis*, *T. aromatica*, *T. chlorobenzoica*, and *T. mechernichensis* are highly similar to one another, but treatment as separate species is supported by mutual DNA–DNA reassociation values that are significantly lower than 70% (Song et al., 1998, 2000a, 2001; Scholten et al., 1999). These four species apparently form a subcluster of related species within the genus (Fig. BXII.β.109). An additional strain, ATCC 700265, is included in the species *T. aromatica*, as justified by the observed similarity (99.2% 16S rRNA identity and 77% DNA–DNA reassociation; Song et al., 1998). Recently, a three-dimensional representation of the DNA–DNA hybridization values among *Thauera* strains has indicated that *T. chlorobenzoica* ATCC 700723^{T}, which is capable of degrading halobenzoates under denitrifying conditions, clusters together with additional isolates that are similarly capable of degrading halobenzoates. As a result, these strains have been separated from *T. aromatica* and placed into a separate species, *T. chlorobenzoica* (Song et al., 2001).

A number of recently isolated bacterial strains also belong to the genus *Thauera* based on their 16S rDNA sequences, but have not yet been fully described. Several of these strains belong to the species *T. aromatica*. One of these, strain mXyN1, which was isolated under denitrifying conditions with *m*-xylene as the sole carbon and energy source (Rabus and Widdel, 1995), exhibits 99.7% 16S rRNA identity with the type strain and 90% relatedness by DNA–DNA reassociation (Scholten et al., 1999). Another strain, AR-1 (DSM 11528), is capable of growing anaerobically on α-resorcylate and shares 99.9% 16S rDNA identity with the type strain (Gallus et al., 1997). Several other strains with 16S rDNA sequence identities of 99 ± 0.1% with the *T. aromatica* type strain have been characterized in a survey of halobenzoate-degrading denitrifying bacteria; these strains are 3CB-2, 3CB-3, 3BB-1, 4FB-1, and 4FB-2 in Fig. BXII.β.109 (Song et al., 2000b). Strains 4FB-1, 4FB-2, and 3BB-1 were later reclassified as reference strains of *T. chlorobenzoica*, and strains 3CB-2 and 3CB-3 were reclassified as reference strains of *T. aromatica*, on the basis of DNA–DNA hybridization studies (Song et al., 2001). The 16S rDNA sequences of two other recently characterized strains cluster between those of *T. selenatis* and *T. chlorobenzoica* (Fig. BXII.β.109). One of these, strain mz1t, was recently isolated directly from a bacterial floc of activated sludge using a micromanipulator (Lajoie et al., 2000), the other, strain PN-1, was isolated 30 years ago from a denitrifying enrichment culture with 4-hydroxybenzoate (Taylor et al., 1970). Strain PN-1 had been classified as *Achromobacter xylosoxidans* by physiological properties (Blake and Hegeman, 1987) and has only recently been iden-

tified as a *Thauera* sp. based on its 16S rRNA sequence (GenBank AF170281). Two other strains of *Thauera* sp., strains O and 1917, isolated from an anoxic leachate treatment reactor, are apparently less related to the species clustering with *T. aromatica*, as indicated by branching of their 16S rDNA sequences before branching of the *T. linaloolentis* sequence (Fig. BXII.β.109; Etchebehere et al., 2001a). Strain O has been reported to degrade benzoate under denitrifying conditions (Etchebehere et al., 2001a), but there is no more information available on the physiology of these strains. Finally, a number of bacterial strains isolated under denitrifying conditions on different aromatic substrates (strains S100, LG356, SP, B4P, and S2; Tschech and Fuchs, 1987; Seyfried et al., 1991) have also been found to be *Thauera* spp. on the basis of >98% 16S rDNA sequence identity with the *T. aromatica* type strain. New species have recently been established for two of these strains, *T. aminoaromatica* (strain S2) and *T. phenylacetica* (strain B4P), while the others were described as further reference strains of *T. aromatica* (for details, see Mechichi et al., 2002).

Nomenclatural problems within the genus *Thauera* arise mainly from the fact that very high degrees of 16S rDNA identity are accompanied by wide physiological variability between the species and even between several strains of one species. Therefore, taxonomy cannot be based on 16S rDNA sequences alone, but rather needs to be complemented by DNA–DNA reassociation studies and the physiological properties of the strains. For example, the establishment of *T. aromatica* and *T. selenatis* as separate species was much more dependant on the profound physiological differences between the strains than on the highly similar 16S rRNA sequences, and this speciation is corroborated by low DNA–DNA reassociation values (Anders et al., 1995). From the speed of description of new *Thauera* isolates in the last few years, it may be expected that the number of strains and species in the genus will expand rapidly in the future.

Differentiation of the species of the genus *Thauera*

Characteristics useful for the differentiation of the species of the genus *Thauera* are listed in Tables BXII.β.117 and BXII.β.118.

List of species of the genus Thauera

1. **Thauera selenatis** Macy, Rech, Auling, Dorsch, Stackebrandt and Sly 1993, 140[VP]

se.le.na′tis. M.L. gen. n. *selenatis* of selenate, according to the electron acceptor used for isolation.

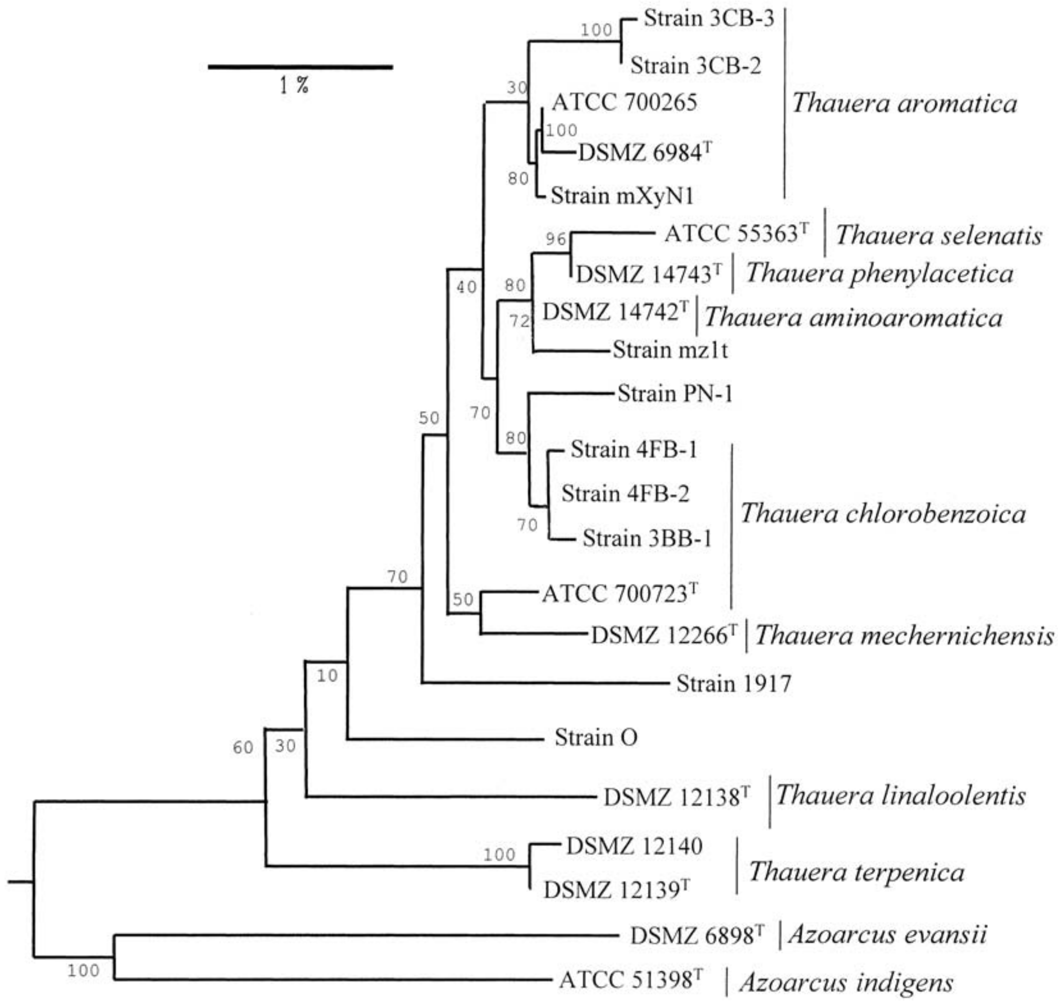

FIGURE BXII.β.109. Phylogenetic tree of the 16S rRNA sequences of bacterial strains affiliated with the genus *Thauera* and the type strains of *Azoarcus evansii* and *Azoarcus indigens*. All sequences larger than 1 kb currently in the database were included. The tree was derived from a multiple alignment of a segment of 1070 bases present in all sequences (bases 177–1244 in 16S rDNA of *T. aromatica* DSM 6984^T) by the neighbor-joining method. Bootstrapping values of the branch points are indicated. Currently affiliated species names are indicated to the right of the strain designations. Strain ATCC 700723 has recently been reclassified as the type strain of the species *T. chlorobenzoica*. Similarly, strains 4FB-1, 4FB-2, and 3BB-1 have been reclassified as reference strains of *T. chlorobenzoica*, and strains 3CB-2 and 3CB-3 as reference strains of *T. aromatica* (Song et al., 2001). Accession numbers for 16S rDNA sequences of not validly described strains, which are not included in the list of species are: strain mXyN1, X83533; strain mz1t, AF110005; strain PN-1, AF170281; strain 1917, AJ277705; strain O, AJ277704. Accession numbers of *T. aminoaromatica* and *T. phenylacetica* are AJ315677 and AJ315678, respectively. Note that database entry Y17591 was used for the 16S rRNA of *T. selenatis*.

[a]Symbols: see standard definitions. Blank space, data not reported or not applicable.

Characteristics are as described for the genus and as listed in Tables BXII.β.117 and BXII.β.118. Additional features are as follows. Cells possess a single polar flagellum. Selenate is reduced to selenite by a periplasmic selenate reductase, and the selenite is further reduced to elemental (red) selenium, which precipitates in the culture medium. No aromatic compounds are catabolized anaerobically. For further descriptive information see Macy et al. (1993). Optimal temperature, 28°C. Isolated from selenate-contaminated water by use of enrichment cultures under selenate-reducing conditions.

The mol% G + C of the DNA is: 66 (T_m).

Type strain: AX, ATCC 55363.*

GenBank accession number (16S rRNA): X68491, Y17591.

2. **Thauera aromatica** Anders, Kaetzke, Kämpfer, Ludwig and Fuchs 1995, 331[VP]

a.ro.ma′ ti.ca. M.L. adj. *aromatic* referring to the nutritional preferences of this organism.

Characteristics are as described for the genus and as listed in Tables BXII.β.117 and BXII.β.118. Additional features are as follows. Cells may have peritrichous flagellation with up to eight flagella or may have lost all but one flagellum ("degenerately peritrichous"). Benzoate and various other aromatic compounds are catabolized anaerobically via the benzoyl-CoA pathway. Selenate is not reduced. Optimal temperature, 28°C. Isolated from (contaminated) water and soil, particularly from denitrification stages of sewage treatment plants. Enrichment is possible under denitrifying conditions with aromatic substrates. Different isolates vary in their catabolic capacities for aromatic compounds.

The mol% G + C of the DNA is: 66–67 (HPLC).

Type strain: K172, DSM 6984.

GenBank accession number (16S rRNA): X77118.

Additional Remarks: The accession numbers for reference strains ATCC 700265, CB-2, and CB-3 are U59176, AF229881, and AF229882, respectively.

3. **Thauera chlorobenzoica** Song, Palleroni, Kerkhof and Häggblom 2001, 600[VP]

Editorial Note: The type strain of *Thauera selenatis* is currently unavailable as it was deposited in association with a patent application that was subsequently abandoned.

chlor.o.ben.zo'i.ca. M.L. adj. *chloro* pertaining to chlorine; from Gr. adj. *chloros* pale green; M.L. adj. *benzoicus* pertaining to benzoic acid; M.L. fem. adj. *chlorobenzoica* indicating the ability to utilize chlorobenzoic acid.

Characteristics are as described for the genus and as listed in Tables BXII.β.117 and BXII.β.118. Additional features are as follows. Cells are 0.85–0.97 × 1.2–2.7 μm and have peritrichous flagellation. In contrast to *T. aromatica*, all known strains of the species grow under denitrifying conditions on 2- and 4-fluorobenzoate; some strains also grow on 3-chlorobenzoate, 3-bromobenzoate, or 3-iodobenzoate. Isolated from river and estuarine sediments and from agricultural soil.

The mol% G + C of the DNA is: 69 (HPLC).

Type strain: 3CB-1, ATCC 700723.

GenBank accession number (16S rRNA): AF123264.

Additional Remarks: The accession numbers for reference strains 4FB-1, 4FB-2, and 3BB-1 are AF229867, AF229868, and AF229887, respectively.

4. **Thauera linaloolentis** Foss and Harder 1999, 2^{VP} (Effective publication: Foss and Harder 1998, 370.)
li.na.lo.o.len'tis. Sp. n. *linaloe* wood of American trees, from which an oil containing mainly linalool is extracted; L. *olere* smell; M.L. adj. *linaloolentis* linaloe-smelling, referring to the ability of the organism to catabolize linalool.

Characteristics are as described for the genus and as listed in Tables BXII.β.117 and BXII.β.118. Additional features are as follows. Catabolizes some open-chain terpenoids, such as linalool or geraniol, anaerobically. No anaerobic catabolism of benzoate or other aromatic compounds occurs. For further descriptive information, see Foss and Harder (1998). Isolated from activated sewage sludge after enrichment for denitrifying bacteria with linalool as the sole substrate. Optimal temperature, 32°C.

The mol% G + C of the DNA is: 66 (HPLC).

Type strain: 47Lol, DSM 12138.

GenBank accession number (16S rRNA): AJ005816.

5. **Thauera mechernichensis** Scholten, Lukow, Auling, Kroppenstedt, Rainey and Kiekmann 1999, 1049^{VP}
me.cher.ni.chen'sis. M.L. adj. *mechernichensis* pertaining to Mechernich, Germany, the site of isolation of the organism.

Characteristics are as described for the genus and as listed in Tables BXII.β.117 and BXII.β.118. Additional features are as follows. The cells have single polar flagella. Anaerobic catabolism of benzoate and other aromatic compounds occurs. Denitrification is not repressed under aerobic conditions. For further descriptive information, see Scholten et al. (1999). Isolated from the nitrification step of a leachate treatment plant after aerobic continuous culture with acetate as the carbon source. Optimal temperature, 40°C.

The mol% G + C of the DNA is: 65 (HPLC).

Type strain: TL1, DSM 12266.

GenBank accession number (16S rRNA): Y17590.

6. **Thauera terpenica** Foss and Harder 1999, 2^{VP} (Effective publication: Foss and Harder 1998, 372.)
ter.pe'ni.ca. M.L. adj. *terpenica* related to terpenes, referring to the nutritional preferences of these organisms.

Characteristics are as described for the genus and as listed in Tables BXII.β.117 and BXII.β.118. Additional features are as follows. Catabolize several monoterpenes anaerobically. The substrate range of catabolized terpenes varies for different isolates. For example, the terpenoid substrates used by strain DSM 12139^{T} include eucalyptol, sabinene, β-pinene, α-phellandrene, and other chemically similar compounds, whereas those used by strain DSM 12140 include menthol, isomenthol and some similar compounds. No anaerobic catabolism of benzoate or other aromatic compounds occurs. For further descriptive information, see Foss and Harder (1998). Isolated from forest ditches after enrichment culture for denitrifying bacteria with defined monoterpenes as sole substrates. Optimal temperature, 32°C.

The mol% G + C of the DNA is: 64 (HPLC).

Type strain: 58Eu, DSM 12139.

GenBank accession number (16S rRNA): AJ005817.

Additional Remarks: The accession number for the 16S sequence for strain DSM 12140 is AJ005818. The recently described *p*-cymene degrading bacterial strain pCyN2 (Harms et al., 1999a) may also belong to this species based on its very similar 16S rDNA sequence (accession number Y17285).

Other Organisms

While this volume was in press, two more *Thauera* species were validly published, *T. aminoaromatica* (DSM 14742) and *T. phenylacetica* (DSM 14743). For further details, see Mechichi et al. (2002). Furthermore, an aerobic butane-degrading bacterium previously desgnated as *"Pseudomonas butanovora"* was recently shown to be affiliated with *T. linaloolentis* on the basis of its 16S rDNA sequence, but has not yet been formally described as a new *Thauera* species (Anzai et al., 2000).

Genus XII. **Zoogloea** *Itzigsohn 1868, 39^{AL} emend. Shin, Hiraishi and Sugiyama 1993, 830*

RICHARD F. UNZ

Zo.o.gloe'a. Gr. adj. *zoos* living; Gr. n. *gloia* glue; M.L. fem. n. *Zoogloea* living glue.

The following description is representative of the genus based on well-characterized isolates recovered directly from naturally occurring, typical, fingered zoogloeae: **Straight to slightly curved, plump rods**, 1.0–1.3 × 2.1–3.6 μm, with rounded ends; sometimes tapered to a blunt point at one or both poles. Nonsporeforming and noncystforming. **Cells in older cultures are demonstrably encapsulated.** Gram negative. **Actively motile**, especially in young cultures, by means of a **single polar flagellum**. **Intracellular granules of poly-β-hydroxybutyrate are formed** on media containing the salts of organic acids. Cultures enter into formation of flocs and films in liquid media at late growth stages; **the cells become embedded in gelatinous matrices to form zoo-**

gloeae, which may be distinguished by a "tree-like" or "finger-like" morphology. Young colonies on solid media under a normal air atmosphere are translucent and punctiform, but may increase to 1 or 2 mm in diameter and exhibit opaque centers. Nonpigmented. **Aerobic, having a strictly respiratory type of metabolism with oxygen or nitrate as the terminal electron acceptor. Denitrification occurs with formation of N_2.** Optimal temperature for growth, 28–37°C. Optimal pH, 7.0–7.5. **Oxidase positive.** Weakly catalase positive. Chemoorganotrophic. **Acid is not formed from carbohydrates except for xylose, glycerol, and ethanol, which are attacked oxidatively by a few strains.** Proteolytic on gelatin. Most strains are urease positive. Litmus milk is unchanged. Hydrogen sulfide is usually not produced from cysteine. Major carbon sources include salts of several organic acids (e.g., lactate, pyruvate, and fumarate), dicarboxylic amino acids (e.g., aspartate, glutamate, and asparagine), alcohols, and salts of certain aromatic acids (e.g., benzoate and *m*-toluate). Benzene derivatives are attacked by *meta* cleavage of the ring structure. Organic nitrogen compounds (e.g., dicarboxylic amino acids) and ammonia serve as nitrogen sources; nitrate is unsuitable. Specific growth factor requirements, if any, are unknown. Major cellular fatty acids are palmitoleic ($C_{16:1}$) and 3-hydroxydecanoic ($C_{10:0\ 3OH}$) acids. Major respiratory quinones are Q-8 and RQ-8. The major polyamine is 2-hydroxyputrescine. **Occur free-living in organically polluted fresh waters and in wastewaters at all stages of treatment.**

The mol% G + C of the DNA is: 67.3–69.0.

Type species: **Zoogloea ramigera** Itzigsohn 1868, 30.

Further descriptive information

Zoogloea strains form flocculent masses of zoogloeae in both complex and defined media containing suitable carbon sources (Fig. BXII.β.110). Arrangement of the bacteria into sharply demarcated columns or "fingers" (Fig. BXII.β.111), which protrude from a cluster or aggregate of cells, constitutes the historically recognized growth form of *Z. ramigera* (Koch, 1877; Butterfield, 1935; Dugan and Lundgren, 1960; Unz and Farrah, 1976b). Cells are embedded in an extracellular matrix, which is discernible by treatment of wet mount specimens with a contrasting agent (Fig. BXII.β.112) or by scanning electron microscopy (Fig. BXII.β.113). However, taken by itself, *Zoogloea* morphology is an unreliable character upon which to base the identification of *Z. ramigera*, since (a) fragmented portions of flocs and pellicles and artifacts created by random coalescence of bacteria may be mistaken under microscopic observation for finger-like zoogloeae, and (b) *Z. ramigera* may form amorphous, rather than finger-like, zoogloeae (Fig. BXII.β.114). The extent of zoogloea production varies among strains and with the culture conditions and may diminish greatly or be lost, especially during frequent transfer of strains in rich culture media.

Cells of *Zoogloea* are plump rods that are motile by means of a single, monopolar flagellum (Fig. BXII.β.115). Chains of cells are rare. Cells in very old cultures may appear elongated.

Colonies produced on CY agar[1] are initially punctiform. After 3 or 4 days, the colonies reach 1 mm in diameter and appear circular, slightly raised, and translucent with opaque centers (Fig. BXII.β.116) or completely gray-white. Colony edges are entire or lobate. Mature colonies are distinctively tenacious and cohesive and may be lifted intact from the agar surface with a needle. Colonies develop poorly on ordinary nutrient agar.

1. CY agar contains (g/l of distilled water): Casitone (Difco), 5.0; yeast autolysate, 1.0; agar, 15.0.

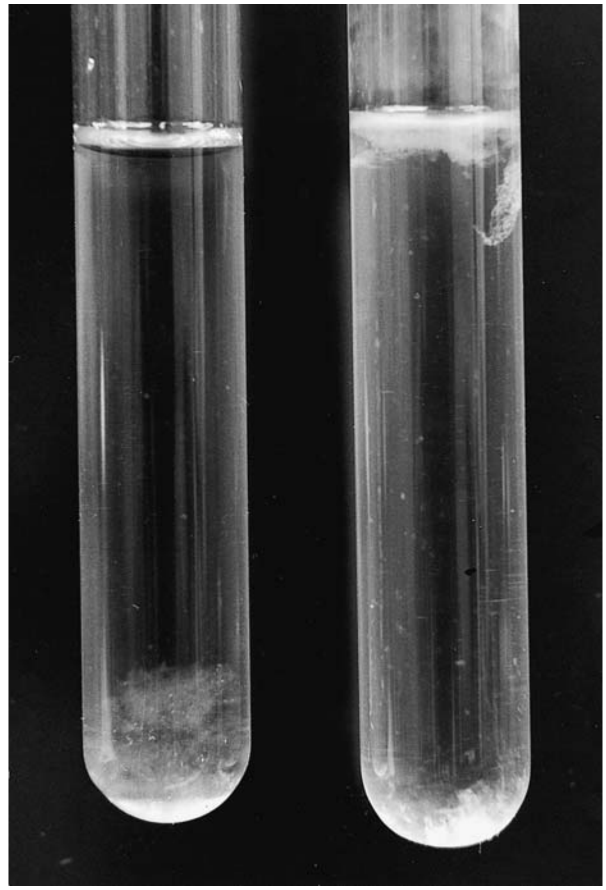

FIGURE BXII.β.110. Flocculent growth habit of *Zoogloea ramigera*. *Left*, ATCC strain 19544. *Right*, strain G4, freshly isolated and exhibiting the development of a thick, straggly, pellicle. Casitone–yeast autolysate medium, 28°C, 72 h.

Growth of *Zoogloea* strains is slow at 9°C and nonexistent at 45°C. The pH range for growth lies between pH 5.0 and 10.0, with poor development occurring at extreme pH values.

Strains survive, but do not grow, under strictly anaerobic conditions in the absence of nitrate. They exhibit a microaerophilic tendency in semisolid agar deeps, as evidenced by the appearance of culture bands 3–5 mm below the agar surface (Unz and Dondero, 1967b). Approximately 50% of strains tested reduce trimethylamine oxide to trimethylamine (Unz and Dondero, 1967b).

Acid was found to be produced oxidatively from xylose by 3 of 65 strains in one study (Unz and Dondero, 1967a), and by 5 of 37 strains in another study (Unz and Farrah, 1972). Acid was also found to be produced oxidatively from glycerol and/or ethanol by 10 of 65 strains (Unz and Dondero, 1967a).

No growth on citrate was found to occur in one study (Unz and Dondero, 1967a), but growth by 20 of 37 strains occurred on Koser's citrate in another study (Unz and Farrah, 1972).

Zoogloea strains are not fastidious nutritionally and may be cultured on a variety of organic carbon sources in a simple defined medium.[2] Carbon sources supporting growth of at least

2. Defined medium (g/l distilled water): carbon source, 0.25–0.5; $(NH_4)_2SO_4$, 0.375; $MgSO_4 \cdot 7H_2O$, 0.2; $CaCl_2$, 0.2; K_2HPO_4, 0.1; and $FeSO \cdot 7H_2O$, 0.005. The pH is adjusted to 7.2 with 0.1 N NaOH. Yeast autolysate (0.01 g) and vitamin B_{12} (1×10^{-6} g) may be included as sources of growth factors to decrease growth lag.

FIGURE BXII.β.111. Finger-like zoogloea. *Zoogloea ramigera* ATCC strain 19544 grown in lactate–mineral salts medium at 28°C for 60 h. Phase contrast. Bar = 50 μm.

90% of *Zoogloea* strains are lactate, pyruvate, α-hydroxybutyrate, fumarate, ethanol, butanol, benzoate, glutamate, aspartate, and asparagine (Unz and Dondero, 1967b).

Resistance to 2.5 U of penicillin G occurs in 67% of the strains tested (Unz and Dondero, 1967a).

Zoogloea strains are found principally in organically polluted fresh waters, wastewaters, and aerobic biological wastewater treatment systems, e.g., activated sludge and trickling filter units.

Enrichment and Isolation Procedures

Finger-producing strains of *Zoogloea* may be cultivated best in enrichment media inoculated with activated sludge or with the films from aerobic wastewater treatment devices. Approximately 2 ml of an inoculum are added to 15 ml of mineral salts solution[3] overlaying 5 ml of a nutrient-enriched agar[4] contained at the bottom of a metal-capped test tube (20 mm OD × 150 mm). The enrichment culture is incubated at 28°C until a pellicle develops, usually within 2 or 3 d if activated sludge is the inoculum. A simpler method for enrichment of fingered zoogloeae involves storage of activated sludge in covered glass containers at room temperature until a surface film appears (Amin and Ganapati, 1967). The latter method is not always reliable, and success may depend on obtaining a proper ratio of the height of activated sludge solids to the total volume of liquid stored in the container.

A wet mount of enrichment-culture surface film is examined at 100× magnification by phase contrast microscopy to confirm the presence of fingered zoogloeae. Several loopfuls of film are

3. Mineral salts solution (g/l): $(NH_4)_2SO_4$, 0.3; NaCl, 5.85; $CaCl_2 \cdot 2H_2O$, 0.2; K_2HPO_4, 0.1; $MgSO_4 \cdot 7H_2O$, 0.14; $FeSO_4 \cdot 7H_2O$, 0.0003; $MnCl_2 \cdot 4H_2O$, 0.0063; $CoSO_4 \cdot 7H_2O$, 0.0001; H_3BO_4, 0.0006; $ZnCl_2$, 0.00022; and $CuSO_4 \cdot 5H_2O$, 0.00008. The medium components are prepared from stock solutions and the pH of the medium is adjusted to 8.5 ± 0.1 pH unit with 0.5 N NaOH.

4. Nutrient-enriched agar: to mineral salts solution containing agar (20 g/l), any of the following sole carbon sources are added in the amount shown per liter: starch, 2.4 g; *m*-toluic acid (neutralized), 1.35 g; *n*-butanol, 1.5 ml; lactic acid (85%), 1.35 g; ethanol (95%), 1.5 ml; or glucose, 2.4 g. After adding the carbon source to the liquid mineral salts–agar mixture, the pH is adjusted to 8.5 ± 0.1 with 0.5 N NaOH.

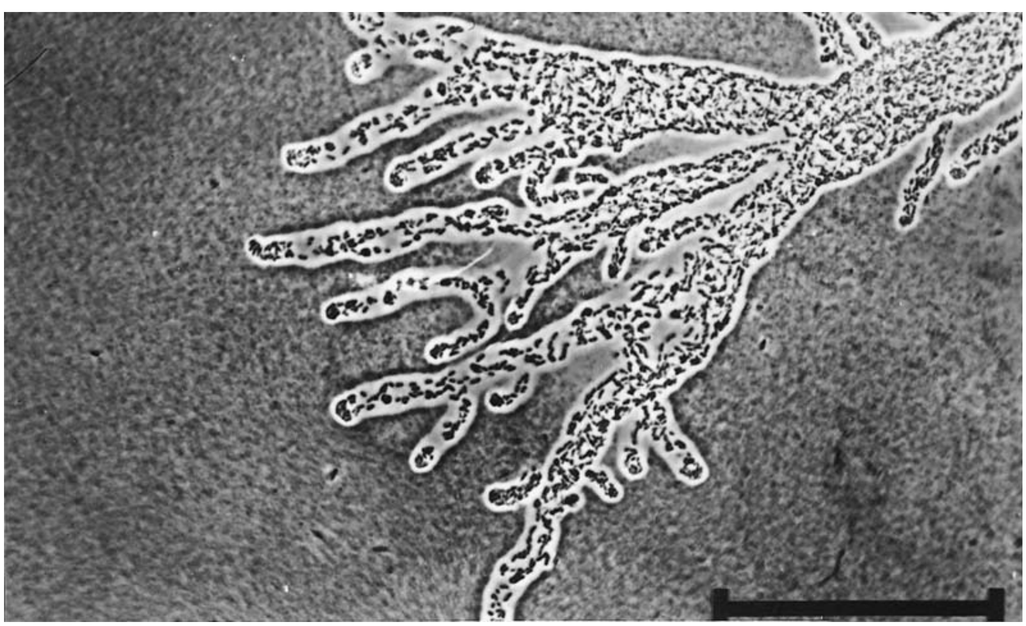

FIGURE BXII.β.112. Finger-like zoogloea treated in wet mount with skim milk to accentuate the exopolymer in which the cells are embedded. *Zoogloea ramigera* ATCC strain 19544. Unz, International Journal of Systematic Bacteriology *21:* 91–99, 1971 ©International Union of Microbiological Societies.)

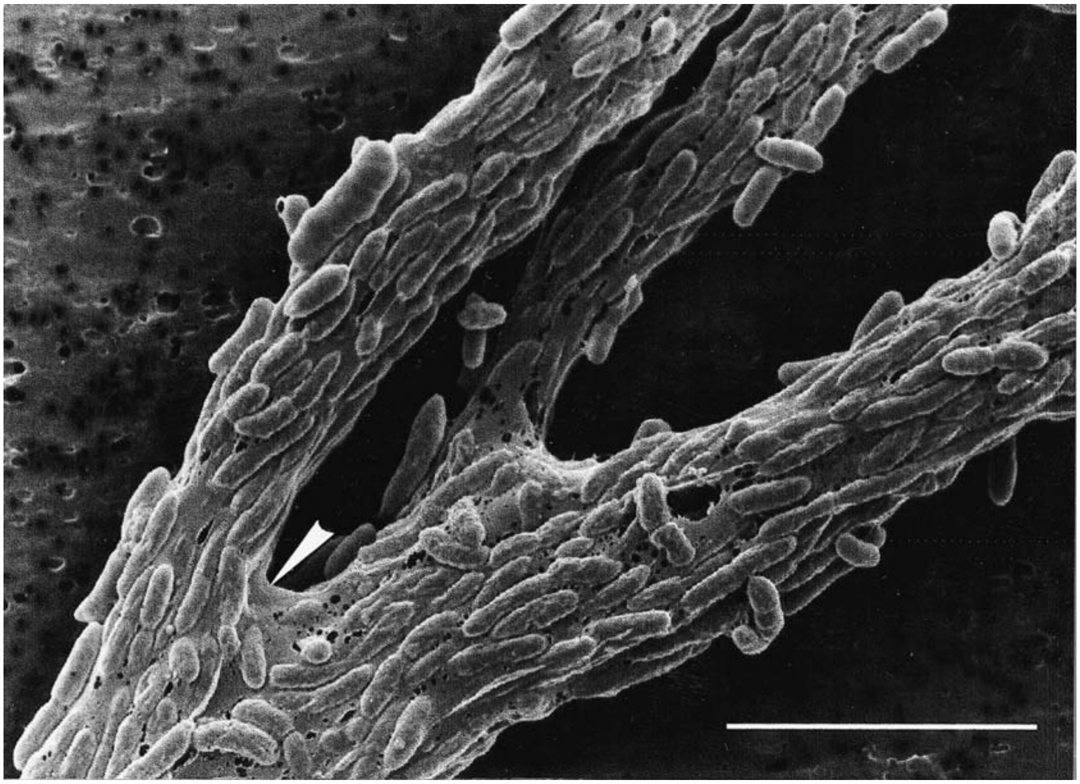

FIGURE BXII.β.113. Finger-like zoogloea mounted on a nucleopore filter, dehydrated, fixed by gradient ethanol dehydration, washed with hexamethyldisilizane, dried, sputter-coated with gold, and observed by field emission scanning electron microscopy. Cells embedded in a gelatinous matrix (*arrow*). *Zoogloea ramigera* ATCC 19544 grown in yeast extract (2.5 g/l)–peptone (2.5 g/l), 28°C. Bar = 7.2 μm.

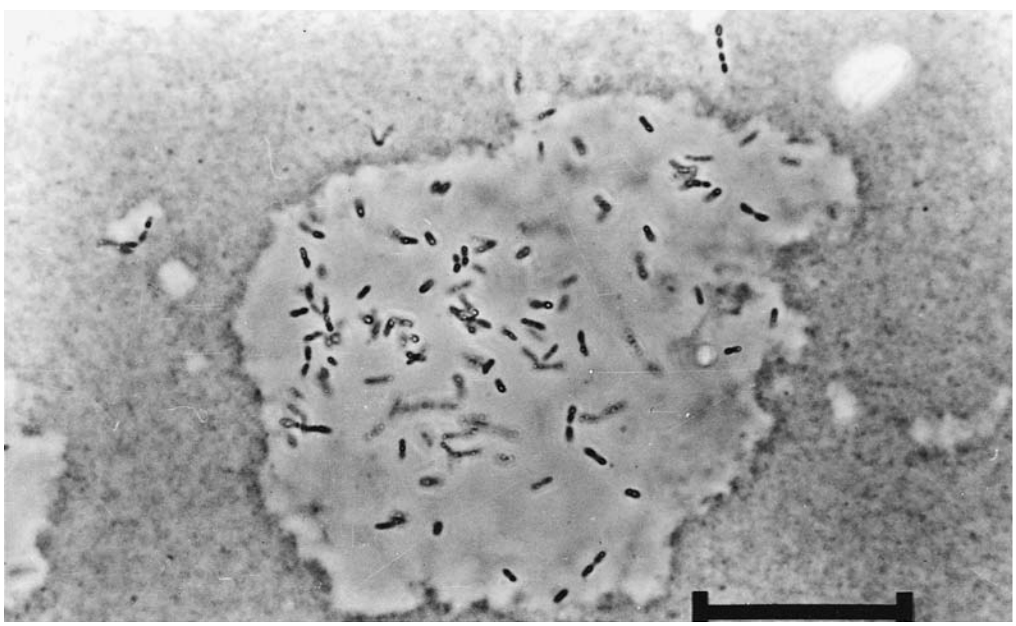

FIGURE BXII.β.114. Amorphous zoogloea treated in wet mount with skim milk to accentuate the exopolymer in which the cells are embedded. *Zoogloea ramigera* ATCC strain 19544. Lactate–mineral salts medium, 28°C, 60 h. Phase contrast. Bar = 100 μm. (Reproduced with permission of R.F. Unz, International Journal of Systematic Bacteriology *21:* 91–99, 1971 ©International Union of Microbiologial Societies.)

transferred to a 2-ml droplet of CY broth contained in a Petri plate. The fingered zoogloeae may be located easily in the droplet under 45-60× magnification. Approximately 10–12 of the fingered zoogloeae are transferred individually and successively by a micropipette through each of four 0.7-ml droplets of CY medium in order to free loosely attached debris and microorganisms

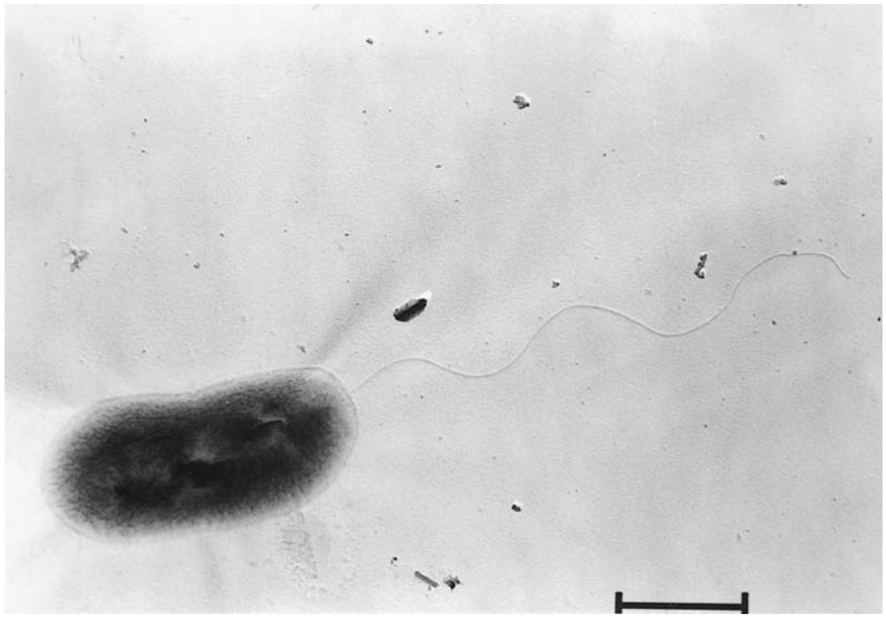

FIGURE BXII.β.115. *Zoogloea ramigera* ATCC strain 19544 showing the single, polar flagellum. Casitone–yeast autolysate medium, 28°C, 24 h. Platinum–carbon shadowed. Bar = 1 μm. FIGURE BXII.β.116. Colonies of *Zoogloea ramigera* ATCC strain 19544. Casitone–yeast autolysate agar, 28°C, 72 h. Photographed by reflected light. Bar = 1 mm. (Reproduced with permission of R.F. Unz, International Journal of Systematic Bacteriology *21:* 91–99, 1971 ©International Union of Microbiological Societies.)

from the zoogloeae. Finally, the washed zoogloeae are collectively transferred to 3 ml of CY medium and subjected briefly to sonic oscillation (e.g., 30 s at 50 watts) to release the cells. A loopful of the sonicate is streaked onto solid CY medium and incubated at 28°C. Typically cohesive colonies of *Zoogloea* are large enough to be transferred intact to CY broth after 3–4 d. Inoculation of CY broth with a single colony usually results in the appearance of slight turbidity and a slippery, glistening pellicle after 3 d at 28°C. Pellicles may be composed entirely of fingered zoogloeae or amorphous zoogloeae, which, following detachment, settle and give rise to a flocculent sediment.

Maintenance Procedures

Zoogloea strains may be maintained in half-strength CY medium at 20°C for at least 2 months between subcultures. The formation of zoogloeal flocs is visibly reduced upon continuous transfer in

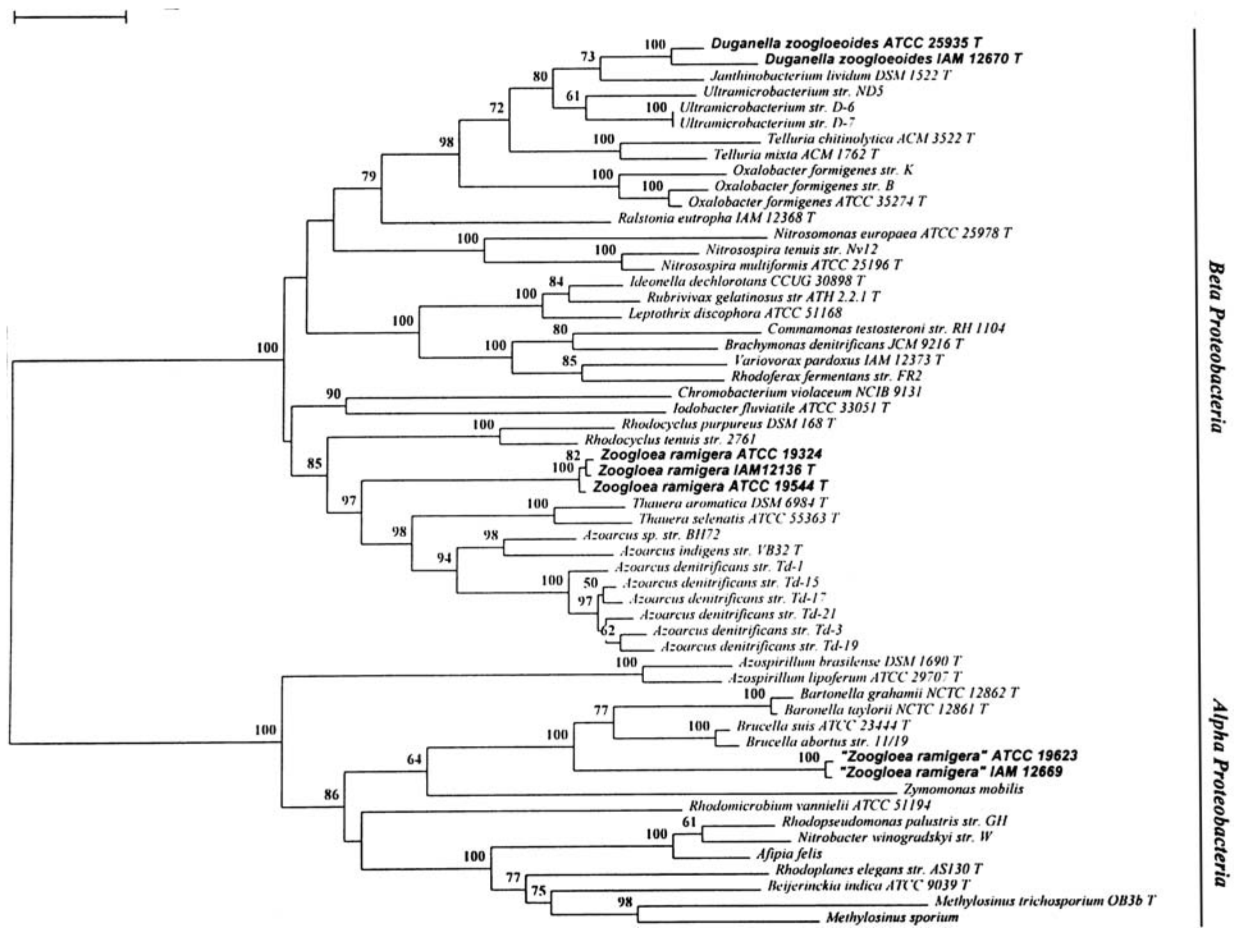

FIGURE BXII.β.117. Dendrogram revealing the phylogenetic position of *Zoogloea ramigera*. The phylogenetic distance tree was generated from 1309 bases of unambiguously aligned 16S rRNA sequences from 39 members of the class *Betaproteobacteria* and 17 members of the class *Alphaproteobacteria*. Positions corresponding to 33–68 plus 104–1376 (*Escherichia coli* numbering) were used. Phylogenetic distances were calculated with correction for multiple substitutions at a single position (Jukes and Cantor, 1969), and the tree was generated using the neighbor-joining method (Saitou and Nei, 1987), as implemented in the TREECON software package (Van de Peer and de Wachter, 1994). Bootstrap resampling (100 replicates) was used to indicate the confidence in the sequence clusters obtained. The values at nodes represent the percentage bootstrap support for the groupings to the right of the node. Bootstrap values below 50% are not shown. Bar = 2 nucleotide changes per 100 nucleotides in the 16S rRNA sequence (see text next page).

laboratory culture media. The zoogloeal growth habit may be restored by plating a broth culture and transferring a colony back to liquid medium.

Strains do not survive prolonged refrigeration; however, they may be preserved indefinitely by lyophilization or cryopreservation.

Differentiation of the genus *Zoogloea* from other genera

The taxonomic status of the genus *Zoogloea* within the family *Pseudomonadaceae* has been called into question based on 16S rDNA sequence analyses and chemotaxonomic data (Shin et al., 1993). The most recent phylogenetic positioning of the type species of the genus *Zoogloea* lies within the *Betaproteobacteria* as shown in Fig. BXII.β.117. Inspection of the phylogenetic tree reveals that the three most closely related genera to the type strain of *Z. ramigera* (ATCC 19544) are *Thauera*, *Azoarcus*, and *Rhodocyclus*. Strains of authentic and misnamed *Z. ramigera* that have received molecular characterization are given in bold face. *Z. ramigera* ATCC 19324 was isolated by single-cell microdissection of a natural, finger-like zoogloea sampled from a trickling filter in a similar fashion as the type strain. Sequence data from independent studies of the type strain obtained from two different culture collections, namely *Z. ramigera* ATCC 19544 (Rosselló-Mora et al., 1993) and *Z. ramigera* IAM 12136 (Shin et al., 1993), are reflected in the dendrogram. Although mol% G + C of the DNA provides a basis for comparison, differentiation of the genus *Zoogloea* from the genera *Thauera*, *Azoarcus*, and *Rhodocyclus* is possible (Table BXII.β.119). Cell flocculation, which was historically held to be a distinctive feature of the genus *Zoogloea*, is widespread among eubacteria, including a species of the dinitrogen-fixing genus *Azoarcus* (Reinhold-Hurek et al., 1993b). The chemical composition of the exopolymers formed by organisms designated as *Zoogloea*, e.g., hexosamine, glucose, xylose, and arabinose (Crabtree et al., 1966); glucose, mannose, and galactose (Wallen and Davis, 1972); glucose and galactose (Parsons and Dugan, 1971); and glucosamine and fucosamine (Tezuka, 1973), is diverse and has not been useful in the taxonomic sense. The mucopolysaccharide (Farrah and Unz, 1976) produced by the neotype strain of *Z. ramigera* (ATCC 19544) appears to be chemically related to

TABLE BXII.β.119. Differential characteristics of the genus *Zoogloea* and phylogenetically related genera of the *Betaproteobacteria*[a]

Characteristics	*Zoogloea*	*Azoarcus*[b]	*Rhodocyclus*[c]	*Thauera*[d]

the exopolymer described by Tezuka (1973); moreover, it exhibits a fine, strand-like mesh (Fig. BXII.β.118), rather than the coarse, fibrillar network of cellulose-like glycans observed for other zoogloeal and nonzoogloeal bacteria (Friedman et al., 1968, 1969) or the cellulose of *Acetobacter* species (Ohad et al., 1962). The exocellular homo- and heteropolysaccharide exopolymers that have been characterized for species of *Xanthomonas*, *Pseudomonas*, *Arthrobacter*, and *Alcaligenes* are variably water-soluble and may increase the consistency of the culture medium (Powell, 1979; Sutherland, 1979a). In contrast, the mucopolysaccharide-producing neotype strain of *Z. ramigera* produces a water-insoluble exopolymer at room temperature and the culture medium is not visibly thickened.

The genus *Comamonas* (Davis and Park, 1962) has been used to classify non-floc-forming bacteria to distinguish them from otherwise similar floc-forming bacteria considered to be *Zoogloea* strains (Dias and Bhat, 1964).

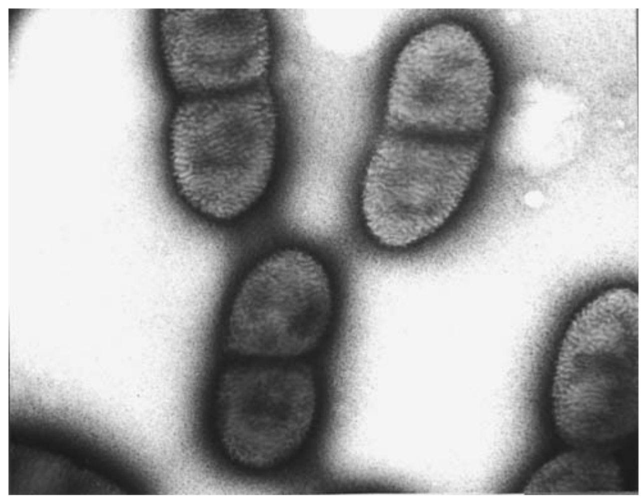

FIGURE BXII.β.118. Cells of *Zoogloea ramigera* ATCC strain 19544 embedded in a fine meshwork of exopolymer. Casitone–yeast autolysate medium, 28°C, 72 h. Preparation negatively stained with 2% phosphotungstic acid for 30 s × 27,000.

Taxonomic Comments

Important developments concerning the genus *Zoogloea* have occurred since the last edition of the *Manual* (Unz, 1984). These pertain to solidifying the position of ATCC 19544 (strain 106; Unz, 1971) as the neotype strain of the species *Z. ramigera* (Judicial Commission, 1979) and resolving the issue of two strains of uncertain affiliation. The type strain and ATCC 25935 (strain 115; Friedman and Dugan, 1968), both members of the class *Betaproteobacteria*, differ on the basis of the presence of rhodoquinone-8 and palmitoleic acid (major cellular fatty acid of the nonpolar fraction) in the former (Hiraishi et al., 1992c), putrescine and 2-hydroxyputrescine content (Hamana and Matsuzaki, 1993), and their 16S rRNA sequences (Rosselló-Mora et al., 1993). ATCC 19623 (strain I-16-M; Crabtree and McCoy, 1967) is confined to the class *Alphaproteobacteria* based on spermidine content (Hamana and Matsuzaki, 1993), ubiquinone Q-10 content (Hiraishi et al., 1992c), and 16S rDNA (Shin et al., 1993) and 16S rRNA (Rosselló-Mora et al., 1993) sequence analyses. The use of molecular biological techniques has resolved the ambiguous taxonomic status of the genus *Zoogloea*, originally attributed to nomenclatural difficulties arising from (a) uncertainties about the type species, which was originally described on the basis of a growth form of an organism in mixed culture, (b) acceptance of the flocculent growth habit as the principal characteristic for the identification of sundry aggregative bacteria as strains of *Zoogloea* or of *Z. ramigera*, and (c) conflicting descriptions of bacteria stated to be *Z. ramigera*.

Z. ramigera ATCC 19544 is one of 147 *Zoogloea* strains of certain origin, in that the bacteria were isolated as single cells during micromanipulation of natural, finger-like zoogloeae under microscopic observation (Unz and Dondero, 1967a). *Z. ramigera* ATCC 19544 forms fingered zoogloeae in liquid culture, which

are similar in appearance to those of the natural type from which it came and to the zoogloeae referred to as “tree-like” ramifications of spherical gelatinous masses in the original description of the species (Itzigsohn, 1868). Recent evidence of a relationship of the type strain to cells in natural, finger-like zoogloeae is provided in the exclusive hybridization between the bacteria of natural zoogloeae and an oligonucleotide probe complementary to a region of 16S rRNA of *Z. ramigera* ATCC 19544, with little or no reaction taking place with probes designed for *Z. ramigera* ATCC 19623 or *Z. ramigera* ATCC 25935 (Rosselló-Mora et al., 1995).

At least 90–100% of *Zoogloea* strains denitrify, demonstrate positive oxidase and catalase reactions, hydrolyze gelatin, carry out *meta* cleavage of aromatic ring structures, and fail to form acid from carbohydrates (Unz and Dondero, 1967a; Unz and Farrah, 1972). Approximately 82% of strains demonstrate urease activity. To define the salient characteristics of the genus is difficult, because minor attributes, such as acid formation from ethanol and glycerol, are often located in strains of a common natural provenance—i.e., progeny of a single zoogloea or of several zoogloea found in a specific wastewater treatment plant or polluted environment.

Floc formation (Finstein, 1967) and major exopolymer production (Unz and Farrah, 1976a) by *Zoogloea* strains take place during the decreasing and stationary growth phases. Consequently, bioflocculation and exopolymer formation are to be regarded as conditional characters of *Zoogloea* strains, albeit ones that are exhibited reliably by freshly-isolated organisms.

Degradation of the benzenoid ring structure by a *meta* cleavage mechanism is a distinctive character of *Zoogloea* strains and is considered taxonomically significant for the acidovorans group of *Pseudomonas* (Stanier et al., 1966). *Z. ramigera* differs from *P. acidovorans* and *P. testosteroni* by its ability to hydrolyze gelatin and to denitrify and by its inability to hydrolyze starch or to utilize glycolate, caproate, and several amino acids.

Acknowledgments

The phylogram presented in Figure BXII.β.117 was kindly generated by Dr. Ian M. Head, University of Newcastle, United Kingdom. Figures BXII.β.110 and BXII.β.116 were prepared by Paul Wichlacz and Terry Williams, formerly of Pennsylvania State University. Figure BXII.β.113 was contributed by Fuha Lu, Jerzy Lukasik, and Samuel R. Farrah, University of Florida, Gainesville.

Zvirbulis, E. and H.D. Hatt.. 1967. Status of the generic name *Zoogloea* and its species. Int. J. Syst. Bacteriol. *17*: 11–21.

Differentiation of the species of the genus *Zoogloea*

Because of the taxonomic difficulties described previously, the characteristics of the neotype strain of *Z. ramigera* are presented for comparison with those of two other strains whose inclusion in the species is considered by this author to be unwarranted (Table BXII.β.120). See also the section on Other Organisms.

List of species of the genus Zoogloea

1. **Zoogloea ramigera** Itzigsohn 1868, 30[AL]
ra.mi′ ge.ra. L. n. *ramus* branch; L. v. *gero* to bear; M.L. adj.*ramigera* branch-bearing.

The morphological, cultural, physiological, and nutritional characters are given in the description of the genus and in the description of the neotype strain (Table BXII.β.120). No growth occurs on Koser’s citrate. H_2S is not produced from cysteine or on Kligler iron agar. Indole is not produced. Ammonia is produced from asparagine. Lipolytic activity occurs.

Growth on benzoate, *m*-toluate, and *o*-cresol occurs with *meta* cleavage of the aromatic ring.

Methanol, formate, and formaldehyde are not utilized as sole carbon sources.

This strain was cultivated from a single cell isolated by micromanipulation of a finger-like zoogloea present in a trickling filter sample collected in Freehold, New Jersey.

The mol% G + C of the DNA is: 68.9 (HPLC).

Type strain: 106 (neotype), ATCC 19544.

GenBank accession number (16S rRNA): X74913.

2. **Zoogloea resiniphila** Mohn, Wilson, Bicho and Moore 1999b, 935[VP] (Effective publication: Mohn, Wilson, Bicho and Moore 1999a, 76.)
re.si.ni′ phi.la. L. fem. n. *resina* resin; Gr. adj. *philos* loving, friendly to; M.L. fem. n. *resiniphila* loving resins.

Gram-negative, nonsporeforming rods. Catalase negative and oxidase positive. Aerobic, using nitrate, but not fermentative. Mesophilic, growing at 45°C but not at 50°C; however, also reported to grow at 30°C and 37°C, but not at 40°C (Mohn, 1995). Cells grown on dehydroabietic acid are 1.5–2.8 × 1 μm and motile, forming clumps bound by exopolymer; colonies are white, smooth, punctiform, and convex, tenaciously stick to agar.

In mineral medium, use abietic, dehydroabietic, palmitic, benzoic, acetic, and pyruvic acids, as well as D-xylose, phenol, ethanol, and β-sitosterol. Use poorly 12- and 14-chlorodehydroabietic acids. Do not use pimaric, isopimaric, or linoleic acids.

Main cellular fatty acids are $C_{16:1\ \omega7c}$, $C_{16:0}$, and $C_{18:1}$.

The 16S rDNA sequences (EMBL AJ011506) groups within the class *Betaproteobacteria*.

Isolated from a laboratory sequencing batch reactor in Vancouver, British Columbia, Canada.

The mol% G + C of the DNA is: not determined.

Type strain: DhA-35, ATCC 700687.

Other Organisms

In addition to the neotype strain of *Z. ramigera*, there exist two other strains that have attained some prominence through experimental use: strain 1-16-M (Crabtree and McCoy, 1967) and strain 115 (Friedman and Dugan, 1968). The three strains all share the property of floc formation, and each was obtained from polluted environments; however, phenotypic (Table BXII.β.120) and phylogenetic (Fig. BXII.β.117) dissimilarities among the strains indicate that strains 1-16-M and 115 should not be included in the genus *Zoogloea*. Additional evidence for this view is that cross-reactions are not observed between strains 1-16-M

[a]Unless otherwise indicated, the sources of data for strains are as follows: ATCC 19544 (strain 106), Unz (1971); ATCC 19623 (strain I-16-M), Crabtree and McCoy (1967); and ATCC 25935 (strain 115), Friedman and Dugan (1968). For symbols see standard definitions.

[b]Proposed as *Duganella zoogloeoides* (Hiraishi et al., 1997b).

[c]Data from Unz (1971).

[d]Vibriostatic agent 0/129 is 2,4-amino-6,7-diisopropylpteridine.

[e]Data from Friedman and Dugan (1968).

[f]Data from Hiraishi et al. (1997b).

[g]Data from Joyce and Dugan (1970).

[h]Data from Unz and Farrah (1972).

[i]Only benzoate tested.

[j]Data from Shin et al. (1993).

[k]Data from Hiraishi et al. (1992c).

[l]Data from Hamana and Matsuzaki (1993).

or 115 and fluorescein-labeled, whole-cell antiserum against the neotype strain (Farrah and Unz, 1975). Weak, whole-cell antigen–antibody reactions do occur between strain 115 and strain 1-16-M, although strain 115 bears a greater antigenic relationship to *Gluconobacter oxydans* subsp. *suboxydans* (ATCC strain 621) (Chorpenning et al., 1978).

Recently, based on 16S rDNA sequence analysis, strain 115 (*Z. ramigera* ATCC 25935) has been proposed as the type strain for

the renamed type species, *Duganella zoogloeoides*, sp. nov., of a proposed genus, *Duganella* gen. nov. (Hiraishi et al., 1997b).

Nonextant strains of *Z. ramigera*, which bear some resemblance to the neotype strain according to published descriptions, are strain Z-1 (Butterfield, 1935) and an early isolate of questionable purity (Bloch, 1918).

Class IV. **Deltaproteobacteria** *class nov.*

JAN KUEVER, FRED A. RAINEY AND FRIEDRICH WIDDEL

Del.ta.pro.te.o.bac.te′ri.a. Gr. n. *delta* name of fourth letter of Greek alphabet; Gr. n. *Proteus* ocean god able to change shape; Gr. n. *bakterion* a small rod; M.L. fem. pl. n. *Deltaproteobacteria* class of bacteria having 16S rRNA gene sequences related to those of the members of the order *Myxococcales*.

The class is defined solely based on sequence similarity of 16S rRNA. It comprises several bacterial groups that had been previously treated as separate systematic assemblages according to phenotypic characteristics. 16S rRNA sequence analyses are not only informative for the definition of orders and families within the *Deltaproteobacteria*. This method is usually also relevant for the establishment of genera and sometimes species; nevertheless, phenotypic features such as nutritional characteristics or chemotaxonomic properties may be equally important at the genus level, and, in combination with DNA–DNA hybridization, at the species level.

The class *Deltaproteobacteria* comprises morphologically diverse, Gram-negative, nonsporeforming bacteria that exhibit either anaerobic or aerobic growth. Members with facultatively anaerobic/aerobic growth are not known so far.

Most anaerobic members can use inorganic electron acceptors that allow energy conservation by anaerobic respiration. By performing such reactions, these bacteria play a major role in the global cycling of elements. Utilization of inorganic electron acceptors is an important physiological and taxonomic characteristic. However, in a number of isolates the reduction of some electron acceptors (e.g., sulfur, ferric iron) may not be associated with growth (as in the case of oxygen reduction). Therefore, the utilization of an electron acceptor (especially in sulfate-reducing bacteria) must be confirmed by definite growth in subcultures. This has not been proven in every case.

Some anaerobic members are fermentative and/or exhibit syntrophic growth by proton reduction and interspecies hydrogen transfer.

One striking feature of the aerobic representatives is the ability to digest other bacteria. Several of these members are important constituents of the microflora in soil and waters.

Orders *Desulfurellales*, *Desulfovibrionales*, *Desulfobacterales*, *Desulfarcales*, *Desulfuromonales*, *Syntrophobacterales*.

Orders *Myxococcales* and *Bdellovibrionales* are exclusively aerobic.

Type order: **Myxococcales** Tchan, Pochon and Prévot 1948, 398.

Order I. **Desulfurellales** *ord. nov.*

JAN KUEVER, FRED A. RAINEY AND FRIEDRICH WIDDEL

De.sul.fu.rel.la′les. M.L. fem. n. *Desulfurella* type genus of the order; *-ales* ending to denote an order; M.L. fem. pl. n. *Desulfurellales* the order of *Desulfurellaceae*.

Cells are rod-shaped and usually motile. Strictly anaerobic chemoorganotrophs or chemolithoautotrophs with a respiratory type of metabolism; in addition, limited fermentative capacities may occur in some members. The common electron acceptor is elemental sulfur (or polysulfide), which is reduced to sulfide; thiosulfate may be used. Sulfate does not serve as electron acceptor. Simple organic compounds serve as electron donors and carbon sources that are completely oxidized to CO_2. So far as known, the mechanism of terminal oxidation is the citric acid cycle. All members are moderate thermophiles with temperature optima between 50 and 60°C. A striking biochemical feature in species investigated so far is the absence of cytochromes, despite a respiratory metabolism. Menaquinones are present. Species have been isolated from geothermally heated, sulfidic freshwater and marine environments. The order currently contains only one family, *Desulfurellaceae*.

Type genus: **Desulfurella** Bonch-Osmolovskaya, Sokolova, Kostrikina, and Zavarzin 1993, 624 emend. Miroshnichenko, Rainey, Hippe, Chernyh, Kostrikina and Bonch-Osmolovskaya 1998, 478 (Effective publication: Bonch-Osmolovskaya, Sokolova, Kostrikina, and Zavarzin 1990, 155.)

Family I. **Desulfurellaceae** *fam. nov.*

JAN KUEVER, FRED A. RAINEY AND FRIEDRICH WIDDEL

De.sul.fu.rel.la' ce.ae. M.L. fem. n. *Desulfurella* type genus of the family; *-aceae,* ending to denote a family; M.L. fem. pl. n. *Desulfurellaceae* the family of *Desulfurella*.

The main properties have been indicated in the description of the order. The family currently comprises two genera, *Desulfurella* and *Hippea*.

Type genus: **Desulfurella** Bonch-Osmolovskaya, Sokolova, Kostrikina, and Zavarzin 1993, 624 emend. Miroshnichenko, Rainey, Hippe, Chernyh, Kostrikina and Bonch-Osmolovskaya 1998, 478 (Effective publication: Bonch-Osmolovskaya, Sokolova, Kostrikina, and Zavarzin 1990, 155.)

Genus I. **Desulfurella** *Bonch-Osmolovskaya, Sokolova, Kostrikina, and Zavarzin 1993, 624[VP] emend. Miroshnichenko, Rainey, Hippe, Chernyh, Kostrikina and Bonch-Osmolovskaya 1998, 478 (Effective publication: Bonch-Osmolovskaya, Sokolova, Kostrikina, and Zavarzin 1990, 155)*

FRED A. RAINEY AND BECKY HOLLEN

De.sul.fur.el' la. L. pref. *de* from; L. n. *sulfur* sulfur; M.L. dim. ending *-ella;* M.L. fem. n. *Desulfurella* a small sulfur reducer.

Short rods. Motile by means of a single polar flagellum or nonmotile. The cell wall is of the Gram-negative type and has an outer S-layer. Spore formation not observed. **Obligately anaerobic, having a mainly respiratory type of metabolism. Energy conservation occurs by S^0 or thiosulfate respiration or by pyruvate fermentation. Molecular hydrogen, organic acids and fatty acids are utilized. Lithotrophic growth can occur. CO_2 and H_2S are produced.** Menaquinones are present. Cytochromes are not detected. Growth occurs optimally at pH 6.8–7.0. **Moderately thermophilic** with a temperature range between 45 and 75–80°C; optimal, 55–60°C. Occur in warm sediments and in thermally heated cyanobacterial or bacterial communities that are rich in organic compounds and elemental sulfur and are at temperatures in the range 50–70°C. The detailed properties of described species of this genus are given in Table BXII.δ.1.

The mol% G + C of the DNA is: 31–34.

Type species: **Desulfurella acetivorans** Bonch-Osmolovskaya, Sokolova, Kostrikina and Zavarzin 1993, 624 (Effective publication: Bonch-Osmolovskaya, Sokolova, Kostrikina and Zavarzin 1990, 155.)

ENRICHMENT AND ISOLATION PROCEDURES

These thermophilic sulfur-reducing bacteria are enriched by using an anaerobically prepared medium containing (per liter): NH_4Cl, 0.33 g; KCl, 0.33 g; KH_2PO_4, 0.33 g; $CaCl_2 \cdot 2H_2O$, 0.33 g; $MgCl_2 \cdot 6H_2O$, 0.33 g; yeast extract, 0.1 g; $Na_2S \cdot 9H_2O$, 0.5 g; $NaHCO_3$, 1.5 g; resazurin, 0.002 g; trace elements solution (Pfennig, 1965), 1.0 ml, and vitamin solution (Pfennig and Lippert, 1966), 1.0 ml. An aqueous suspension of elemental sulfur is added to give a final concentration of 10 g/l. Various organic substrates and possible electron acceptors can be added at 0.5% (w/v) and 0.2% (w/v), respectively. Medium is dispensed in 15-ml Hungate tubes, and the headspace is replaced with a N_2/CO_2 or H_2/CO_2 mixture (80:20). Pure cultures can be obtained by either serial dilution or colony isolation in agar roll tubes. In agar roll tubes, polysulfide can be used to replace the elemental sulfur.

MAINTENANCE PROCEDURES

Desulfurella strains can be preserved indefinitely by suspending cells in an anaerobic medium (see above) containing 5% dimethylsulfoxide and storing in liquid nitrogen.

TABLE BXII.δ.1. Differential characteristics of the species of the genus *Desulfurella*[a]

Characteristics[b]	*D. acetivorans*	*D. kamchatkensis*	*D. multipotens*	*D. propionica*

Mol% G + C of the DNA	31.4	31.6	33.5	32.2

[a]For symbols, see standard definitions.

[b]All species consist of short rods that can live by anaerobic respiration with elemental sulfur.

[c]All species can use acetate, stearate, palmitate, and H_2 as growth substrates.

Differentiation of the genus *Desulfurella* from other genera

Desulfurella can be differentiated from *Hippea* based on its lack of a requirement for NaCl and yeast extract. Moreover, *Desulfurella* has an optimal temperature of 55–60°C, whereas *Hippea* has an optimal temperature of 52–54°C. Also, the mol% G + C content of the DNA of *Desulfurella* is 31–34 , whereas the value for *Hippea* is 40.

Taxonomic Comments

A phylogenetic analysis based on 16S rDNA sequence comparisons showed *Desulfurella acetivorans* to be equidistant to members of the four then-recognized subclasses of the *Proteobacteria* (Rainey et al., 1993). The highest levels of 16S rDNA sequence similarity were found between *Desulfurella* and sulfate-reducing members of the *Deltaproteobacteria*, but the similarity levels were less than 84%. With the isolation and description of *Hippea maritima* (Miroshnichenko et al., 1999), an additional member was added to this distinct lineage within the *Proteobacteria*. The 16S rRNA gene sequence determined for *Desulfurella* shares 88% sequence similarity with that of *Hippea maritima*.

List of species of the genus Desulfurella

1. **Desulfurella acetivorans** Bonch-Osmolovskaya, Sokolova, Kostrikina and Zavarzin 1993, 624[VP] emend. Miroshnichenko, Gongadze, Lysenko and Bonch-Osmolovskaya 1994, 92 (Effective publication: Bonch-Osmolovskaya, Sokolova, Kostrikina and Zavarzin 1990, 155.)
a.ce.ti.vo′rans. L. n. m. *acetat* acetate; L. adj. fem. *vorans* eating; L. adj. fem. *acetivorans* acetate-eating.

The characteristics are as given for the genus and as listed in Table BXII.δ.1. Cells occur singly or in pairs. Motile by a single polar flagellum. White, irregular colonies 1 mm in diameter develop on agar containing polysulfide. Acetate, pyruvate, pentadecanate, palmitate, and stearate are used for growth. Growth is stimulated by yeast extract. Growth by-products include H_2S and CO_2. Cells are obligately sulfur-respiring. The temperature range for growth is 44–70°C; optimal, 52–55°C. The pH range for growth is 4.3–7.5; optimal, 6.4–6.8.

The mol% G + C of the DNA is: 31.4 (T_m).
Type strain: A-63, ATCC 51451, DSM 5264.
GenBank accession number (16S rRNA): X72768.

2. **Desulfurella kamchatkensis** Miroshnichenko, Rainey, Hippe, Chernyh, Kostrikina and Bonch-Osmolovskaya 1998, 478[VP]
kam.chat.ken′sis. M.L. adj. *kamchatkensis* pertaining to the Kamchatka Peninsula in the Russian Far East.

The characteristics are as given for the genus and as listed in Table BXII.δ.1. Cells occur singly or in pairs. Obligate anaerobe. Motile by a single polar flagellum. H_2/CO_2, acetate, pyruvate, lactate, fumarate, malate, palmitate, and stearate are used for growth. Glucose, sucrose, starch, peptone, yeast extract, formate, propionate, benzoate, hexadecane, succinate, ethanol, and methanol are not used for growth. Elemental sulfur is required for growth. Yeast extract is not required for growth. Growth products include H_2S and CO_2. The temperature range for growth is 40–70°C; optimal, 54°C. The optimal pH range for growth is 6.9–7.2.

The mol% G + C of the DNA is: 31.6 (T_m).
Type strain: K-119, ATCC 700655, DSM 10409.
GenBank accession number (16S rRNA): Y16941.

3. **Desulfurella multipotens** Miroshnichenko, Gongadze, Lysenko and Bonch-Osmolovskaya1996, 625[VP] (Effective publication: Miroshnichenko, Gongadze, Lysenko and Bonch-Osmolovskaya 1994, 92.)
mul.ti.po′tens, L. adj. *multum* many, L. part. *potens* able, *multipotens* having many abilities.

The characteristics are as given for the genus and as listed in Table BXII.δ.1. Cells occur singly or in pairs. Motile by a single polar flagellum. Colonies on agar with polysulfide are white, irregular, and measure 1 mm in diameter. H_2/CO_2, acetate, pyruvate, butyrate, and saturated acids are used for growth. Formate, propionate, lactate, isobutyrate, caproate, alcohols, carbohydrates, and peptides are not used for growth. Cell growth produces H_2 and CO_2. Yeast extract is not required for growth. Cells are lithoautotrophic when grown on mineral medium containing H_2, CO_2, and S^0. Obligately sulfur-respiring. The temperature range for growth is 42–77°C; optimal, 58–60°C. The pH range for growth is 6.0–7.2; optimal, 6.4–6.8.

The mol% G + C of the DNA is: 33.5 (T_m).
Type strain: RH-8, DSM 8415.
GenBank accession number (16S rRNA): Y16943.

4. **Desulfurella propionica** Miroshnichenko, Rainey, Hippe, Chernyh, Kostrikina and Bonch-Osmolovskaya 1998, 479[VP]
pro.pi.o′ni.ca. N.L. fem. adj. *propionica* propionate-utilizing.

The characteristics are as given for the genus and as listed in Table BXII.δ.1. Cells occur singly or in pairs. Nonmotile. Cells have multiple pilus-like structures. H_2/CO_2, acetate, propionate, pyruvate, lactate, fumarate, malate, palmitate, and stearate are used for growth. Glucose, sucrose, starch, peptone, yeast extract, formate, benzoate, hexadecane, succinate, ethanol, and methanol are not used for growth. All growth substrates are oxidized to CO_2. Growth on pyruvate occurs in the absence of sulfur. Elemental sulfur and thiosulfate are reduced to H_2S. The temperature range for growth is 33–63°C; optimal, 55°C. The optimal pH range for growth is 6.9–7.2.

The mol% G + C of the DNA is: 32.2 (T_m).
Type strain: U-8, ATCC 700656, DSM 10410.
GenBank accession number (16S rRNA): Y16942.

Genus II. **Hippea** *Miroshnichenko, Rainey, Rhode and Bonch-Osmolovskaya 1999, 1037[VP]*

THE EDITORIAL BOARD

Hip' pea. L. fem. n. *Hippea* named after Hans Hippe, a German microbiologist, in recognition of his significant contribution to the characterization of new, obligately anaerobic procaryotes and the understanding of their physiology.

Obligately anaerobic and **moderately thermophilic** Gram-negative rods. **Grow lithotrophically using sulfur and hydrogen gas.** Able to oxidize fatty acids and alcohols. Habitat is marine hot vents.

The mol% G + C of the DNA is: 40.

Type species: **Hippea maritima** Miroshnichenko, Rainey, Rhode and Bonch-Osmolovskaya 1999, 1037.

FURTHER DESCRIPTIVE INFORMATION

The three *Hippea maritima* strains studied were isolated from marine hot vent environments that have high levels of both elemental sulfur and organic matter. Like *Desulfurella* spp., which inhabit similar terrestrial environments, *Hippea maritima* is a moderate thermophile that can grow lithotrophically on H_2 and sulfur as well as coupling sulfur reduction to the oxidation of organic compounds.

The temperature range for growth was 40–65°C; the pH range was 5.7–6.5.

Yeast extract (0.02% w/v), NaCl (2.0–3.0% w/v), and elemental sulfur were required. The organisms could not use cystine, ferric iron, fumarate, sulfate, sulfite, or thiosulfate as electron acceptors. Substrates used by all three strains studied included acetate, hydrogen gas, pyruvate and saturated fatty acids; one strain could also use ethanol. Substrates that could not be used by any strain included glucose, butyrate, formate, hexadecane, lactate, pyruvate, succinate, methanol, starch, or peptone. All three strains produced only CO_2 and H_2S as growth products on all substrates (Miroshnichenko et al., 1999).

Analysis of 16S rDNA sequences showed that the three *Hippea maritima* strains were most closely related to the four described species of the genus *Desulfurella* (Miroshnichenko et al., 1999).

ENRICHMENT AND ISOLATION PROCEDURES

The three *Hippea maritima* strains were isolated from marine sands collected from hot vents in the tidal zone of Matupi Harbour, Papua New Guinea, and at 40 m depth in the Bay of Plenty, New Zealand. The medium contained 10 g/l elemental sulfur (as sulfur flowers), 25 g/l NaCl, 5 g sodium acetate, 0.1 g/l yeast extract, vitamins, and trace elements (Miroshnichenko et al., 1999). Samples were incubated with this medium in Hungate tubes under an atmosphere of N_2 and CO_2 (4:1 v/v) at 55°C. Isolated colonies were obtained by serial dilution of the liquid enrichment cultures in an agar medium modified from the enrichment medium by the addition of agar and the substitution of polysulfide for the sulfur flowers. One isolate was obtained from an enrichment in which 0.5% ethanol was used in place of the sodium acetate (Miroshnichenko et al., 1999).

DIFFERENTIATION OF THE GENUS *HIPPEA* FROM OTHER GENERA

Hippea maritima strains differ from *Desulfurella* strains in having slightly lower optimal temperature and pH ranges for growth as well as in requiring 2–3% NaCl and yeast extract for growth. The three *Hippea maritima* strains examined by Miroshnichenko et al. (1999), showed optimal growth at 52–54°C and pH 5.8–6.0; the corresponding values for *Desulfurella* spp. are 55–60°C and pH 6.8–7.0.

List of species of the genus Hippea

1. **Hippea maritima** Miroshnichenko, Rainey, Rhode and Bonch-Osmolovskaya 1999, 1037[VP]

   ma.ri' ti.ma. L. fem. adj. *maritima* inhabiting marine environments.

   Short, obligately anaerobic rods (0.4–0.8 × 1.0–3.0 μm). Single polar flagellum. Grow at 40–65°C (optimal 53–54°C) and pH 5.4–6.5 (optimal 6.0). Substrates for growth include acetate, ethanol, hydrogen gas, pyruvate and saturated fatty acids. Require elemental sulfur, 2.5–3.0% NaCl, and 0.02% yeast extract. Do not use cystine, ferric iron, fumarate, sulfate, sulfite, or thiosulfate as electron acceptors. Sole growth products CO_2 and H_2S.

   The mol% G + C of the DNA is: 40.

   Type strain: MH2, DSM 10411.

   GenBank accession number (16S rRNA): Y18292.

Order II. **Desulfovibrionales** *ord. nov.*

JAN KUEVER, FRED A. RAINEY AND FRIEDRICH WIDDEL

De.sul.fo.vi.bri.o.na' les. M.L. masc. n. *Desulfovibrio* type genus of the type family of the order; suff. *ales* denotes order; M.L. fem. pl. n. *Desulfovibrionales* the order that comprises *Desulfovibrionaceae* and other families.

Cells are curved or rod shaped and often motile. **Strictly anaerobic chemoorganotrophic or chemolithoheterotrophic** (H_2, acetate, sulfate) **growth by respiratory metabolism**; in addition, fermentative abilities are found in several members. **The common electron acceptor is sulfate, which is reduced to sulfide.** Sulfite or thiosulfate may be used in addition; some members may also reduce elemental sulfur (or polysulfide) to sulfide or nitrate to ammonia. **Members of the genera *Bilophila* and *Lawsonia* are unable to use sulfate as an electron acceptor.** Simple organic compounds serve as electron donors and carbon sources. Oxi-

dation is usually incomplete, leading to formation of acetate; the capacity for complete oxidation has been observed so far only in *Desulfothermus naphthae*. Growth by disproportionation of sulfur, thiosulfate, and sulfite may occur. Most members are mesophilic; in addition, some moderate thermophiles with temperature optima between 50 and 60°C have been isolated. Cells contain various cytochromes, other redox proteins, and menaquinones. Mesophilic species have been isolated from almost every type of aquatic environment, including marine habitats, freshwater habitats, technical water systems, and digestive tracts; few clinical isolates without obvious pathogenic properties have been reported. Thermophilic members have been isolated from geothermally heated marine environments. Whereas most members grow preferentially under neutral conditions, some alkaliphilic isolates are known.

The order comprises the families *Desulfovibrionaceae*, *Desulfomicrobiaceae*, *Desulfohalobiaceae*, and *Desulfonatronumaceae* (see Fig. BXII.δ.1).

Type genus: **Desulfovibrio** Kluyver and van Niel 1936, 397.

Family I. **Desulfovibrionaceae** *fam. nov.*

Jan Kuever, Fred A. Rainey and Friedrich Widdel

De.sul.fo.vi.bri.o.na.ce′ ae. M.L. masc. n. *Desulfovibrio* type genus of the family; suffix *-ceae* denotes family; M.L. fem. pl. n. *Desulfovibrionaceae* the family that comprises the genus *Desulfovibrio*.

The usual electron acceptor for the genera *Desulfovibrio* and *Desulfonatronum* is sulfate, which is reduced to sulfide. Members of the genera *Bilophila* and *Lawsonia* are unable to use sulfate as electron acceptor. All known members are mesophilic bacteria. Organic substrates are incompletely oxidized to acetate.

The family comprises three described genera, *Desulfovibrio*, *Bilophila*, and *Lawsonia*. Detailed properties of described species of these genera are given in Table BXII.δ.2.

Type genus: **Desulfovibrio** Kluyver and van Niel 1936, 397.

Genus I. **Desulfovibrio** *Kluyver and van Niel 1936, 397*[AL]

Jan Kuever, Fred A. Rainey and Friedrich Widdel

De.sul.fo.vi′ bri.o. L. pref. *de* from; L. n. *sulfur* sulfur; L. v. *vibrio* to vibrate; M.L. masc. n. *Vibrio* that which vibrates, a generic name; M.L. n. *Desulfovibrio* a vibrio that reduces sulfur compounds.

Curved or occasionally straight **rods**, sometimes **sigmoid or spirilloid, 0.5–1.5 × 2.5–10.0 µm**. The morphology is influenced by age and environment; descriptions refer to freshly grown cultures in anoxic sulfate media. **Spore formation is absent.** Gram negative. **Motile** by means of a single or lophotrichous polar flagella. Obligately anaerobic growth in pure cultures. **Possess mainly a respiratory type of metabolism with sulfate or other sulfur compounds as the terminal electron acceptors, being reduced to H_2S**; however, the metabolism is sometimes fermentative. Media containing a reducing agent are required for growth. In a few cases, a vitamin requirement has been reported. Some species and subspecies are moderately halophilic. Optimal growth temperature, usually 25–35°C; upper limit normally 44°C. No thermophilic species have been reported. Thermophilic *Desulfovibrio* species formerly described have been reclassified and currently belong to the genera *Thermodesulfovibrio* and *Thermodesulfobacterium*. Chemoorganotrophic. **Most species oxidize organic compounds such as lactate incompletely to acetate, which cannot be oxidized further.** Carbohydrates are utilized by few species. One species, *D. inopinatus*, can use hydroquinone as electron donor and carbon source for growth. Cells contain *c*-type cytochromes (such as c_3) and usually *b*-type cytochromes. All members of the genus *Desulfovibrio* contain desulfoviridin. Hydrogenase is usually present. Strains of some species may show chemolithoheterotrophic growth, using H_2 as electron donor and assimilating acetate and CO_2, or yeast extract, as carbon sources. Gelatin is not liquefied. Nitrate is sometimes reduced to ammonia. Some species can reduce oxygen or metal ions, but growth has never been observed with these electron acceptors in pure cultures. Molecular nitrogen is sometimes fixed. Species generally show some degree of antigenic cross reaction. Habitats: anoxic mud of fresh and brackish water and marine environments; intestines of animals; manure and feces.

The mol% G + C of the DNA is: 46.1–61.2.

Type species: **Desulfovibrio desulfuricans** (Beijerinck 1895) Kluyver and van Niel 1936, 397 (*Spirillum desulfuricans* Beijerinck 1895, 113.)

Further descriptive information

Young (i.e., early stationary phase) cultures are morphologically rather homogenous, though morphology is somewhat influenced by the composition of the culture medium. Sigmoid or spirilloid forms are rare, but the species *D. africanus* has a tendency to an elegant sigmoid form and *D. salexigens* tends to be stubby. Old, stressed, or very sulfide-rich cultures may show aberrant cell forms. Rod-shaped strains have been reported but are a minority. Internal structure is rarely visible except in the large species *D. gigas*, which often possesses refractile zones.

Desulfovibrio species usually exhibit a random, rapid, progressive motility. Motility may be suppressed at high sulfide concentrations. Flagella are always polar and are lophotrichous in certain species.

All described *Desulfovibrio* strains contain desulfoviridin as sulfite reductase, and MK-6 or MK-6H_2 as the major menaquinone (Collins and Widdel, 1986). The major cellular fatty acids of *Desulfovibrio* strains are $C_{15:0\ iso}$, $C_{17:0\ iso}$ and $C_{17:1\ iso\ \omega 9c}$ (Vainshtein et al., 1992; Kohring et al., 1994).

Desulfovibrio species have been investigated in much detail with respect to enzymes (e.g., hydrogenases, enzymes of the sulfur metabolism), other redox proteins (e.g., cytochromes c_3), and genes encoding these proteins. In addition, hypothetical models of energy conservation in sulfate-reducing bacteria were mostly

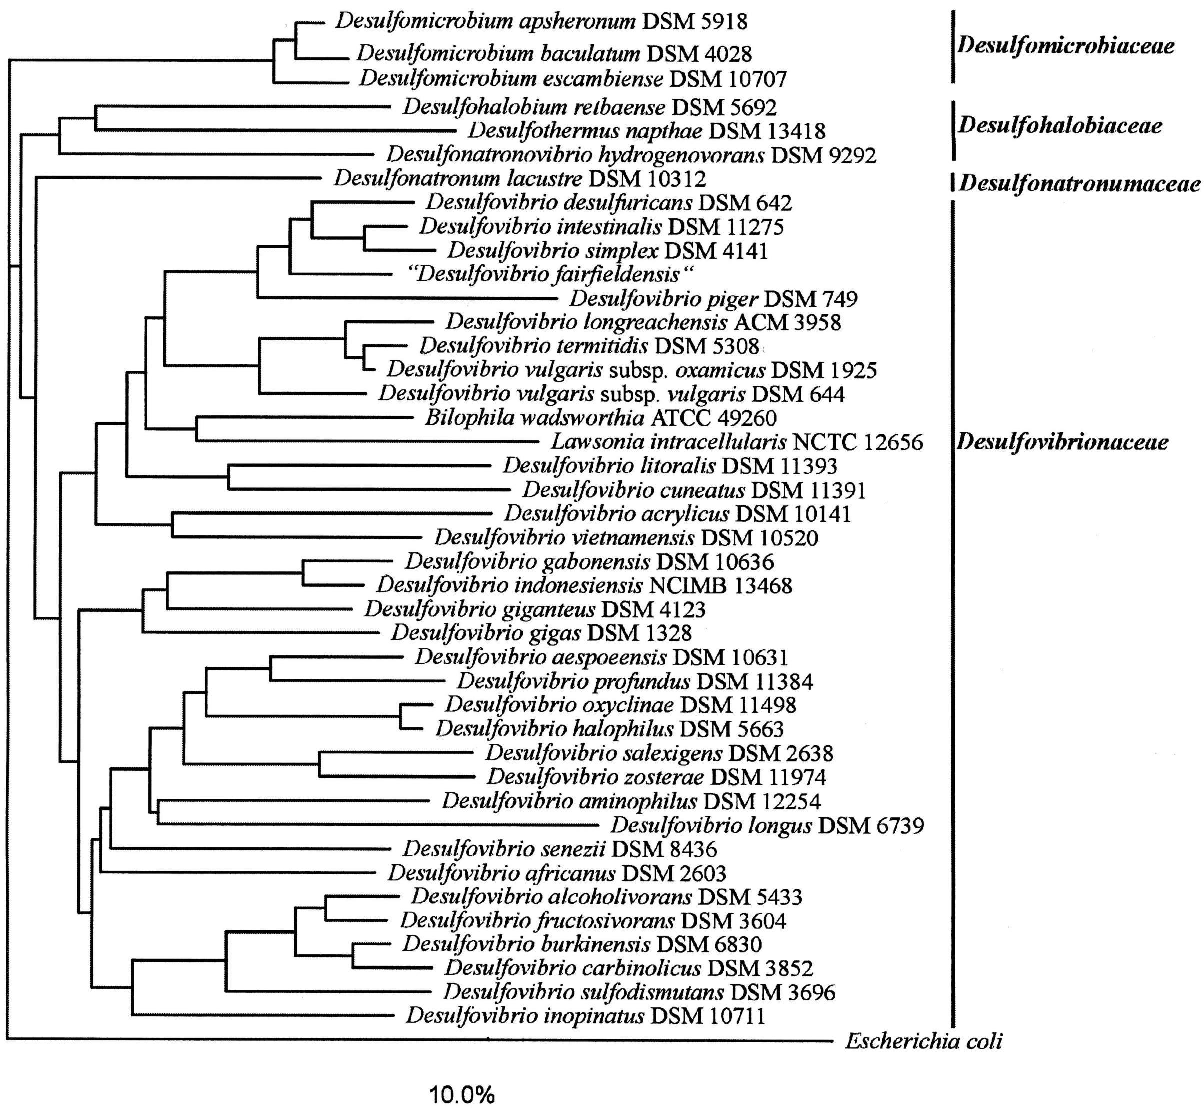

FIGURE BXII.δ.1. Phylogenetic relationships based on 16S rRNA gene sequence analyses of the taxa within the order *Desulfovibrionales* for which 16S rRNA gene sequences are available. The scale bar represents 10 inferred nucleotide substitutions per 100 nucleotides. The dendrogram was reconstructed from distance matrices using the neighbor-joining method.

developed from studies with *Desulfovibrio* species (for overview see Odom and Singleton, 1993; Voordouw, 1995; Rabus et al., 2000a).

Although *Desulfovibrio* spp. are not usually considered pathogenic, there are several reports concerning the isolation of *Desulfovibrio* spp. or closely related organisms from humans and animals. Some strains have been isolated from human patients showing clinical symptoms (Postgate, 1984b, a; Gebhart et al., 1993; McOrist et al., 1995a; Tee et al., 1996; Cooper et al., 1997; McDougall et al., 1997; La Scola and Raoult, 1999c; Loubinoux et al., 2000). An intracellular isolate from intestines of pigs with proliferative enteropathy disease was described as *Lawsonia intracellularis*; it shares 91% 16S rRNA gene sequence similarity with *D. desulfuricans* (ATCC 27774) (McOrist et al., 1995a). It therefore remains unclear whether certain close relatives of *Desulfovibrio* strains are potentially pathogenic to man, or whether they are opportunistic.

Desulfovibrio species are robust sulfate-reducing bacteria with relatively simple growth demands. They may grow rapidly (often with doubling times of only 3–5 h) in various media if oxygen is excluded and sulfate and a suitable electron donor and carbon source are present. Either lactate or a mixture of H_2 and CO_2 in the presence of acetate (as additional carbon source for cell synthesis) is a highly suitable growth substrate. Two different media are commonly used. One is the traditional yeast-extract-containing high-iron medium and its modifications[1] developed

1. The most commonly used of Postgate's media (often referred to as medium B) has the following composition (g/l of tap water): KH_2PO_4, 0.5; NH_4Cl, 1; $CaSO_4$, 1; $MgSO_4\cdot7H_2O$, 2; sodium lactate, 3.5; yeast extract, 1; ascorbic acid, 0.1; thioglycollic acid (fresh), 0.1; $FeSO_4\cdot7H_2O$, 0.5. pH is adjusted between 7 and 7.5. For marine strains, addition of 25 g/l NaCl is recommended. Agar may be used up to 10 g/l for gelling. One modification is a low-iron medium (0.004 g/l $FeSO_4\cdot7H_2O$) with or without sodium citrate dihydrate (0.3 g/l). For details see Postgate (1984a). The reducing capacity of thioglycollic acid and ascorbic acid is best maintained if these are not directly dissolved and autoclaved in the medium, but rather dissolved separately in 10 ml water, filter sterilized, and added to the medium after autoclaving. Also, preparation of medium and solutions under nitrogen (instead of air) favors maintenance of anoxic conditions.

TABLE BXII.δ.2. Characteristics of the genera of the family *Desulfovibrionaceae*[a]

Genus	*Desulfovibrio*	*Bilophila*	*Lawsonia*
Morphology:			
Rod-shaped	+	+	−

[e]*Lawsonia* exhibits no sulfate reduction.

by Postgate (1984a). The other medium is the defined bicarbonate-buffered medium used for *Desulfobacter* species and other sulfate-reducing bacteria, as described in later sections of this chapter (vitamins may be omitted for *Desulfovibrio* species). Reductants are usually included in the media, but fresh cells of *Desulfovibrio* may often grow upon transfer if oxygen is removed only by physical means (e.g., sparging with N_2), without any chemical reduction. In the case of brackish water or marine strains, concentrations of NaCl and $MgCl_2$ should be added to match roughly the salinity of the original habitat. The medium of Postgate usually contains high concentrations of ferrous iron, forming a whitish precipitate. It reacts with sulfide to produce intensely black ferrous sulfide, thus acting as an indicator of metabolic activity and growth.

Enrichment and Isolation Procedures

Enrichment of *Desulfovibrio* species is usually straightforward, and highly enriched and even pure cultures can be obtained within 3–4 weeks. Sulfate media with 1–3.5 g sodium lactate, or alternatively 0.1 g sodium acetate trihydrate, per liter medium and with 80–95% H_2 and 5–20% CO_2 in a head space above the medium (head space–medium ratio approx. 1:1) usually allow selective, rapid growth. In addition, ethanol (0.05%, v/v; presence of CO_2 or bicarbonate needed) or other substrates described for *Desulfovibrio* species (see species descriptions) may be used. In some instances, use of sodium lactate may lead to the development of fermentative bacteria that do not form sulfide. Yeast extract and ascorbate may be omitted since they favor development of various fermentative bacteria that may interfere with isolation procedures. If iron-rich medium (Postgate's medium B) is used, development of sulfate-reducing bacteria is recognized by blackening of the precipitate (formation of FeS). The salinity of the medium should be roughly adjusted to that of the material used as inoculum. For marine cultures, seawater may also be used for medium preparation.

Screw-capped bottles (50 or 100 ml) or culture tubes (20 ml) are satisfactory containers for enrichment cultures. Screw-capped bottles or tubes are completely filled to maintain anoxic conditions. Alternatively, tubes or bottles with anoxic head space (obligatory in the case of H_2 as electron donor) sealed with butyl

rubber may be used. A detailed description of anoxic techniques is given by Widdel and Bak (1992). Enrichment may be achieved in batch cultures, with 1–5% (v/v) sample (mud, sediment) added to the medium, or in liquid dilution series (subsequent dilution steps of 1:10), as used for determination of the most probable number (so-called MPN method). Whereas the former method selects for the most rapidly growing strains, the latter method usually reveals the most abundant type of sulfate-reducing bacterium, which is not necessarily a *Desulfovibrio* species, in a sample.

Sediment-free enrichment cultures are obtained by subsequent transfer of inocula (2–10% of culture volume) to fresh media. Pure cultures are obtained by repeated application of the agar dilution method. A solution of agar (33 g/l) is prepared in distilled water; the agar should be washed several times in cold distilled water before preparing the solution. The agar solution is dispensed in 3-ml amounts into test tubes, which are stoppered with cotton or aluminum caps and autoclaved. Agar tubes may be stored for 2–4 months. The agar tubes are kept molten (or remelted at 100°C) and placed in a water bath at 55°C. Defined culture medium is prewarmed to 41°C and 6-ml amounts are added to the tubes of liquefied agar; exposure to air is minimized by dipping the tip of the pipette into the agar medium. To compensate for the diluting effect of the aqueous agar, it is recommended to increase the amounts of NaCl and $MgCl_2 \cdot 6H_2O$ to 30 and 4.5 g, respectively, per liter of medium (e.g., by addition of sterile salt concentrate) before the medium is added to the agar. Addition of salts to the agar before autoclaving is not recommended as an alternative, because this may promote hydrolysis of the agar. Starting with 0.1 to 0.5 ml of an enrichment culture as inoculum, serial dilutions of approximately 1:10 are made using 6–8 tubes. In general, for isolation of *Desulfovibrio* species addition of dithionite is not required. All agar tubes are then hardened in cold water and immediately sealed with butyl rubber stoppers under a mixture of N_2/CO_2 (90:10). The tubes are incubated in the dark for 2–4 weeks at 25–35°C. Well-separated colonies that occur in the higher dilutions can be removed with sterile Pasteur pipettes (thinned upon heating in a flame); the cells are used as inoculum for subsequent agar dilution cultures. The process is repeated until the cultures are pure, as indicated by homogenous colonies and homogenous cells.

Purity of cultures is checked by microscopy of growth in various media that may allow growth of non-sulfate-reducing bacteria. Contaminant aerobes are excluded by plating out on any nutrient agar containing glucose, yeast extract, and peptone, and incubation under air. No colonies should appear. Contaminant anaerobes are excluded by inoculation of parallel sets of media containing glucose (0.5 g/l) and sodium pyruvate (1 g/l) with or without yeast extract (1 g/l; routinely present in Postgate's medium). Glucose supports growth of only a few *Desulfovibrio* species, but growth of many non-sulfate-reducing anaerobes. Pyruvate is a common growth substrate for *Desulfovibrio*. Microscopy should always reveal the same cell type.

Maintenance Procedures

Pure cultures are best maintained in a medium that is rich in FeS precipitate. Cultures are refrigerated before, or at the beginning of, the stationary phase. Transfers are made every 4–6 months. Lyophilization in the presence of skim milk is used by culture collections for preservation of *Desulfovibrio* spp.

Differentiation of the genus *Desulfovibrio* from other genera

A curved cell morphology and progressive motility often provide a provisional identification of *Desulfovibrio* species. Members of the genus do not have heat-resistant forms and sensitivity to heating for 5 min at 100°C distinguishes them unequivocally from *Desulfotomaculum*. All members of the genus *Desulfovibrio* give a positive reaction to the desulfoviridin test: a characteristic red fluorescence (due to the sirohydrochlorin chromophore of that pigment) appears when a cell suspension is inspected in light of wavelength 365 nm immediately after addition of a few drops of 2.0 N NaOH. This test and morphological characters such as motility and vibrioid form distinguish most strains from *Desulfobacter*, *Desulfococcus*, *Desulfosarcina*, and *Desulfobulbus*. However, a clear differentiation requires a comparative 16S rDNA sequence analysis.

Characteristics useful in differentiating the species of *Desulfovibrio* are listed in Table BXII.δ.3.

Taxonomic Comments

The classification of *Desulfovibrio* species given in the present edition of the *Manual* is based on comparative analysis of the 16S rDNA sequences. The closest relatives to the genus *Desulfovibrio* are members of the genera *Desulfomicrobium*, *Bilophila*, and *Lawsonia*. A set of 16S rRNA oligonucleotide probes which allows the detection of most described *Desulfovibrio* strains was developed by Manz et al. (1998). The signature sequences for nearly all described *Desulfovibrio* species and other closely related sulfate-reducing bacteria are 5′-CCCGATCGTCTGGGCAGG-3′ (oligonucleotide probe DSD131), 5′-CCGAAGGCCTTCTTCCCT-3′ (oligonucleotide probe DSV407), 5′-GTTCCTCCAGATATCTACGG-3′ (oligonucleotide probe DSV698), and 5′-CAATCCGGACTGGGACGC-3′ (oligonucleotide probe DSV1292), which bind to the 16S rRNA corresponding to positions 5′-131–148-3′, 5′-407–424-3′, 5′-698–717-3′, and 5′-1292–1309-3′ of the *Escherichia coli* 16S rRNA sequence, respectively (Manz et al., 1998).

List of species of the genus Desulfovibrio

1. **Desulfovibrio desulfuricans** (Beijerinck 1895) Kluyver and van Niel 1936, 397[AL] (*Spirillum desulfuricans* Beijerinck 1895, 113.)
de.sul.fu′ri.cans. L. pref. *de* from; L. n. *sulfur* sulfur; M.L. part. adj. *desulfuricans* reducing sulfur compounds.

The morphology is as described in Table BXII.δ.3 and as depicted in Fig. BXII.δ.2. Sigmoid forms may occur. Other characteristics are listed in Table BXII.δ.3. Sulfite or thiosulfate can be used as electron acceptors instead of sulfate. Organic substrates are lactate, pyruvate, formate, choline, or certain simple primary alcohols, including ethanol, 1-propanol, and 1-butanol. The latter two serve merely as hydrogen donors and are oxidized to propionate and butyrate, respectively (acetate is required as a carbon source). Nitrate can be used as an electron acceptor and is reduced to ammonia (Seitz and Cypionka, 1986). Oxygen,

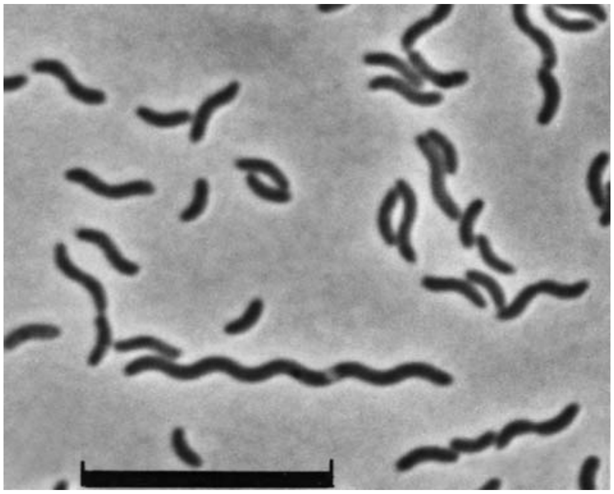

FIGURE BXII.δ.2. Phase-contrast micrograph of *Desulfovibrio desulfuricans* (viable cells). Bar = 10 μm.

chelated Fe(III), and U(VI) can be used as electron acceptors, but these processes are not connected to growth (Dilling and Cypionka, 1990; Lovley and Phillips, 1992; Lovley et al., 1993b). Choline and pyruvate support fermentative growth without sulfate.

Found in freshwater, in particular in polluted waters showing blackening and sulfide formation in the sediment; also found in anoxic or waterlogged soils rich in organic materials, and in marine or brackish waters.

The mol% G + C of the DNA is: 55 (Bd), 59 (T_m), (HPLC).
Type strain: Essex 6, ATCC 29577, DSM 642, NCIB 8307.
GenBank accession number (16S rRNA): M34113, AF192153.

Several subspecies of *D. desulfuricans* (like strain El Agheila Z, ATCC 27774, and ATCC 7757) and *D. vulgaris* have to be reclassified and are not closely related to the type strains (Devereux et al., 1990; Vainshtein et al., 1992). This is also true for strain MB (ATCC 27774), which is often referred to as *Desulfovibrio desulfuricans*; however, it does not resemble the type strain and has a different phylogenetic position within the genus *Desulfovibrio.* Newly published 16S rRNA gene sequences indicate that strain MB (ATCC 27774) is more closely related to *Desulfovibrio intestinalis* (sequence identity of 98.5%) than to the type strain of *D. desulfuricans* (ATCC 29577, strain Essex 6; sequence identity of 97.3%) (Loubinoux et al., 2000).

2. **Desulfovibrio acrylicus** Van der Maarel, Van Bergeijk, Van Werkhoven, Laverman, Meijer, Stam and Hansen 1997, 242[VP] (Effective publication: Van der Maarel, Van Bergeijk, Van Werkhoven, Laverman, Meijer, Stam and Hansen 1996, 114.)
a.cry' li.cus. L. adj. *acrylicus* derived from *acidum acrylicum* acrylic acid.

Characteristics are summarized in Table BXII.δ.3. Isolated from anoxic marine sediments.

The mol% G + C of the DNA is: 65 (HPLC).
Type strain: W218, DSM 10141.
GenBank accession number (16S rRNA): U32578.

3. **Desulfovibrio aespoeensis** Motamedi and Pedersen 1998, 313[VP]
ae.spoe.en' sis. M.L. adj. *aespoeensis* pertaining to Äspo, in southeastern Sweden.

Characteristics are summarized in Table BXII.δ.3. Isolated from deep, subterranean, granitic groundwater (600 m) of southeastern Sweden.

The mol% G + C of the DNA is: 61 (T_m).
Type strain: Aspo-2, DSM 10631.
GenBank accession number (16S rRNA): X95230.

4. **Desulfovibrio africanus** Campbell, Kasprzycki and Postgate 1966, 1127[AL]
af.ri.ca' nus. L. adj. *africanus* pertaining to Africa.

Characteristics are similar to those of *D. vulgaris*; exceptions are noted in Table BXII.δ.3. Contain cytochrome *c.* Isolated from salt and fresh waters in Africa. Has a wide salt tolerance (Campbell et al., 1966; ; Skyring and Jones, 1972; Singleton et al., 1979).

The mol% G + C of the DNA is: 61 (Bd), 65 (T_m).
Type strain: Benghazi, DSM 2603, NCIB 8401.
GenBank accession number (16S rRNA): M37315, X99236.

5. **Desulfovibrio alcoholovorans** Qatibi, Nivière and Garcia 1995, 879[VP] (Effective publication: Qatibi, Nivière and Garcia 1991, 147.)
al.co.ho.lo.vor.ans. E. M. alcohol; L. v. *voro* to devour; M.L. part. adj. *alcoholovorans* devouring alcohol.

Characteristics are summarized in Table BXII.δ.3. Isolated from a pilot fermenter containing alcohol distillery waste-water, France. Optimal growth at a NaCl concentration of 5–10 g/ l.

The mol% G + C of the DNA is: 64.5 (HPLC).
Type strain: SPSN, DSM 5433.
GenBank accession number (16S rRNA): AF053751.

6. **Desulfovibrio aminophilus** Baena, Fardeau, Labat, Ollivier, Garcia and Patel 1999, 341[VP] (Effective publication: Baena, Fardeau, Labat, Ollivier, Garcia and Patel 1998, 503.)
a.mi.no.phi.lus. Gr. n. *aminus*; adj. *philos* loving; M.L. *aminophilum* amino acid loving.

Characteristics are summarized in Table BXII.δ.3. Isolated from anoxic sludge of a dairy wastewater treatment plant in Santa Fe de Bogota, Columbia, with alanine as electron donor and carbon source. Does not require NaCl. Can grow by fermentation of peptone, Casamino acids, serine, glycine, threonine, and cysteine. Thiosulfate and sulfite are disproportionated to sulfate and sulfide.

The mol% G + C of the DNA is: 66 (HPLC).
Type strain: Ala-3, DSM 12254.
GenBank accession number (16S rRNA): AF067964.

7. **Desulfovibrio burkinensis** Ouattara, Patel, Cayol, Cuzin, Traore and Garcia 1999, 642[VP]
bur.ki.nen' sis. N.L. adj. *burkinensis* pertaining to Burkina Faso, West Africa.

Characteristics are summarized in Table BXII.δ.3. Isolated from an anoxic layer of a rice field in Burkina Faso, West Africa, using lactate.

The mol% G + C of the DNA is: 67 (HPLC).
Type strain: HDv, DSM 6830.
GenBank accession number (16S rRNA): AF053752.

8. **Desulfovibrio carbinolicus** Nanninga and Gottschal 1995, 879[VP] (Effective publication: Nanninga and Gottschal 1987, 807.)

car.bi.no' li.cus. M.L. adj. *carbinolicus* referring to carbinols syn. alcohols; *carbinolicus* metabolizing alcohols.

Characteristics are summarized in Table BXII.δ.3. Isolated from an anaerobic purification plant, the Netherlands, using ethanol (Nanninga and Gottschal, 1986, 1987).
The mol% G + C of the DNA is: 65 (T_m).
Type strain: EDK82, DSM 3852.

9. **Desulfovibrio cuneatus** Sass, Berchtold, Branke, König, Cypionka and Babenzien 1998b, 1083[VP] (Effective publication: Sass, Berchtold, Branke, König, Cypionka and Babenzien 1998a, 218.)
cu.ne' a.tus. M.L. adj. *cuneatus* cuneiform, referring to the tapered ends of the cells.

Characteristics are summarized in Table BXII.δ.3. Isolated using lactate from an MPN series inoculated with material from the uppermost 10 mm of the littoral sediment of the oligotrophic Lake Stechlin, Germany. Typical cells are tapering off at one end; conical ends sometimes appear as a short stalk. Cells form aggregates and attach to the surface of the culture flasks. Oxygen can be used as an electron acceptor for the oxidation of H_2, formate, pyruvate, lactate, sulfite, and sulfide, but does not lead to growth. Catalase is present. Grows by disproportionation of sulfite in the presence of acetate.
The mol% G + C of the DNA is: 52.7 (HPLC).
Type strain: STL1, DSM 11391.
GenBank accession number (16S rRNA): X99501.

10. **Desulfovibrio fructosovorans** Ollivier, Cord-Ruwisch, Hatchikian and Garcia 1990, 105[VP] (Effective publication: Ollivier, Cord-Ruwisch, Hatchikian and Garcia 1988, 449.)
fruc.to.so.vo.rans. E.M. fructose; L. v. *voro* to devour; M.L. part. adj. *fructosovorans* devouring fructose.

Characteristics are summarized in Table BXII.δ.3. Isolated from a defined mixed culture on sucrose. Originally isolated from estuarine sediment, USA, with H_2 as electron donor (Jones et al., 1984). Methanol is used as electron donor after the cells have been grown on pyruvate. Fermentative growth occurs on fructose and other substrates (Cord-Ruwisch et al., 1986; Ollivier et al., 1988).
The mol% G + C of the DNA is: 64.1 (Bd).
Type strain: JJ, ATCC 49200, DSM 3604.
GenBank accession number (16S rRNA): AF050101.

11. **Desulfovibrio furfuralis** Folkerts, Ney, Kneifel, Stackebrandt, Witte, Forstel and Schoberth 1989b, 495[VP] (Effective publication: Folkerts, Ney, Kneifel, Stackebrandt, Witte, Forstel and Schoberth 1989a, 168.)
fur.fur.al.is. M.L. adj. *furfuralis* pertaining to furfural (2-furaldehyde).

Characteristics are summarized in Table BXII.δ.3. Isolated from anaerobic wastewater of a paper-producing plant using furfural.
The mol% G + C of the DNA is: 61 (T_m).
Type strain: F1, DSM 2590.

12. **Desulfovibrio gabonensis** Tardy-Jacquenod, Magot, Laigret, Kaghad, Patel, Guezennec, Matheron and Caumette 1996, 714[VP]
ga.bo' nen.sis. M.L. adj. *gabonensis* pertaining to Gabon, a country in West Africa.

Characteristics are summarized in Table BXII.δ.3. Isolated from an oil pipeline, Gabon, West Africa, using lactate. Moderately halophilic, requires at least 10 g NaCl/l for growth.
The mol% G + C of the DNA is: 59.5 (T_m).
Type strain: SEBR 2840, DSM 10636.
GenBank accession number (16S rRNA): U31080.

13. **Desulfovibrio giganteus** Esnault, Caumette and Garcia 1988b, 328[VP] (Effective publication: Esnault, Caumette and Garcia 1988a, 150.)
gi.gan' te.us. L. adj. *giganteus* giant, gigantic.

Characteristics are summarized in Table BXII.δ.3. Isolated from anoxic sediments of Berre Lagoon, Marseilles, France. Slightly halophilic, requires at least 2 g NaCl/l for growth. Can use cysteine and glycerol as electron donors.
The mol% G + C of the DNA is: 55.5 (T_m).
Type strain: 8601, DSM 4123.

14. **Desulfovibrio gigas** Le Gall 1963, 1120[AL]
gi' gas. L. n. *gigas* giant.

The morphology is as described in Table BXII.δ.3 and as depicted in Fig. BXII.δ.3. Characteristics are summarized in Table BXII.δ.3. The cells are often in chains, appearing as spirilla. Young organisms show areas of low contrast when examined by phase-contrast microscopy. Growth is slower than that of other species. Isolated from Etang de Berre, near Marseilles, France. Despite its saltwater origin, saline media are not needed for its cultivation. A slightly different strain was isolated from a sewage plant (Schoberth, 1973).
The mol% G + C of the DNA is: 60.2 (Bd); 65 (T_m).
Type strain: VKM B-1759, ATCC 19364, DSM 1382, NCIB 9332.
GenBank accession number (16S rRNA): M34400.

15. **Desulfovibrio halophilus** Caumette, Cohen and Matheron 1991b, 331[VP] (Effective publication: Caumette, Cohen and Matheron 1991a, 36.)
ha.lo' phi.lus. Gr. n. *halos* salt; Gr. v. *philein* love, like; M.L. adj. *halophilus* salt-loving.

Characteristics are summarized in Table BXII.δ.3. Isolated from an anoxic, benthic, microbial mat of Solar Lake, Sinai, Egypt, with lactate as electron donor. Requires at least 30 g NaCl/ l for growth.
The mol% G + C of the DNA is: 60.7 (Bd).
Type strain: SL 8903, DSM 5663.
GenBank accession number (16S rRNA): U48243.

16. **Desulfovibrio indonesiensis** Feio, Beech, Carepo, Lopes, Cheung, Franco, Guezennec, Smith, Mitchell, Moura and Lino 2000, 1415[VP] (Effective publication: Feio, Beech, Carepo, Lopes, Cheung, Franco, Guezennec, Smith, Mitchell, Moura and Lino 1998, 128.)
in.do' ne.si.en.sis. L. adj. *indonesiensis* from Indonesia, referring to the country of isolation.

Characteristics are summarized in Table BXII.δ.3. Isolated from the corroded hull of an oil storage vessel off the Indonesian coast, Indonesia, with lactate as electron donor and carbon source. Does not require NaCl.
The mol% G + C of the DNA is: not reported.
Type strain: Ind 1, NCIMB 13468.
GenBank accession number (16S rRNA): Y09504.

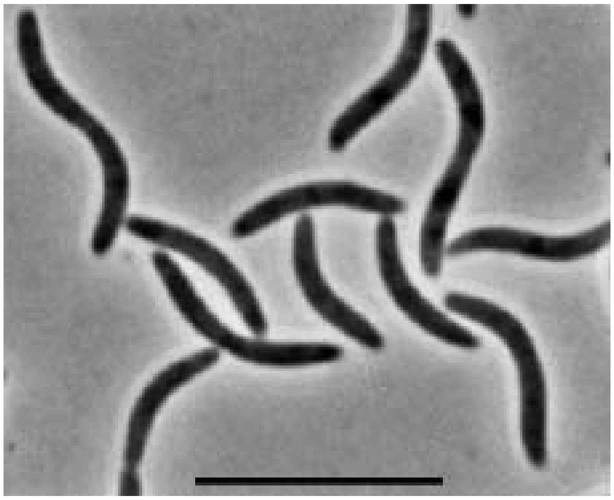

FIGURE BXII.δ.3. Phase-contrast micrograph of *Desulfovibrio gigas* (viable cells). Bar = 10 μm.

17. **Desulfovibrio inopinatus** Reichenbecher and Schink 1999, 1[VP] (Effective publication: Reichenbecher and Schink 1997, 343.)
in.o.pi.na′ tus. L. adj. *inopinatus* unexpected, referring to the utilization of an aromatic compound by a member of the genus *Desulfovibrio*.

Characteristics are summarized in Table BXII.δ.3. Isolated from anoxic mud (Venice, Italy), with hydroxyhydroquinone as electron donor and carbon source. Requires at least 10g NaCl/l and 1.5 g/l $MgCl_2 \cdot 6H_2O$ for growth. Can oxidize ribose, fructose, and hydroxyhydroquinone incompletely to acetate and CO_2 with sulfate as electron acceptor.
The mol% G + C of the DNA is: 49.7 (HPLC).
Type strain: HHQ 20, DSM 10711.
GenBank accession number (16S rRNA): AF177276.

18. **Desulfovibrio intestinalis** Fröhlich, Sass, Babenzien, Kuhnigk, Varma, Saxena, Nalepa, Pfeiffer and König 1999b, 1325[VP] (Effective publication: Fröhlich, Sass, Babenzien, Kuhnigk, Varma, Saxena, Nalepa, Pfeiffer and König 1999a, 150.)
in.tes.ti′ na.lis. M.L. adj. *intestinalis* the isolate lives in the intestine of termites.

Characteristics are summarized in Table BXII.δ.3. Isolated from the hindgut of the lower termite *Mastotermes darwiniensis* Frogatt, with lactate as electron donor and carbon source.
The mol% G + C of the DNA is: 55.0 (HPLC).
Type strain: KMS2, DSM 11275.
GenBank accession number (16S rRNA): Y12254.

19. **Desulfovibrio litoralis** Sass, Berchtold, Branke, König, Cypionka and Bebenzien 1998b, 1083[VP] (Effective publication: Sass, Berchtold, Branke, König, Cypionka and Bebenzien 1998a, 218.)
li.to′ ra.lis. M.L. adj. *litoralis* from the shore, pertaining to the habitat from where the organism was isolated.

Characteristics are summarized in Table BXII.δ.3. Isolated using lactate from a MPN series inoculated with material from a depth of 20–30 mm of littoral sediment of the oligotrophic Lake Stechlin, Germany. Typical cells are tapering off at one end; conical ends sometimes appear as a short stalk. Cells form aggregates and attach to the surface of the culture flasks. Oxygen can be used as electron acceptor for the oxidation of H_2, formate, pyruvate, lactate, ethanol, sulfite, and sulfide, but does not lead to growth. Catalase is present.
The mol% G + C of the DNA is: 36.7 (HPLC).
Type strain: STL6, DSM 11393.
GenBank accession number (16S rRNA): X99504.

20. **Desulfovibrio longreachensis** Redburn and Patel 1995, 879[VP] (Effective publication: Redburn and Patel 1994, 37.)
long.reach′ en.sis. M.L. gen. n. *longreachensis* of Longreach; named after the town in Australia.

Characteristics are summarized in Table BXII.δ.3. Isolated from the water of a free-flowing bore of the Great Artesian Basin in Australia, using lactate.
The mol% G + C of the DNA is: 62.3 (HPLC).
Type strain: AB16910a, ACM 3958.
GenBank accession number (16S rRNA): Z24450.

21. **Desulfovibrio longus** Magot, Caumette, Desperrier, Matheron, Dauga, Grimont and Carreau 1992, 402[VP]
long′ us. L. adj. *longus* long.

Characteristics are summarized in Table BXII.δ.3. Isolated from production fluid from an oil-producing well in the Paris Basin, France. Does not require NaCl, but best growth occurs in the presence of 10–20 g/l NaCl.
The mol% G + C of the DNA is: 62.3 (HPLC).
Type strain: DSM 6739, SEBR 2582.
GenBank accession number (16S rRNA): X63623.

22. **Desulfovibrio oxyclinae** Krekeler, Sigalevich, Teske, Cypionka and Cohen 2000, 1699[VP] (Effective publication: Krekeler, Sigalevich, Teske, Cypionka and Cohen 1997, 373.)
o.xy′ cli.nae. Gr. adj. *oxys* acidic; Gr. v. *clinein* decline; *oxyclinae* referring to the oxycline as habitat.

Characteristics are summarized in Table BXII.δ.3. Isolated from the oxic zone of a hypersaline cyanobacterial mat of Solar Lake, Sinai, Egypt. Requires at least 22 g/l NaCl, with a growth optimal at 5–10 g NaCl. Oxygen can be used as electron acceptor for the oxidation of H_2, lactate, sulfite, and sulfide, but does not lead to growth. Catalase is present. Growth by disproportionation of sulfite and thiosulfate in the presence of acetate.
The mol% G + C of the DNA is: not reported.
Type strain: P1B, DSM 11498.
GenBank accession number (16S rRNA): U33316.

23. **Desulfovibrio piger** (Moore, Johnson and Holdeman 1976) Loubinoux, Valente, Pereira, Costa, Grimont and Le Faou 2002, 1307[VP] (*Desulfomonas pigra* Moore, Johnson and Holdeman 1976, 238.)
pig′ er. L. adj. *piger* lazy (referring to the limited number of substrates utilized by the species).

The morphology is as described in Table BXII.δ.3 and as depicted in Fig. BXII.δ.4. Characteristics are summarized in Table BXII.δ.3. Comparative 16S rDNA sequence analysis and testing of biochemical characteristics clearly indicate that *Desulfomonas pigra* should be reclassified as *Desulfovibrio piger*.
The mol% G + C of the DNA is: 64 (HPLC).
Type strain: ATCC 29098, DSM 749.

GenBank accession number (16S rRNA): M34404.

24. **Desulfovibrio profundus** Bale, Goodman, Rochelle, Marchesi, Fry, Weightman and Parkes 1997, 520[VP]
pro.fun' dus. L. adj. *profundus* deep.

Characteristics are summarized in Table BXII.δ.3. Isolated from deep marine sediment (500 m below sea floor), Japan Sea, Japan, with lactate as electron donor and carbon source. Barophilic. Requires at least 2 g/l NaCl for growth; the optimal NaCl concentration for growth is 6–8 g/l. Nitrate, ferric iron, dimethyl sulfoxide, and lignosulfonates are used as alternative electron acceptors.
The mol% G + C of the DNA is: 53 (HPLC).
Type strain: 500-1, DSM 11384.
GenBank accession number (16S rRNA): U90726.

25. **Desulfovibrio salexigens** Postgate and Campbell 1966, 735[AL]
sal.ex' i.gens. L. n. *sal* salt; L. v. *exigo* to demand; M.L. part. adj. *salexigens* salt demanding.

The morphology is as described in Table BXII.δ.3 and as depicted in Fig. BXII.δ.5. Characteristics are summarized in Table BXII.δ.3. Requires Cl^- ions for growth, which are supplied as NaCl (>6 g/l, usually 25–50 g/l). Found in seawater, marine and estuarine muds, and pickling brines.
The mol% G + C of the DNA is: 46 (Bd).
Type strain: ATCC 14822, DSM 2638, NCIB 8403.
GenBank accession number (16S rRNA): M34401.

26. **Desulfovibrio senezii** Tsu, Huang, Garcia, Patel, Cayol, Baresi and Mah 1999, 341[VP] (Effective publication: Tsu, Huang, Garcia, Patel, Cayol, Baresi and Mah 1998, 316.)
se.ne' zi.i. M.L. gen. *senezii* named to honor the French microbiologist Jacques C. Senez.

Characteristics are summarized in Table BXII.δ.3. Isolated from solar saltern of Chula Vista (San Diego Bay area, California, U.S.A.). Halotolerant.
The mol% G + C of the DNA is: 62 (HPLC).
Type strain: CVL, DSM 8436.
GenBank accession number (16S rRNA): AF050100.

27. **Desulfovibrio simplex** Zellner, Messner, Kneifel and Winter 1990, 470[VP] (Effective publication: Zellner, Messner, Kneifel and Winter 1989, 333.)
sim' plex. M.L. masc. *simplex* meaning ordinary, simple, inconspicuous.

Characteristics are summarized in Table BXII.δ.3. Isolated from an anaerobic digester for the biomethanation of sour whey (originally inoculated with sewage sludge), Regensburg, Germany. Requires at least 2 g/l NaCl for growth, optimal NaCl concentration for growth is 6–8 g/l. Nitrate is used as alternative electron acceptor for growth after adaptation. Can use aromatic aldehydes as electron donors for growth.
The mol% G + C of the DNA is: 47.5 (T_m).
Type strain: XVI, DSM 4141.

28. **Desulfovibrio sulfodismutans** Bak and Pfennig 1988, 136[VP] (Effective publication: Bak and Pfennig 1987, 189.)
sul.fo.dis' mu.tans. L. n. *sulfur* sulfur; L. pref. *dis* apart; L. part. adj. *mutans* that which changes; M.L. part. adj. *sulfodismutans* dismutating sulfur compounds.

Characteristics are summarized in Table BXII.δ.3. Isolated from anoxic freshwater sediments, Konstanz, Germany, with sulfite as electron donor and acetate and bicarbonate as carbon source. Requires at least 0.1% (w/v) NaCl and 0.04% (w/ v) $MgCl_2 \cdot 6H_2O$ for growth. Thiosulfate, sulfite, and dithionite are disproportionated to sulfate and sulfide and allow growth in the presence of acetate and bicarbonate.
The mol% G + C of the DNA is: 64.1 (Bd).
Type strain: ThAc01, DSM 3696.
GenBank accession number (16S rRNA): Y17763.

29. **Desulfovibrio termitidis** Trinkerl, Breunig, Schauder and König 1991, 178[VP] (Effective publication: Trinkerl, Breunig, Schauder and König 1990, 376.)
ter.mi' ti.dis. M.L. nom. *termes* the termite; M.L. gen. nom. *termidites* of a termite.

Characteristics are summarized in Table BXII.δ.3. Isolated from the hindgut of the termite *Heterotermes indicola* (Wasmann).
The mol% G + C of the DNA is: 67 (T_m).
Type strain: HI1, ATCC 49858, DSM 5308.
GenBank accession number (16S rRNA): X87409.

30. **Desulfovibrio vietnamensis** Nga, Ha, Lai and Stan-Lotter

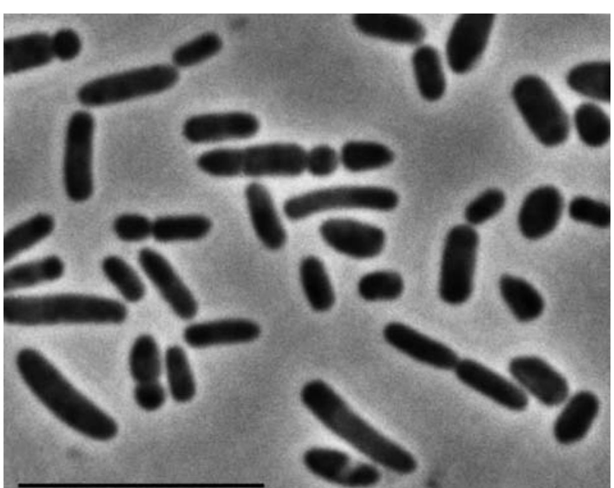

FIGURE BXII.δ.4. Phase-contrast micrograph of *Desulfovibrio piger* (basonym *Desulfomonas pigra*) (viable cells). Bar = 10 μm.

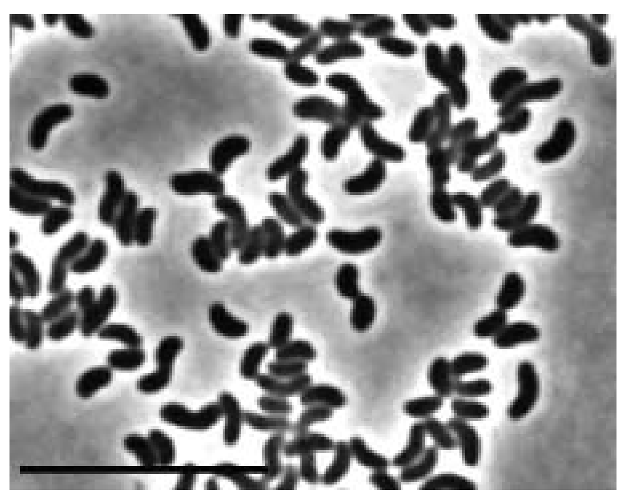

FIGURE BXII.δ.5. Phase-contrast micrograph of *Desulfovibrio salexigens* (viable cells). Bar = 10 μm.

2002, 1075[VP] (Effective publication: Nga, Ha, Lai and Stan-Lotter 1996, 391.)
viet.na′men.sis. L. adj. *vietnamensis* from Vietnam, referring to the country of isolation.

Characteristics are summarized in Table BXII.δ.3. Isolated from the production fluid of an offshore oil field, Vietnam. Does not require NaCl, although optimal growth occurs in the presence of 5% (w/v) NaCl.

The mol% G + C of the DNA is: 60.6 (HPLC).
Type strain: G3 100, DSM 10520.
GenBank accession number (16S rRNA): X93994.

31. **Desulfovibrio vulgaris** Postgate and Campbell 1966, 734[AL]
vul.ga′ris. L. adj. *vulgaris* common.

Characteristics are summarized in Table BXII.δ.3. Similar to *D. desulfuricans*, except for some characteristics indicated in Table BXII.δ.3; notably, it does not show sulfate-free growth on pyruvate and has a higher G + C content of the DNA (see below). The type strain can use Cr(VI) and chelated Fe(III) as electron acceptors, but the reduction is not connected to growth (Lovley et al., 1993b; Lovley and Phillips, 1994b).

The mol% G + C of the DNA is: 61 (Bd).
Type strain: DSM 644, NCIB 8303.
GenBank accession number (16S rRNA): M34399.

The subspecies *D. vulgaris* subsp. *oxamicus* of Postgate and Campbell (1966) (NCIB 9442, DSM 1925) and strain Marburg should be regarded as separate species and should be reclassified.

32. **Desulfovibrio zosterae** Nielsen, Liesack and Finster 1999, 864[VP]
zo.ste.ra′e. N.L. bot. n. *zostera;* N.L. gen. n. *zosterae* denoting that the bacterium was isolated from the plant *Zostera marina.*

Characteristics are summarized in Table BXII.δ.3. Isolated from roots of the marine macrophyte *Zostera marina* in Logstor Broad, Denmark, with lactate as electron donor and carbon source. Grows diazotrophically. Catalase present. Aerotolerant.

The mol% G + C of the DNA is: 42.7 (HPLC).
Type strain: lac, DSM 11974.
GenBank accession number (16S rRNA): Y18049.

Other Organisms

1. *"Desulfovibrio fairfieldensis"* Tee, Dyall-Smith, Woods and Eisen 1996.
fair.field′en.sis. L. adj. *fairfieldensis* from Fairfield, referring to the location of isolation.

The information about this proposed species is rather limited.

The mol% G + C of the DNA is: 62 (HPLC).
Deposited strain: None available.
GenBank accession number (16S rRNA): U42221.

Genus II. **Bilophila** *Baron, Summanen, Downes, Roberts, Wexler and Finegold 1990, 320[VP] (Effective publication: Baron, Summanen, Downes, Roberts, Wexler and Finegold 1989, 3410)*

Ellen Jo Baron

Bi.lo′phi.la. L. n. *bilis* gall, bile; Gr. adj. *philus* loving; M.L. fem. n. *Bilophila* bile-loving organism.

Regularly shaped rods 0.7–1.0 × 1.0–2.0 μm when grown in peptone–yeast glucose broth with 1% pyruvate. Rods have rounded ends and occasionally form long filaments, but no internal structures are visible by light microscopy. Cells do not possess pili or flagella and are nonmotile. Nonsporeforming. Gram negative. **Anaerobic.** Nonfermentative; metabolism is by anaerobic respiration. Chemoorganotrophs. Growth is enhanced by 20% bile and 1% pyruvate. **Metabolize peptone but not carbohydrates. The major product from peptone is acetic acid with lesser to trace amounts of succinic acid.** Able to reduce nitrate to nitrite; some strains reduce nitrate to nitrogen gas. Hydrogen sulfide is produced from sulfur-containing amino acids, but the organisms do not reduce sulfur. In the presence of formate, *B. wadsworthia* utilizes taurine as an electron acceptor, oxidizing it to acetate with the reduction of sulfonate sulfur to sulfide. **Strongly catalase positive** (when tested with 15% H_2O_2). **Approximately 75–90% of strains produce urease, depending on the test system.** (Claros et al., 1999). In the presence of formate, *B. wadsworthia* utilizes taurine as an electron acceptor, with the production of acetate and the reduction of sulfonate sulfur to sulfide (Laue et al., 1997; Cook et al., 1999). The dissimilatory sulfite reductase (desulfoviridin) of *B. wadsworthia* is related to that of *Desulfovibrio* (Laue et al., 2001). Isolated from gastrointestinal, genital, and oral (periodontal) cavities of humans and other mammals (dogs).

The mol% G + C of the DNA is: 59.2 (HPLC).

Type species: **Bilophila wadsworthia** Baron, Summanen, Downes, Roberts, Wexler and Finegold 1990, 320 (Effective publication: Baron, Summanen, Downes, Roberts, Wexler and Finegold 1989, 3410.)

Further descriptive information

One described species, *Bilophila wadsworthia.* Cells are small to medium rods, 0.7–1.1 × 1.0–2.0 μm, that are regularly shaped when cultured on pyruvate-containing media. Cultures on less supportive media exhibit pleomorphic cell structures including filaments. Freeze-fracture electron micrographs show a smooth outer membrane with few structures (Summanen et al., 1989). There is no obvious peptidoglycan layer visible in transmission electron micrographs of the cell wall (Summanen et al., 1989, 1993).

Fatty acid methyl ester analysis reveals a unique series of whole cell fatty acids, which include $C_{15:0\ iso}$, $C_{16:0}$, $C_{17:0\ cyclo\ \omega7c}$, and $C_{19:0\ cyclo\ \omega9c}$ (Baron et al., 1989).

Under anaerobic conditions, small amounts of malate dehydrogenase and glutamate dehydrogenase can be detected in some species (Baron, 1997).

Bilophila strains require strictly anaerobic atmospheric conditions for growth. Freshly prepared or anaerobically stored media may be necessary. The organisms grow slowly, with colonies

often visible only after 48–72 h. Supplementation of media, particularly broth media, with 1% pyruvate may be required for growth or metabolic reactivity of most strains. Growth at temperatures other than 35–37°C has not been attempted.

Strains have been recovered from numerous infected tissues in humans and dogs, usually in mixed culture, but occasionally in pure culture, such as from blood (Bennion et al., 1990a; Baron et al., 1992a, b; Baron, 1997; Gerardo et al., 1997; Schumacher and Bucheler, 1997). Although the organism comprises only 0.01% of the normal human fecal flora, it is the third most common isolate among anaerobes recovered from patients with perforated or gangrenous appendicitis (Bennion et al., 1990a,b; Baron et al., 1992a). Environmental strains (sewage) and urease-negative strains may have PCR profiles different from those of clinical strains when specific primers are used for amplification (Claros et al., 1999). Unpublished observations suggest that some strains can produce abscesses in the mouse peritoneal abscess model (A. Onderdonk, personal communication) without other associated enhancers, as do *Bacteroides fragilis* species. Some strains possess adherence mechanisms for laminin (Schumacher, 1997), but not for lipids (Schumacher et al., 2000). Cell walls contain endotoxin, as demonstrated by limulus amebocyte lysate assay, but endotoxin activity is not as great as that of other Gram-negative bacilli (Mosca et al., 1995).

Enrichment and Isolation Procedures

Anaerobic blood-containing media supplemented with Vitamin K and hemin minimally support the growth of *Bilophila* species. *Brucella* agar base has been used primarily; comparisons with other agar bases have not been published. The organism grows slowly on *Bacteroides* bile esculin (BBE) agar; therefore, plates should be held for at least 7 days before they are discarded as negative. Addition of 20% bile (oxgall) and 1% pyruvate to all media enhances growth and promotes the formation of regular rod-shaped cell morphology. Pyruvate enrichment may be necessary for growth in some broths, for accurate growth-dependent susceptibility testing, and for demonstration of some metabolic activities, such as β-lactamase production (Bennion et al., 1990a; Summanen et al., 1992; Mochida et al., 1998).

Maintenance Procedures

Fresh subcultures can be maintained for at least one month on anaerobic blood agar sealed in an oxygen-free atmosphere in a small, gas-impermeable foil bag or a plastic anaerobic pouch containing a strong oxygen-removing catalyst packet (Downes et al., 1990). Other methods for maintaining anaerobic bacteria, such as freezing a heavy suspension made from a fresh subculture in 10% glycerol, defibrinated sheep blood, or chopped meat broth, are also acceptable.

Differentiation of the genus *Bilophila* from other genera

Table BXII.δ.4 shows key characteristics of organisms that may appear similar to *Bilophila* in some respects, especially when recovered from anaerobic blood agar. If colonies are first noted on BBE agar, the typical small, translucent, black-centered colony should suggest the possibility that the colony represents *Bilophila*. The strong catalase reaction of *Bilophila* is unlike that of virtually any other anaerobic organism tested and can therefore rule out other anaerobes and the occasional *Enterococcus* that yields a similar colony on BBE.

Taxonomic Comments

Based on 16S rRNA sequence analyses, *Bilophila* is located within the *Deltaproteobacteria*, along with a number of species of *Desulfovibrio* (Sapico et al., 1994) within the family *Desulfovibrionaceae*.

Crude whole chromosomal dot-blots have shown that, of twenty ATCC type strains of *Bacteroides*, *Porphyromonas*, *Prevotella*, *Desulfomonas*, *Desulfovibrio*, and *Mitsuokella* tested, only *Bacteroides vulgatus* exhibits some homology with *Bilophila* (at the 30% level) (Baron et al., 1989).

List of species of the genus Bilophila

1. **Bilophila wadsworthia** Baron, Summanen, Downes, Roberts, Wexler and Finegold 1990, 320[VP] (Effective publication: Baron, Summanen, Downes, Roberts, Wexler and Finegold 1989, 3410.)
wads.wor′ thi.a. M.L. fem. adj. *wadsworthia* originating from the Wadsworth Anaerobe Laboratories of the Wadsworth Veterans Administration Medical Center.

Characteristics are as described for the genus and as listed in Table BXII.δ.5, with the following additional characteristics. After a minimum of 48 h incubation, surface colonies on *Brucella* blood agar are 0.6–0.8 mm in diameter, transparent to translucent, raised with a circular, erose edge. After 72 h incubation, surface colonies on *Bacteroides* bile esculin agar are 1–2 mm in diameter, and either low convex, black, opaque, and irregular, or translucent, umbonate, circular with an erose edge, and often showing a black central area of precipitation of hydrogen sulfide. Subsurface colonies (created by stabbing the agar during inoculation) display heavy black precipitated H_2S. To maximize detection of these small colonies, BBE agar should be incubated for 7 d.

TABLE BXII.δ.4. Differential characteristics of species similar to *Bilophila*[a]

Characteristic[a]	*Bilophila*	*Bacteroides putredinis*	*Bacteroides ureolyticus*	*Campylobacter gracilis*	*Desulfomonas*	*Desulfovibrio*	*Fusobacterium* species	*Sutterella wadsworthensis*

TABLE BXII.δ.5. Characteristics of the genus *Bilophila*[a]

Characteristic	Result or reaction
Acid products formed in cultures grown in peptone–yeast extract glucose broth supplemented with 1% pyruvate	+[b]
H_2S produced	+
Starch and esculin hydrolyzed	−
Nitrate reduced to nitrite and occasionally to N_2	+
Indole produced	−
Motility	−
Urease	d (75%)
Growth in 20% bile	+
Catalase (tested with 15% H_2O_2)	+ (strong)
Gelatin digested	−
Lecithinase, lipase	−
Milk reaction	−
Acid from carbohydrates	−
Acid phosphatase (API ZYM)	+
Sulfate reduced	−

[a]For symbols see standard definitions.

[b]Mainly acetic acid plus smaller amounts of succinic acid.

Peptone broth cultures with 1% pyruvate show diffuse, cloudy growth. Many strains produce acid phosphatase and the cellular enzymes malate and glutamate dehydrogenase. Testing in an anaerobic atmosphere is often required for detection (Baron, 1997). Esculin is not hydrolyzed. Approximately 75% of strains hydrolyze urea, as demonstrated either by a rapid urease disk test, by overnight anaerobic incubation on Christensen's urea agar, or with PRAS urea broth. All strains tested so far have been susceptible to metronidazole (8.0 μg/ml) (Baron et al., 1993; Mochida et al., 1998). Strains appear to be inhibited by clindamycin (4 μg/ml), imipenem (32 μg/ml), ampicillin/sulbactam (16/8 μg/ml), and cefoxitin (32 μg/ml), but method and inoculum differences contribute to major differences in endpoints (Baron et al., 1993; Mochida et al., 1998). Although a hazy, trailing endpoint in agar dilution studies with imipenem has been associated with viable spheroplast formation; the clinical implications of this finding are not known (Summanen et al., 1993). Detection of β-lactamase, present in >85% of strains, requires growth on 1% pyruvate-containing medium (Summanen et al., 1992; Mochida et al., 1998). *B. wadsworthia* has been isolated from inflamed and gangrenous appendices, other intra-abdominal infections, brain abscesses, Bartholin cyst abscesses, liver abscesses, breast abscesses, empyema, gingivitis, Fournier's gangrene, osteomyelitis, and other common sites of mixed aerobic and anaerobic infections in humans (Baron et al., 1992b; Summanen et al., 1995; Baron, 1997), as well as otitis media, and blood cultures (Kasten et al., 1992; Bernard et al., 1994; Gerardo et al., 1997; Schumacher and Bucheler, 1997). *B. wadsworthia* is found in human feces, saliva, and vaginal discharge in the absence of infection (Baron et al., 1989, 1992b; Baron, 1997) and in periodontal pockets of dogs (Baron et al., 1992b).

The mol% G + C of the DNA is: 59.2 (HPLC, Laue et al., 2001; originally published as 39–40 (T_m).

Type strain: ATCC 49260 (WAL 7959).

Genus III. **Lawsonia** *McOrist, Gebhart, Boid and Barns 1995a, 824*[VP]

Steven McOrist and Connie J. Gebhart

Law.so'ni.a. L. dim. ending *-ia* M.L. masc. n. *Lawsonia* named after Gordon H.K. Lawson, the Scottish veterinarian who first recognized the organism causing porcine proliferative enteropathy.

Curved, vibrioid, or occasionally straight rods, 0.3–0.4 × 1.5–2.0 μm. The morphology is influenced by age and environment; descriptions refer to organisms within naturally infected intestinal epithelial cells or freshly grown co-cultures of intestinal epithelial cells. Gram negative. Single polar bacterial cell appendages have been observed in some preparations of co-cultured strains, with rapid darting motion apparent in active cultures. Endospores not formed. **Obligately intracellular, cell-dependent, and microaerobic.** Optimal temperature usually 35–37°C. Strains have demonstrated survival, but not growth, at lower temperatures. The organisms react with the IG4 monoclonal antibody shown to be specific for *Lawsonia* sp. Habitats: intestines of pigs and other animals; feces. The causal agent of proliferative enteropathy. Key aspects of the 16S rDNA sequence are given in McOrist et al., 1995a. A 16S rRNA signature sequence for the genus is 5′-GAUUAAGAGGUGCCUUUCGGGGAGCCUCAA–3′, corresponding to the nucleotide positions 1015–1042 of the *E. coli* 16S rRNA sequence.

The mol% G + C of the DNA is: 34; total genome length 1.713 Mbp.

Type species: **Lawsonia intracellularis** McOrist, Gebhart, Boid and Barns 1995a, 824.

Further descriptive information

The placement of the *Lawsonia* genus within the *Desulfovibrionaceae* is based on 16S rDNA sequence similarities and morphologic similarities (Gebhart et al., 1993; McOrist et al., 1995a). A full-length (1552 nucleotide) 16S rDNA sequence was obtained from a genomic clone of the type strain purified from porcine intestinal mucosa. Comparison of this sequence with sequences available in the Ribosomal RNA Database Project (RDP) indicated highest similarity with the 16S sequences of the *Desulfovibrionaceae*. Extensive phylogenetic analysis of this sequence and those of the *Desulfovibrionaceae*, using distance matrix, maximum parsimony, and maximum likelihood techniques, has suggested placement within this group.

Cells of *Lawsonia* are typical vibrioid-shaped, curved to straight rods (Rowland and Lawson, 1974). This morphology appears to be similar in organisms observed within host cells, associated with host cells, or present within artificial co-cultures (Rowland and Lawson, 1974; Frisk and Wagner, 1977; Lawson et al., 1993). The life cycle of *Lawsonia* within infected cells closely resembles that of another (unrelated) obligately intracellular bacterium *Orientia tsutsugamushi* (McOrist et al., 1995b). Following a brief (<3 h) association with the mammalian cell border, *Lawsonia* cells enter via induced endocytosis. Viability of the mammalian cells, but not of the bacteria, is required for uptake (Lawson et al., 1995). Following a further brief (<3 h) period within endocytic vacuoles, bacteria quickly escape into the cytosol (McOrist et al., 1995b). It is possible that *Lawsonia* possesses a phospholipase or some other enzymatic method for quick release from vacuoles, but this has not been definitely established. *Lawsonia* spp. have

only been observed to grow and multiply within the cytosol, often in close proximity to cell mitochondria. It is possible that *Lawsonia* possesses a requirement for preformed triphosphates. The trilaminar cell wall and fine structure of *Lawsonia* are typical of Gram-negative bacteria (Rowland and Lawson, 1974); however, no S-layer was observed in other limited studies (McOrist et al., 1997).

The *Lawsonia* organism was originally described in various papers as a *Campylobacter*-like organism on the sole basis of a morphologic similarity. However, unlike both the *Desulfovibrio* and *Campylobacter* genera, *Lawsonia* is an obligately intracellular bacterium. A single polar flagellum has been observed on extracellular organisms in some preparations of co-cultured *Lawsonia* strains. This structure has not been observed on *Lawsonia* present inside cells or *in vivo*. There is no evidence of sulfate reductase gene sequences in *Lawsonia*. Presumably, active sulfate reduction would be an evolutionary disadvantage in its intracellular habitat. When the relationship of *Lawsonia* to *Desulfovibrio* became known, many workers, including the authors, attempted cell-free growth in conditions suitable for the latter genus. Many (over 80) media preparations and various atmospheres have been tested on isolates already adapted to laboratory co-culture, but the growth conditions of *Lawsonia* have remained resolutely obligately intracellular. The nutrition and growth requirements of *Lawsonia* are therefore the fastidious ones listed below for co-culture in cell lines. Growth of the organism in various chambers of chicken eggs has not been successful, despite several efforts by different groups.

The DNA sequences of the 16S ribosomal subunits of various strains of *Lawsonia* have been determined and are similar; see GenBank accession numbers L15739, U30147 (cultured porcine strains; Gebhart et al., 1993; McOrist et al., 1995a), U06423, U65995 (cultured hamster strains; Peace et al., 1994; Cooper et al., 1997), U65996, U65997, U65998, U07570 (uncultured strains purified from the intestines of deer, ostrich, horse, and ferret, respectively; see Fox et al., 1994a; Cooper et al., 1997). The partial DNA sequence of a chaperonin (GroEL) of one strain of *Lawsonia* has been determined; see GenBank accession number U45241 (uncultured strain purified from the intestines of a pig; Dale et al., 1998). No plasmids have been detected in *Lawsonia* spp. (McOrist et al., 1990).

The antigenic structure of *Lawsonia* has been identified in PAGE and immunoblotting studies of the outer membranes of several strains. The major structural protein is probably an observed 55-kDa protein, while highly immunoreactive components of the outer cell membrane, probably glycoproteins, are 27–29 kDa (McOrist et al., 1989a, 1995a).

Because *Lawsonia* is an animal pathogen, the antibiotic and drug sensitivity of several strains have been determined (McOrist et al., 1995c). The methods used were adapted from ones used successfully for the evaluation of the microaerobic, cell-dependent *Treponema pallidum*. *Lawsonia* appears to be resistant to the actions of aminoglycosides and various anti-Gram-positive compounds such as bacitracin and vancomycin, at standard concentrations. *Lawsonia* spp. appear to be relatively sensitive to the actions of compounds such as macrolides, lincosamides, and pleuromutilins. This is probably due to an ability of these compounds to concentrate in the cytosol of mammalian cells in concentrations that are likely to allow both bacterial uptake and inhibition of bacterial protein synthesis.

Lawsonia is an obligately intracellular bacterium that has only been identified in the intestinal epithelial cells of mammals (particularly pigs and hamsters) or ratite birds. It is one of the few bacterial genera consistently associated with the proliferation of a monotype of mammalian cells, namely the infected intestinal epithelial cells. Studies of *Lawsonia* pathogenesis indicate that once the epithelial cells of an intestinal crypt become infected, these infected cells fail to mature and instead continue as the undifferentiated, proliferative phenotype (Johnson and Jacoby, 1978; McOrist et al., 1989b). *Lawsonia* isolates have therefore been derived solely from the intestinal mucosa of animals demonstrated, by histologic assay of adjacent portions of mucosa, to have been suffering from proliferative enteropathy (ileitis). Oral inoculation of pigs or hamsters with cultured *Lawsonia* leads to characteristic intracellular infection and resulting intestinal lesions (Stills 1991; McOrist et al., 1993, 1994b). Staining of these sections by specific *in situ* immunoassay or by DNA probes for *Lawsonia* spp. confirms the diagnosis and presence of the causative agent at this site (McOrist et al., 1993; Gebhart et al., 1994). No such lesions or bacteria have ever been observed in pigs or hamsters not exhibiting proliferative enteropathy, or in humans, even those with enteric disease. The pathogenesis of proliferative enteropathy is discussed more fully in the referenced publications (see McOrist et al., 1989b, 1993, 1996). Once *Lawsonia* are cleared from intestinal cells, normal cell differentiation and apoptosis resume, with normal architecture returning within two weeks (McOrist et al., 1996). Presumably, the consequent proliferation of target cells following infection is a useful evolutionary adaptation for the transmission of *Lawsonia* among susceptible animals. Very few other bacterial genera are so closely associated with mammalian cell proliferation. *Bartonella bacilliformis* are consistently associated with proliferation of human endothelial cells and *Citrobacter rodentium* causes a colonic hyperplasia in mice, but neither organism is an intracellular bacterium *in vivo*. Presumably, some members of these three unrelated genera have the ability to produce substances capable of influencing either the mammalian genome or other factors active on it, but no definitive work addressing this trait has appeared with regard to any of the genera.

Enrichment and Isolation Procedures

Initial purification and isolation of the intracellular bacteria from fresh intestinal mucosa samples can be accomplished by following established co-culture techniques (Lawson et al., 1993). Cell cultures used for co-culture should be demonstrated to be free of *Chlamydia* spp., *Mycoplasma* spp., and extracellular bacteria by both assays with commercially available kits and routine bacteriologic culture under aerobic, microaerophilic, and anaerobic atmospheres. Homogenization and trypsinization of the intestinal mucosa from infected intestines to release the bacteria, followed by differential centrifugation or filtration steps, gives a purified *Lawsonia* suspension suitable for inoculation into established cell lines of intestinal epithelial cells, such as IEC-18 or INT 407. Addition of antibiotics that retard contaminants from the initial bacterial suspension, but do not retard *Lawsonia* growth, is required until *Lawsonia* growth is advanced and the culture is purified by cell passage. Antibiotics suitable for this purpose include neomycin and vancomycin. *Lawsonia* spp. prefer rapidly dividing cells for intracellular growth. The intracellular growth curve typically reaches peak infection 1–5 d after initial infection in established cultures (peak infection is reached more slowly in initial passages). Examination of infected cell cultures by routine light microscopy during this active growth phase does not reveal any visible changes or evidence of infection. Older, mature co-cultures exhibit reduced bacterial growth, increased cell death, and bacterial release into the culture medium. Growth of *Lawsonia* can be confirmed by staining of the co-cultures with

a modified Zeehl–Neilsen stain or immunostain with IG4 *Lawsonia*-specific monoclonal antibody. To date, co-culture of more than a small number of isolates (~14) has not been possible due to the tedious nature of intracellular bacterial cultivation from a contaminated environment such as the intestine (Knittel et al., 1996). A *Lawsonia* co-culture is illustrated in Fig. BXII.δ.6.

A general procedure for isolation and cultivation of *Lawsonia* is as follows: The experimental system is the laboratory culture of the bacterium *Lawsonia* in rat intestinal epithelial cells. An established cell line of rat intestinal epithelial cells, designated IEC-18 (ATCC CRL 1569, see Quaroni and May, 1980), is the cell line of choice. The cells are maintained in a standard cell culture medium, namely Dulbecco's modification of Eagle's medium (DMEM) supplemented with 5% bovine fetal serum, and 2 mM L-glutamine. Cells are transferred weekly into fresh tissue culture flasks by standard trypsin/EDTA methods. Following trypsinization of a seven-day culture of the cells, up to 2.5×10^4 cells/ml of fresh DMEM medium are inoculated into fresh flasks for establishment of cell growth. Cultures are incubated in an atmosphere of 5% CO_2 in air at 37°C for one day. The 1-d-old cell cultures are inoculated with 2×10^4 *Lawsonia*/ml suspended in medium and then incubated in an atmosphere of $O_2/CO_2/N_2$ (8%:8.8%:83.2%) at 37°C for 5–7 d.

Maintenance procedures and preparation of *Lawsonia* suspensions by lysis of infected cells are as described below. At intervals of 1 d, 2 d and 5 d following inoculation, the medium overlying the co-cultures is replaced with fresh medium and co-cultures re-incubated. Because flasks are difficult to stain, small cell culture vessels, each containing a glass coverslip, may be used for parallel sentinel co-cultures. During the period 1–7 d after inoculation, individual glass coverslips carrying each co-culture may be removed and stained for *Lawsonia*. For immunostaining, co-cultures are washed, fixed in acetone, and stained by an indirect immunoassay incorporating the mouse monoclonal antibody (IG4) specific to *L. intracellularis*. A count of the number of heavily infected cells (>30 bacteria/cell) may be used as a guide to infection. Upon serial passages over a period of weeks, *Lawsonia* infections of cells should attain 100%. Tumbling or darting motion of *Lawsonia* may be evident in heavily infected cells in these active infections. Co-cultures are considered optimized when at least 90% of the surface area of each culture flask and glass coverslip is covered by cells. The confluence of the cell monolayer in each test system may be recorded as a percentage of the entire surface area. Careful monitoring of cell culture growth has not yet established any specific *in vitro* effect on cell proliferation (McOrist et al., 1997). Dedicated incubators and gas supplies, laminar flow hoods, and clean work areas are essential to optimize cultures.

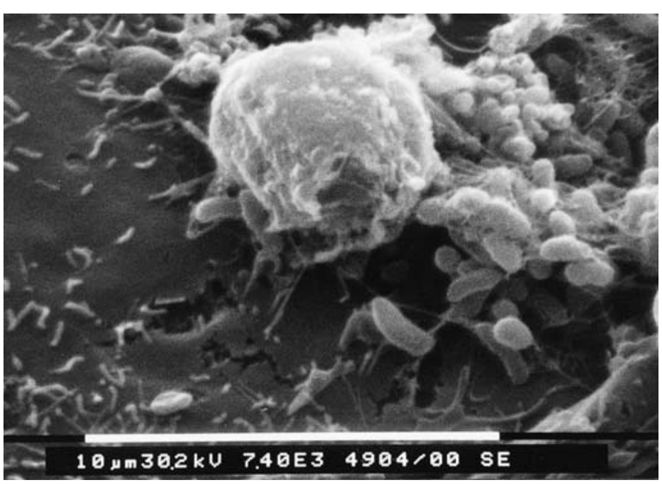

FIGURE BXII.δ.6. Scanning electron micrograph of *Lawsonia intracellularis* co-culture.

Maintenance Procedures

Preparation of *Lawsonia* suspensions for inoculation of fresh cell cultures in order to maintain co-cultures requires the lysis of infected cells. Passage of whole infected cells, trypsinized cells, or bacteria from cells lysed by vigorous methods does not lead to successful passages. Cell lysis and bacterial release are best accomplished by gentle lysis of infected cells within flasks. The addition of 0.1% potassium chloride in water as an overlay to monolayers for 10 minutes at 20°C, followed by physical removal of the infected cell suspension and further disruption of cells by passage through a small gauge needle, is recommended. Subsequent differential centrifugation supplies a pelleted *Lawsonia*, ready for re-suspension in DMEM and maintenance inoculations.

Bacterial storage is best achieved in SPG buffer with 5% bovine fetal serum (Lawson et al., 1993) at −70°C. Freeze-drying has not been widely tested.

Procedures for Testing Special Characters

A specific DNA probe has been developed for detection of *Lawsonia* in clinical specimens by dot blot or *in situ* hybridization (Gebhart et al., 1991, 1994). Successful and specific PCR assays have also been developed using primer pairs derived from the DNA sequence of porcine *Lawsonia intracellularis* (Jones et al., 1993). These probes and PCRs have detected *Lawsonia* DNA in organisms identified in intestinal tissues (fresh or formalin-fixed) or feces of pigs, hamsters, horses, deer, ostriches, and rabbits (Gebhart et al., 1991; McOrist et al., 1994a; Cooper and Gebhart, 1998).

PCR primers were developed from *Lawsonia intracellularis* NCTC 12656^T. Primers C and D were derived from a closed genomic segment (GenBank accession number L08049) and primers 878F and 1050R from a segment of the 16S rDNA sequence (L15739). The sequences of these primers are: C (antisense), 5′-TTACAGGTGAAGTTATTGGG-3′; D (sense), 5′-CTTTCTCATGTCCCATAAGC-3′; 878F (sense), 5′-TAACGCGTTAAGCA(C or T)C-3′; 1050R (antisense), 5′-GTCTTGAGGCTCCCCGAAAGGCACCTCTTAATC-3′.

PCR is performed in a 50 µl volume containing PCR buffer (10 mM Tris-HCl, pH 8.3, 50 mM KCl, 3 mM $MgCl_2$), 62 ng each C and D primers, 177 ng each 878F and 1050R primers, 0.2 mM each dATP, dGTP, dCTP, dTTP, and 1 µl extracted sample DNA (5–10 ng) or 1 µl dH_2O as a negative control. The mixture is heated to 95°C for 5 min and cooled to 4°C before adding 2.5 units of Taq polymerase. The sample is subjected to 35 cycles of PCR in a Perkin-Elmer thermal cycler with an amplification program of 93°C for 30 sec, 45°C for 1 min, and 72°C for 1 min. The expected sizes of the PCR products from these primers are 258 bp for the C and D primer set and 182 bp for the 878F and 1050R primer set.

The monoclonal antibody IG4 was prepared in 1986 and has since been used as a specific marker for immunostaining of *Lawsonia* (McOrist et al., 1987). No reactions have been detected with *Desulfovibrio* spp. or other related genera. IG4 was originally prepared as a fusion between splenic lymphocytes from a mouse immunized with whole *Lawsonia intracellularis* and NS0 cells. It

reacts with a 27–29-kDa glycoprotein on the outer surface of *Lawsonia* (McOrist et al., 1989a, b).

Differentiation of the genus *Lawsonia* from other genera

Lawsonia may be differentiated from other vibrioid-shaped organisms in the intestine by its obligately intracellular habitat and its special characters, namely, the PCR reaction and monoclonal antibody staining. The specific 16S rDNA sequence of *Lawsonia* can be confirmed by PCR (see above), and its specific outer surface components can be detected by reaction with the IG4 specific monoclonal antibody. A 16S rRNA signature sequence for the genus is 5′-GAUUAAGAGGUGCCUUUCGGGAGCCUCAA-3′, corresponding to the nucleotide positions 1015–1042 of the *E. coli* 16S rRNA sequence.

Taxonomic Comments

Lawsonia was placed within the *Desulfovibrionaceae* in 1995 based on 16S rDNA sequence data. According to this classification, its closest genetic relatives are *Bilophila wadsworthia*, with 92% sequence identity, and *Desulfovibrio desulfuricans*, with 91% sequence identity (Gebhart et al., 1993; McOrist et al., 1995a). The most recent analysis of all available sequences from *Lawsonia* isolates confirms that they form a closely related cluster within the family *Desulfovibrionaceae*, with *Bilophila wadsworthia* as the closest non-*Lawsonia* relative. *B. wadsworthia* is an anaerobic organism capable of extracellular growth. It has been isolated from the large intestine and other sites in humans (Sapico et al., 1994). Analysis of PCR-amplified rDNA from *Lawsonia* organisms derived from a variety of infected host animals (pig, hamster, deer, horse, ostrich, ferret) has shown very high levels of sequence similarity (98–100%). This indicates that isolates from a variety of hosts are all members of the *Lawsonia* genus and perhaps of the same species as well.

In one DNA study, a *Lawsonia* isolate from a ferret was erroneously placed in the *Desulfovibrio* genus purely on DNA sequence data (Fox et al., 1994a). Biologic, phenotypic, and epigenetic characteristics, such as the smaller size of *Lawsonia*, its novel habitat, pathogenicity for animals, lack of anaerobiosis, lack of black pigment, lack of extracellular growth, and different bacterial protein profiles, as compared to *D. desulfuricans* and other members of the *Desulfovibrio* genus, all clearly indicate that *Lawsonia* is a separate genus. A single polar flagellum has been observed on organisms in some extracellular preparations of cocultured *Lawsonia* strains. This is consistent with the rapid, darting motility of *Lawsonia* observed when in the cytoplasm of coculture cell monolayers. However, the flagellum structure has not been observed on *Lawsonia* present inside cells or *in vivo*. The type and exact role of the *Lawsonia* flagellum is not known. There is no evidence of sulfate reductase gene sequences present in *Lawsonia*. The relatively small size of the *Lawsonia* genome is consistent with the genome reduction noted in many other obligate intracellular bacteria.

Following the first identification of *Lawsonia* in diseased pig tissues in 1973 (Rowland and Lawson, 1974), it was another 20 years before successful culture of the organism occurred, with subsequent fulfillment of Koch's postulates (Lawson et al., 1993; McOrist et al., 1993). During this 20-year period there was considerable confusion about the exact identity of the bacterium, particularly as a range of *Campylobacter* spp. were cultured from diseased tissues. Prior to definitive 16S rDNA sequencing work, *Lawsonia* spp. were shown to be separate from these *Campylobacter* spp. by DNA restriction enzyme analysis and DNA probe analysis (McOrist et al., 1990; Gebhart et al., 1991). Comparison of the outer membranes of these genera by immunoblotting with monoclonal antibodies also indicated their separate status (McOrist et al., 1989b). This led to the nomenclatural form of *Campylobacter*-like organisms, then to the vernacular form, ileal symbiont intracellularis, both of which are considered synonyms of *Lawsonia* when referring to vibrioid organisms present within the intestinal epithelial cells of pigs, horses, or hamsters affected with proliferative enteropathy.

Further work needs to be done to address the relationship among the isolates from various host species and geographical sites. All DNA sequencing and protein analysis work to date indicates that *Lawsonia* has just one genetic monotype, with a unique life cycle in a particular cell type. *In vitro* work corroborates the observation *in vivo* that the organism can rapidly and readily enter intestinal epithelial cells (Johnson and Jacoby, 1978; McOrist et al., 1989b, 1995b). It is possible that there is limited, if any, variation in strains derived from various host species, merely one well-adapted organism, which has been spread widely by contact among different host species.

List of species of the genus Lawsonia

1. **Lawsonia intracellularis** McOrist, Gebhart, Boid and Barns 1995a, 824[VP]
in.tra.cel.lu.la'ris. L. prep. *intra* within; L. n. *cella* small room; L. adj. *intracellularis* within cell.

The morphology, phenotypic characters, and co-culture conditions are as described for the *Lawsonia* genus. Originally isolated from intestinal mucosa of pigs affected with proliferative enteropathy.

Naturally occurring bacteria resembling the original pig isolates and containing 16S rDNA sequences identical to these isolates have been identified in or co-cultured from the following host species: hamster, ostrich, horse, deer, and ferret. In all cases, these bacteria were prepared from intestines affected with proliferative enteropathy, reacted with the IG4 antibody, and are considered to be *Lawsonia intracellularis*. Bacteria resembling the original pig isolates have also been identified in other host species in intestines affected with proliferative enteropathy, and these have shown positive reactions with IG4 antibody. These bacteria are considered highly likely to be *Lawsonia intracellularis*, although they have not been cultured nor had their DNA examined. These bacteria have been identified in rat, rhesus monkey, and emu. Other naturally occurring bacteria that resemble the original pig isolates but have not been further identified have been found in the host species dog, guinea pig, and fox.

The mol% G + C of the DNA is: 34 (enumeration in complete genome sequence; the genome size is 1.713 Mbp).

Type strain: 1482/89, NCTC 12656.

GenBank accession number (16S rRNA): U30147.

Family II. **Desulfomicrobiaceae** *fam. nov.*

JAN KUEVER, FRED A. RAINEY AND FRIEDRICH WIDDEL

De.sul.fo.mi.cro.bi.a.ce'ae. M.L. masc. n. *Desulfomicrobium* type genus of the family; suffix *-ceae* denotes family; M.L. fem. pl. n. *Desulfomicrobiaceae* the family that comprises the genus *Desulfomicrobium*.

All known members are mesophilic sulfate-reducing bacteria. Organic substrates are incompletely oxidized to acetate. The family comprises one genus so far, *Desulfomicrobium.*

Type genus: **Desulfomicrobium** Rozanova, Nazina and Galushko 1994, 370 (Effective publication: Rozanova, Nazina and Galushko 1988, 518.)

Genus I. **Desulfomicrobium** *Rozanova, Nazina and Galushko 1994, 370*[VP] *(Effective publication: Rozanova, Nazina and Galushko 1988, 518)*

BARBARA R. SHARAK GENTHNER AND RICHARD DEVEREUX

De.sul.fo.mi.cro'bi.um. L. pref. *de* from; L. n. *sulfur* sulfur; G. adj. *micros* small; G. n. *bios* life; M.L. neut. n. *Desulfomicrobium* sulfate-reducing, small life.

Short, straight rod- or ellipsoidal-shaped cells, 0.5–0.9 × 1.3–2.9 μm, with rounded ends, either singly or in pairs (Sharak Genthner et al., 1994). **Gram-negative** stain reaction and cell-wall structure. Cells are **motile, usually by a single polar flagellum**. Endospores not formed. **Anaerobic.** Pre-reduced medium or reducing agent required in medium for growth. **Growth can occur by anaerobic respiration with sulfate or sulfoxyanions as terminal electron acceptor, producing H_2S.** Simple organic compounds that serve as electron donors during sulfate respiration include lactate, pyruvate, ethanol, formate, and hydrogen. Sulfate respiration with lactate as electron donor is incomplete, with the formation of acetate and CO_2. Hydrogenase present. **Cells contain *b*- and *c*-type cytochromes. Metabolism can also be fermentative** on simple organic substrates, including pyruvate, malate, or fumarate. **Carbohydrates are not fermented.** No specific vitamins required. **Nitrate not reduced.** No requirement for NaCl. **Desulfoviridin absent.** Optimal temperature 25–30°C. Found in freshwater to brackish to marine anaerobic sediments and mud, in anaerobic stratal or overlying water, and in saturated mineral or organic deposits.

The mol% G + C of the DNA is: 52.5–59.6.

Type species: **Desulfomicrobium baculatum** (Rozanova and Nazina 1976) Rozanova, Nazina and Galushko 1994, 370 (Effective publication: Rozanova, Nazina and Galushko 1988, 519) (*Desulfovibrio baculatus* Rozanova and Nazina 1976, 825; *Desulfomicrobium baculatus* (sic) Rozanova, Nazina and Galushko 1988, 519.)

ENRICHMENT AND ISOLATION PROCEDURES

Stringent anaerobic techniques (Breznak and Costilow, 1994) must be used for enrichment and cultivation of species belonging to the genus *Desulfomicrobium.* Strains can be enriched from various anaerobic habitats such as freshwater to brackish to marine anaerobic sediments and mud; anaerobic stratal or overlying water; and saturated mineral or organic deposits. Samples can be enriched in anaerobic lactate/sulfate mineral medium (Widdel and Bak, 1992; Sharak Genthner et al., 1994, 1997a; DSM medium 63) with the addition of yeast extract (0.02% w/v); however, this medium is nonselective and can result in growth of *Desulfovibrio* species or other lactate-utilizing, sulfate-reducing bacteria. Initial enrichment in lactate/sulfate or pyruvate/sulfate, followed by enrichment in a fermentation medium containing pyruvate, malate and/or fumarate as the energy source, may be useful for enrichment and isolation of *Desulfomicrobium* spp.

MAINTENANCE PROCEDURES

SRB medium described above and prepared by the serum bottle/tube method of Balch and Wolfe (1976) can be used for short-term (weeks) storage of cultures. Stab-cultures in anaerobic agar deeps can be employed for longer-term storage (months) at −70°C without breakage of tubes when heavy-walled anaerobic culture tubes (Bellco Glass, Inc.) are employed. Liquid nitrogen or freeze-drying can be employed for very long term storage of cultures, but care must be taken to use stringent anaerobic techniques when preparing cultures and storage medium (Ljungdahl and Wiegel, 1986; Malik, 1990a; Impey and Phillips, 1991; Gherna, 1994).

DIFFERENTIATION OF THE GENUS *DESULFOMICROBIUM* FROM OTHER GENERA

Desulfomicrobium contains dissimilatory sulfate-reducing species that are physiologically similar to *Desulfovibrio* species but have a nonvibrioid cellular morphology and lack desulfoviridin (Miller and Saleh, 1964), a pigment considered diagnostic for the genus *Desulfovibrio* (Postgate, 1959). The simple desulfoviridin test (Postgate, 1959) can be used to distinguish members of the genus *Desulfomicrobium* from members of the genus *Desulfovibrio.* The ability to ferment pyruvate, malate, or fumarate distinguishes *Desulfomicrobium* spp. from *Desulfovibrio* spp. other than *Desulfovibrio desulfuricans*, although growth is minimal with some of the *Desulfomicrobium* spp. *Desulfomicrobium* spp. are further distinguished from *Desulfovibrio* by the inability to ferment choline.

TAXONOMIC COMMENTS

Macrorestriction analysis using pulsed-field gel electrophoresis revealed unique fragmentation patterns among the four strains (Fig. BXII.δ.7), indicating genotypic variability between *D. apsheronum*, *D. escambiense*, *D. baculatum*, and *D. norvegicum*. *D. escambiense* strain ESC 1 (Lane B) and *D. escambiense* ATCC 51164 (Lane D), the ATCC-deposited culture of *D. escambiense* strain ESC 1, were compared as a control. These two cultures have identical fragmentation patterns, except for a few faint bands not visible in the photograph that were observed during visual inspection of the gel.

Comparisons of 16S rRNA gene sequences and DNA–DNA homologies show the genus to be composed of closely related species (Fig. BXII.δ.8). Similarities of 16S rRNA gene sequences range from 96.7% to 99.7% (Table BXII.δ.6). *D. apsheronum* and

D. baculatum are the most similar species phylogenetically but are physiologically distinct (Tables BXII.δ.7 and BXII.δ.8). Separation of *Desulfomicrobium* from *Desulfovibrio* species is clearly indicated by the low (~87%) similarity in 16S rRNA gene sequence.

Differentiation of the species of the genus *Desulfomicrobium*

Tables BXII.δ.7 and BXII.δ.8 present characteristics that differentiate the species of *Desulfomicrobium*. Additional characteristics of the species are presented in Table BXII.δ.9. A requirement for yeast extract, or more defined nutritional supplements, may explain earlier discrepancies in reported electron donor usage and fermentation of substrates by the four *Desulfomicrobium* species.

List of species of the genus Desulfomicrobium

1. **Desulfomicrobium baculatum** (Rozanova and Nazina 1976) Rozanova, Nazina and Galushko 1994, 370[VP] (Effective publication: Rozanova, Nazina and Galushko 1988, 519) (*Desulfovibrio baculatus* Rozanova and Nazina 1976, 825; *Desulfomicrobium baculatus* (sic) Rozanova, Nazina and Galushko 1988, 519.)
ba.cu.la'tum. M.L. adj. *baculatum* shaped like a rod; isolated from water-saturated manganese carbonate ore.

Characteristics are as described for the genus and as presented in Tables BXII.δ.7, BXII.δ.8, and BXII.δ.9. Tungstate or molybdate are required for ethanol utilization (Hensgens et al., 1994). Oxidation of lactate with sulfate as the electron acceptor is incomplete to acetate and CO_2. Preferentially reduces fumarate and malate to succinate over reduction of sulfate to sulfide when both are present in medium (Sharak Genthner et al., 1997a). Originally reported to not use S^0 (Rozanova et al., 1988) as an electron acceptor, but some sulfate-reducing bacterial strains thought to belong to the species *D. baculatum* have been found to use S^0 (Biebl and Pfennig, 1977). Catalyzes S^0 to sulfate with Mn(IV) as an electron acceptor, although the reaction does not support growth (Lovley and Phillips,

1994a). Reported to fix nitrogen (Rozanova et al., 1988). Uses sulfite or thiosulfate as electron acceptor. Growth in the absence or presence of up to 6% NaCl with 1% NaCl optimal. Optimal growth temperature, 28–37°C; range, 2–41°C. Isolated from water-saturated manganese carbonate ore.

The mol% G + C of the DNA is: 56.8 (T_m).

Type strain: X, DSM 4028, VKM B-1378.

GenBank accession number (16S rRNA): AF030438.

2. **Desulfomicrobium apsheronum** Rozanova, Nazina and Galushko 1994, 370[VP] (Effective publication: Rozanova, Nazina and Galushko 1988, 519.)

ap.she.ron′ um. M.L. adj. *Apsheronum* pertaining to waters of the Apsheronum peninsula in Russia; isolated from stratal waters of oil-bearing deposits in the Apsheronum peninsula in Russia.

Characteristics are as described for the genus and as presented in Tables BXII.δ.7, BXII.δ.8, and BXII.δ.9. Oxidation of lactate during sulfate respiration is incomplete: to acetate and CO_2. Autotrophic growth with formate or H_2 has been reported during sulfate respiration. Sulfite and thiosulfate, but not elemental sulfur, are used as electron acceptors (Rozanova et al., 1988). Growth occurs in the absence of NaCl or in the presence of up to 6% NaCl.

TABLE BXII.δ.9. Other characteristics of the species of the genus *Desulfomicrobium*[a]

Choline, lactate, glucose	−	−	−	−[c]

[a]For symbols, see standard definitions; nr, not reported.

[b]Yeast extract required at supplemental concentrations.

[c]Other fermentation substrates not used include adonitol, amygdalin, arabinose, arginine, cellobiose, dulcitol, esculin, fructose, galactose, glycerol, glycogen, inositol, inulin, lactose, maltose, mannitol, mannose, melezitose, melibiose, raffinose, rhamnose, salicin, sorbitol, soluble starch, sucrose, threonine, trehalose, and xylose.

Isolated from stratal waters of oil-bearing deposits in the Apsheronum peninsula.

The mol% G + C of the DNA is: 52.5 (T_m).

Type strain: 1105, DSM 5918, VKM B-1804.

GenBank accession number (16S rRNA): U64865.

3. **Desulfomicrobium escambiense** Sharak Genthner, Mundfrom and Devereux 1996, 1189[VP] (Effective publication: Sharak Genthner, Mundfrom and Devereux 1994, 218.)
es.cam' bi.ens.e. M.L. adj. *escambiensis* pertaining to the Escambia River in northwest Florida.

Characteristics are as described for the genus and as presented in Tables BXII.δ.7, BXII.δ.8, and BXII.δ.9. Sulfate and thiosulfate are reduced. Incomplete oxidation of lactate occurs during sulfate respiration with the formation of acetate and CO_2. Reduces benzoate and halogenated benzoate derivatives to corresponding benzyl alcohols during fermentative growth with pyruvate (Sharak Genthner et al., 1997b). Casein and esculin are not hydrolyzed. Gelatin is not liquefied. Isolated from a 3-chlorobenzoate-dechlorinating coculture originally inoculated with anaerobic freshwater sediment.

The mol% G + C of the DNA is: 59.6 (T_m).

Type strain: ESC 1, ATTC 51164, DSM 10707.

GenBank accession number (16S rRNA): U02469.

4. **Desulfomicrobium norvegicum** Sharak Genthner, Friedman and Devereux 1997a, 891[VP]
nor.ve' gi.cum. M.L. adj. *norvegicum* Norwegian.

Characteristics are as described for the genus and as presented in Tables BXII.δ.7, BXII.δ.8, and BXII.δ.9. Tungstate or molybdate are required for ethanol utilization (Hensgens et al., 1994). Uses S^0 as a terminal electron acceptor (Biebl and Pfennig, 1977). Cytochrome c_3 is reported to be the sulfur reductase in this species (Fauque et al., 1979; Cammack et al., 1984). Reduces Fe(III) to Fe(II) with hydrogen and oxidizes elemental sulfur to sulfate with Mn(IV), but does not gain energy for growth from these processes (Lovley and Phillips, 1994a; *D. norvegicum* designated *D. baculatum* DSM 1743 in this publication). Fumarate has been reported as an additional product of malate fermentation (Miller et al., 1970). Preferentially reduces fumarate and malate to succinate over reduction of sulfate to sulfide when both are present in medium (Sharak Genthner et al., 1997a).

The mol% G + C of the DNA is: 56.8 (Bd).

Type strain: Norway 4, DSM 1741, NCIB 8310.

Other Organisms

Several sulfate-reducing strains that have characteristics in common with the members of the genus *Desulfomicrobium* have been isolated. Additional physiological and phylogenetic characterization will be necessary to confirm placement of these strains in the genus *Desulfomicrobium* as either new species or strains of accepted species.

Strain 4474, isolated from an alder swamp near Hamburg, Germany, and strain 5174, isolated from a forest pond near Braunschweig, Germany and designated DSM 1742, were obtained from an enrichment culture on S^0 (Biebl and Pfennig, 1977). Strain 9974 was isolated from a culture designated "*Chloropseudomonas ethylica* N2" (DSM 1743). All three strains consist

of short, straight, nonsporeforming, sulfate-reducing rods that are motile by a single polar flagellum and that ferment pyruvate, and contain cytochrome c_3 but do not contain desulfoviridin (Biebl and Pfennig, 1977), thus resembling members of the genus *Desulfomicrobium.* All three strains reduce S^0 to sulfide using ethanol as the electron donor in a medium supplemented with yeast extract (0.1%), as does *D. norvegicum* NCIB 8310 (Biebl and Pfennig, 1977). Cytochrome c_3 is the sulfur reductase (Fauque et al., 1979) in *D. norvegicum* and strain 9974 (DSM 1743). Strain 9974 transports sulfate electroneutrally in symport with sodium ions (Kreke and Cypionka, 1995; designated *Desulfovibrio baculatus* DSM 1743 in this study).

Strain H.L21 is a rod-shaped, sulfate-reducing bacterial strain isolated from intertidal mud (Hoogwatum, Netherlands) in lactate/sulfate marine enrichment medium (Laanbroek and Pfennig, 1981; also designated DSM 2555); it can also grow in a freshwater lactate/sulfate medium. In addition to lactate, strain H.L21 uses H_2, formate, malate, and ethanol as an electron donor for sulfate reduction in the presence of acetate. It also ferments pyruvate and fumarate but not lactate or glucose. It was designated a strain of *Desulfovibrio baculatus* by Laanbroek and Geerligs (1983), i.e., *Desulfomicrobium baculatum.*

Desulfovibrio desulfuricans subsp. *desulfuricans* strain New Jersey (NCIMB 8313) was proposed to belong to the genus *Desulfomicrobium* and was designated *Desulfomicrobium baculatus* strain New Jersey by Pereira et al. (1996). Inclusion in *Desulfomicrobium baculatum* was based on a high degree of similarity between proteins (hydrogenase, cytochrome c_3, adenylyl sulfate reductase, sulfite reductase, i.e., desulforubidin) isolated from this strain and from *Desulfomicrobium baculatus* strain Norway 4, i.e., *Desulfomicrobium norvegicum.* This strain was isolated from a corroding cast iron heat exchanger and was implicated in corrosion of the steel.

The sulfate-reducing bacterial strain WHB (DSM 10293) was tentatively assigned to the genus *Desulfomicrobium* by Drzyzga et al. (1996) based on shared morphological and physiological characteristics. Strain WHB was isolated from anoxic, black, marine sediment from tidal shallows (near Wilhelmshaven, Germany) in lactate/sulfate marine (20 g/l NaCl) enrichment medium, and requires 10–20 g/l NaCl for growth. This strain consists of straight, Gram-negative, motile rods (0.5–0.6 × 1.6–2.4 μm) that lack desulfoviridin, contain cytochrome c_3, and perform incomplete oxidation during sulfate reduction using lactate, H_2, formate, ethanol, and malate but not fumarate, acetone, acetate, butyrate, 2-methylbutyrate, or several aromatic compounds (phenol, benzoate, *para*-hydroxybenzoate, or phenyl acetate). The medium used was chemically defined. Strain WHB is apparently an autotroph because the authors did not indicate that addition of yeast extract or acetate was necessary to support growth on formate or H_2. Fermentative capabilities were not examined. Strain WHB reduced dinitrophenylamines to aminodiphenylamines during oxidation of lactate. The major differences between strain WHB and accepted species of *Desulfomicrobium* are its inability to grow in fumarate/sulfate medium, and the high mol% G + C content of the DNA (82.2% compared with 52–56% for *Desulfomicrobium* species).

A sulfate-reducing bacterium (strain CN-A) which was recently isolated from subsurface sandstone (New Mexico, USA) has been tentatively placed in the *Desulfomicrobium* genus as a new species, *"D. hypogeium"*. (L. Krumholz, personal communication). This strain is a nonsporeforming, motile (single, polar flagellum), Gram-negative, short rod (0.6–0.8 × 1.4–1.9 μm) that lacks desulfoviridin. It incompletely oxidizes lactate to acetate and uses ethanol, pyruvate, formate, and H_2 as electron donors during sulfate reduction, requiring either acetate or yeast extract for growth. Growth does not occur with sulfate when acetate, fumarate, fructose, methanol, malate, or choline are electron donors. Pyruvate, lactate, malate, fumarate, and choline do not support fermentative growth. Sulfite and thiosulfate are also used as electron acceptors, but fumarate and nitrate are not. Strain CN-A grows better at 30°C than at either 23°C or 37°C. Based on 16S rDNA sequence analysis, strain CN-A exhibits 98.4–99.0% similarity to accepted *Desulfomicrobium* species and is most closely related to *D. baculatum* and *D. norvegicum* (98.9% and 99.0% similarity, respectively). Failure to use fumarate as an energy source in any capacity and failure to ferment pyruvate, fumarate, or malate~~ev~~en poorly~~di~~fferentiates strain CN-A from the other *Desulfomicrobium* species.

Family III. **Desulfohalobiaceae** *fam. nov.*

Jan Kuever, Fred A. Rainey and Friedrich Widdel

De.sul.fo.ha.lo.bi.a.ce' ae. M.L. masc. n. *Desulfohalobium* type genus of the family; suffix *ceae* denotes family; M.L. fem. pl. n. *Desulfohalobiaceae* the family that comprises the genus *Desulfohalobium* and other genera.

Members are either mesophilic or moderately thermophilic sulfate-reducing bacteria. Known mesophilic members oxidize organic substrates incompletely to acetate, whereas the thermophilic member (*Desulfothermus*) performs complete oxidation of organic substrates. The family comprises three genera so far, *Desulfohalobium*, *Desulfonatronovibrio*, and *Desulfothermus*. Detailed properties of all described species of these genera are given in Table BXII.δ.10.

Type genus: **Desulfohalobium** Ollivier, Hatchikian, Prensier, Guezennec and Garcia 1991, 78.

TABLE BXII.δ.10. Differential characteristics of the genera of the family *Desulfohalobiaceae*[a]

Habitat (anoxic)	Hypersaline lake	Alkaline soda lakes	Marine

[a]Symbols: nr, not reported; +, present, observed in all species; −, not present, not observed; ±, variable; (+), poorly motile, poor growth; DV, desulfoviridin; DR, desulforubidin; I, incomplete; C, complete.

[b]Carbon monoxide dehydrogenase, a key enzyme indicative of the C_1-pathway for acetyl-CoA.

[c]High CO-DH activity was reported.

[d]Disproportionation of thiosulfate to sulfide and sulfate might indicate growth.

Genus I. **Desulfohalobium** *Ollivier, Hatchikian, Prensier, Guezennec and Garcia 1991, 78[VP]*

BERNARD OLLIVIER, BHARAT K.C. PATEL AND JEAN-LOUIS GARCIA

De.sul.fo.hal.o′ bium. L. pref. *de* from; L. n. *sulfur* sulfur; Gr. n. *hals* the sea, salt; Gr. n. *bios* life; M.L. adj. *halobius* living on salt; M.L. masc. n. *Desulfohalobium* a sulfate-reducing, salt-requiring, rod-shaped bacterium.

Rod-shaped cells, 0.7–0.9 × 1–3 µm, with rounded ends. Occur singly or in pairs when H_2 is the energy source. Longer cells, up to 20 µm in length, occur in lactate-containing medium. Motile by one or rarely two polar flagella. Spores are not observed. Gram negative. **Anaerobic, having a respiratory type of metabolism with sulfate or other oxidized sulfur compounds serving as terminal electron acceptors and being reduced to H_2S. The cells contain desulforubidin.** Desulfoviridin is absent. Chemoorganotrophic, using simple organic compounds as carbon sources and as electron donors for anaerobic respiration. **These compounds are incompletely oxidized to acetate and CO_2. Moderately halophilic** with NaCl and $MgCl_2$ required for growth. Vitamins, which can be replaced by yeast extract or bio-Trypcase and acetate, act as carbon sources when cells are grown on H_2. The optimal temperature range for growth is 37–40°C. Isolated from sediments of a hypersaline lake.

The mol% G + C of the DNA is: 57.

Type species: **Desulfohalobium retbaense** Ollivier, Hatchikian, Prensier, Guezennec and Garcia 1991, 78.

FURTHER DESCRIPTIVE INFORMATION

The cells are rods (Fig. BXII.δ.9) that form long chains at the end of growth. Electron micrographs of thin sections of the bacterium reveal a multilayered cell wall that is typical of Gram-negative bacteria. *Desulfohalobium retbaense* grows optimally in the presence of 10% NaCl. Its doubling time when cultivated on lactate medium[1] is about 5 h. It is mesophilic, with 45°C being the upper temperature limit for growth; however, the first subculture from an inoculum incubated at 37°C will grow at temperatures between 45°C and 52°C.

A soluble extract of *D. retbaense* exhibits the characteristic absorption bands of cytochrome c_3. Desulfoviridin, the dissimilatory sulfite reductase present in most species of the genus *Desulfovibrio* (Devereux et al., 1989), is absent. *Desulfohalobium retbaense* pos-

1. Lactate medium (g/l of the basal medium described in Enrichment and Isolation Procedures): bio-Trypcase (Biomérieux, Craponne, France), 1.0; yeast extract, 1.0; and NaCl, 100.0; sodium lactate (instead of sodium acetate), 1.0.

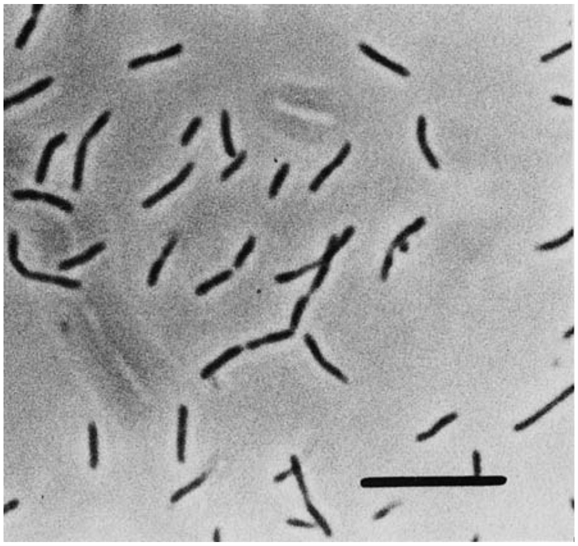

FIGURE BXII.δ.9. Phase contrast micrograph of *Desulfohalobium retbaense*. The isolate was cultivated in lactate medium containing 1 g/l yeast extract and 1 g/l bio-Trypcase. Bar = 10 μm. (Reproduced with permission from B. Ollivier et al., International Journal of Systematic Bacteriology *41:* 74–81, 1991, ©International Union of Microbiological Societies.)

sesses a desulforubidin bisulfite reductase similar to that of *Desulfomicrobium norvegicum* (Lee et al., 1973; Sharak Genthner et al., 1994, 1997a). However, the absorption spectrum of *Desulfohalobium retbaense* bisulfite reductase differs slightly from that of the homologous protein of *Desulfomicrobium norvegicum* in that the former has an additional weak absorption band at 700 nm and a more distinguishable shoulder in the 580-nm region.

The fatty acid distribution of the membrane phospholipids indicates that branched saturated fatty acids account for 30% of the total fatty acids. The following monounsaturated fatty acids are also present: $C_{16:1\ \omega9}$, $C_{16:1\ \omega7}$, $C_{18:1\ \omega9}$, $C_{18:1\ \omega7c}$, and $C_{17:1\ \omega8}$ fatty acids. The fatty acid profile also contains branched-chain components, such as iso-$C_{17:1\ iso\ \omega7c}$ (4%) and $C_{18:1\ \omega6}$.

Halophilic microorganisms are divided into three major groups and include (i) the slight halophiles, which exhibit optimal growth at salinities of 2–5%, (ii) the moderate halophiles, which grow optimally at 6–10% NaCl, and (iii) the extreme halophiles, which grow optimally with 20–25% NaCl (Ollivier et al., 1994). Currently, the only moderately halophilic sulfate-reducing bacteria known to exist in hypersaline environments are *Desulfohalobium retbaense*, *Desulfovibrio halophilus* (Caumette et al., 1991a), *Desulfovibrio gabonensis* (Tardy-Jacquenod et al., 1996), *Desulfovibrio oxyclinae* (Krekeler et al., 1997), *Desulfovibrio profundus* (Bale et al., 1997), *Desulfovibrio vietnamensis* (Nga et al., 1996), and *Desulfocella halophila* (Brandt et al., 1999). Extremely halophilic sulfate-reducing bacteria have so far not been isolated from these environments, and, therefore, it has been suggested that the reduction of sulfate in hypersaline ecosystems may be due only to the activity of moderately halophilic microorganisms (Caumette, 1993). However, *D. retbaense*, while not an extreme halophile, can grow at NaCl concentrations as high as 24%. Interestingly, the salt content of the environment from which *D. retbaense* was isolated is 34%, which indicates either that this bacterium cannot be very active in its ecosystem (Lake Retba, Senegal, West Africa) and perhaps prefers to grow in niches with lower concentrations of NaCl (e.g., areas of freshwater river inflow where the salt concentration is decreased), or that the artificial conditions under which this bacterium is cultured in the laboratory differ from the mineral or organic content of the natural environment and thus might influence and alter the growth response of the bacterium.

Enrichment and Isolation Procedures

Desulfohalobium retbaense can be enriched from sediments of hypersaline lakes using an anaerobic medium (Ollivier et al., 1991) that contains NaCl at a concentration of 100–240 g/l, H_2 or lactate as the energy source, and Na_2S or sodium dithionite as the reductive agent[2]. At least three subcultures under the same growth conditions with incubation at temperatures of up to 45°C are necessary for initiating enrichments. Subsequently, the enrichment cultures are serially diluted using the method of Hungate (1969) in anaerobic roll tubes containing the basal medium, H_2 as the energy source, sulfate as the electron acceptor, and purified agar at a concentration of 2%. Several colonies are picked, and the process of serial dilution in roll tubes is repeated. Culture purity is tested on (1) a complex sulfate-free medium containing 0.1% bio-Trypcase, 0.1% yeast extract, and 20 mM glucose and (2) a rich complex NaCl-free medium. There should be no growth on these media.

Maintenance Procedures

Stock cultures are maintained in the medium described by Ollivier et al. (1991) by monthly serial transfers. Liquid cultures retain viability after several weeks of storage at 4°C. Cultures can be maintained indefinitely by lyophilization or by storage at −80°C in the basal medium containing 20% glycerol (v/v). Viability is best maintained if the cells are obtained from mid-log phase cultures.

Differentiation of the genus *Desulfohalobium* from other genera

Differentiation of the genus from the genera *Desulfomicrobium* and *Desulfonatronovibrio*, with which it might be confused, is presented in Table BXII.δ.11. Major differences between *Desulfohalobium retbaense* and the six other moderately halophilic sulfate-reducing species, namely *Desulfovibrio halophilus*, *Desulfovibrio gabonensis*, *Desulfovibrio oxyclinae*, *Desulfovibrio profundus*, *Desulfovibrio vietnamensis*, and *Desulfocella halophila* are listed in Table BXII.δ.12.

Taxonomic Comments

Desulfohalobium retbaense is currently a member of the family *Desulfohalobiaceae* in the *Deltaproteobacteria*, together with the genera *Desulfonatronovibrio* and *Desulfothermus* (Fig. BXII.δ.10). However, we believe that future revision of the family *Desulfohalobiaceae* should be considered in view of the following: (1) *Desulfohalobium retbaense* together with *Desulfonatronovibrio hydrogenovorans* and *De-*

2. Anaerobic medium of Ollivier et al. (1991) (per liter of distilled water): NH_4Cl, 1.0 g; K_2HPO_4, 0.3 g; KH_2PO_4, 0.3 g; Na_2SO_4, 3.0 g; NaCl, 100.0 g; sodium acetate, 1.0 g; resazurin, 0.001 g; $MgCl_2{\cdot}6H_2O$, 20.0 g; KCl, 4.0 g; trace element solution of Imhoff-Stuckle and Pfennig (1983), 1 ml; sodium selenite solution of Pfennig et al. (1981), 1 ml. After autoclaving, 0.2 ml of 2% (w/v) $Na_2S{\cdot}9H_2O$ and 1 ml of 10% (w/v) $NaHCO_3$ (sterile, anaerobic solutions), as well as 0.2 ml of the vitamin solution of Pfennig et al. (1981) and 0.1 ml of a 0.2% (w/v) sodium dithionite solution (filter-sterilized solutions), are injected into the 60-ml serum bottles (20 ml of medium) before inoculation. In the case of roll tubes, 2% agar is added to the medium in Hungate tube (5 ml). A gas mixture containing H_2/CO_2 (80:20) is added at a pressure of 200 kPa after sterilization.

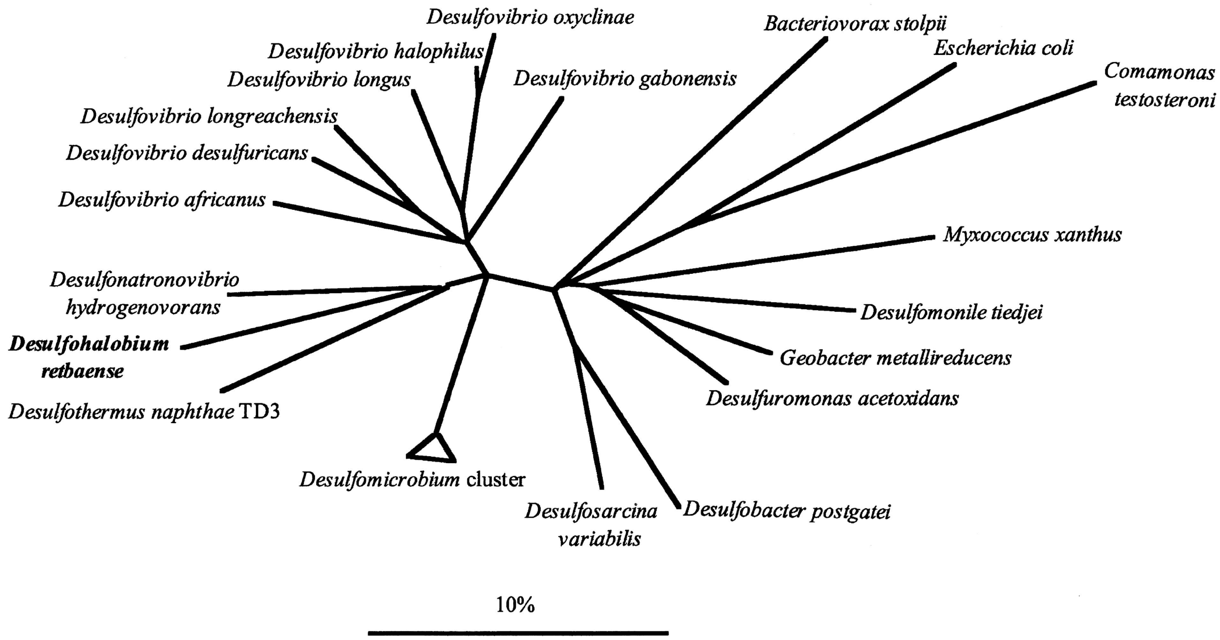

FIGURE BXII.δ.10. Phylogenetic relationship, based on 16S rRNA sequence analysis, of *Desulfohalobium retbaense*, a member of the family *Desulfohalobiaceae*, with other members of that family, including *Desulfonatronovibrio hydrogenovorans* and *Desulfothermus naphthae* TD3; and with species of the genera *Desulfovibrio* (family *Desulfovibrionaceae*) and *Desulfomicrobium* (family *Desulfomicrobiaceae*). All sequences were obtained from the Ribosomal Database Project (RDP) (Maidak et al., 1996), with the exception of the sequences for *Desulfonatronovibrio hydrogenovorans* and *Desulfovibrio oxyclinae*, which were obtained from EMBL (accession number X99234) and GenBank (accession number U33316), respectively. The methods for alignment and phylogenetic evaluation were performed as described previously (Andrews and Patel, 1996). Bar = 10 nucleotide changes per 100 nucleotides.

sulfothermus naphtae are closely related to members of the genus *Desulfomicrobium*; (2) desulfoviridin is absent in *Desulfohalobium retbaense*, in *Desulfonatronovibrio hydrogenovorans*, in *Desulfothermus naphtae*, and in members of the genus *Desulfomicrobium*, but is found in all members of the genus *Desulfovibrio* (Devereux et al., 1989); and (3) desulforubidin is present in *Desulfohalobium retbaense* (Ollivier et al., 1991), *Desulfomicrobium baculatum* (DerVartanian, 1994), and *Desulfomicrobium norvegicum* (Lee et al., 1973; Sharak Genthner et al., 1994, 1997a). However, the presence of desulforubidin has yet to be investigated in *Desulfonatronovibrio hydrogenovorans* (Zhilina et al., 1997), *Desulfothermus naphtae* (Rueter et al., 1994), and *Desulfomicrobium* spp. (Rozanova et al., 1988; Gogotova and Vainshtein, 1989; Sharak Genthner et al., 1994; Krumholz et al., 1999; Langendijk et al., 2001). If it is detected in these species, then the establishment of a new family should be considered in order to accommodate members of the genera *Desulfohalobium*, *Desulfonatronovibrio*, *Desulfothermus*, and *Desulfomicrobium*.

Acknowledgments

The authors thank P. Roger for helpful discussion.

ret.ba.en′se. M.L. adj. *retbaense* pertaining to Retba Lake in Senegal.

The characteristics are as described for the genus and as listed in Tables BXII.δ.11 and BXII.δ.12. Additional characteristics are as follows. Cells contain cytochrome c_3 and desulforubidin. Lactate, ethanol, and pyruvate are incompletely oxidized to acetate and CO_2. Pyruvate is fermented slowly. Glycerol, fructose, glucose, fumarate, malate, succinate, choline, yeast extract, and bio-Trypcase are not used. NaCl and $MgCl_2$ are required for growth. Moderately halophilic, growing in media with up to 24% NaCl. The optimal NaCl concentration for growth is 10%.

Optimal temperature, 37–40°C. The pH range for growth is 5.5–8.0; optimal, 6.5-7.

Isolated from sediments of a hypersaline African lake, Retba Lake, near Dakar, Senegal.

The mol% G + C of the DNA is: 57 (HPLC).

Type strain: HR100, DSM 5692.

GenBank accession number (16S rRNA): U48244, X99235.

Genus II. **Desulfonatronovibrio** *Zhilina, Zavarzin and Rainey* in *Zhilina, Zavarzin, Rainey, Pikuta, Osipov and Kostrikina 1997, 149*[VP]

George A. Zavarzin and Tatjana N. Zhilina

De.sul.fo.nat.ro.no.vib' rio. L. pref. *de* from; L. n. *sulfur* sulfur; M.L. n. *natron* soda; M.L. masc. n. *vibrio* that which vibrates; L. n. *Desulfonatronovibrio* sulfate-reducing vibrio from soda environment.

Cells are minute vibrios, single or sigmoid in pairs, sometimes spirilloid, 0.5 × 1.5-2 μm. Gram negative. **Motile by a single polar flagellum.** Endospores not formed. **Anaerobic. Possess a respiratory type of metabolism, with sulfate or other oxidized sulfur compounds serving as terminal electron acceptors and being reduced to sulfide. Extremely alkaliphilic.** No growth at pH 7; optimal pH 9.0–9.7; maximum pH 10.2. **Obligately dependent on sodium and carbonates in the growth medium.** Optimal temperature 37–40°C. **Lithoheterotrophic.** Utilize H_2 or formate for reduction of sulfur compounds. Utilize acetate plus vitamins or yeast extract for anabolism. Desulfoviridin is absent. Cells contain *c*-type cytochromes. Habitat: soda lakes. The genus currently includes only a single species.

The mol% G + C of the DNA is: 47.9–48.5.

Type species: **Desulfonatronovibrio hydrogenovorans** Zhilina, Zavarzin and Rainey *in* Zhilina, Zavarzin, Rainey, Pikuta, Osipov and Kostrikina 1997, 149.

Further descriptive information

The cells are vibrioid with a single polar flagellum (Fig. BXII.δ.11) and occur singly or in S-shaped pairs. Short spirilla develop under suboptimal conditions (Fig. BXII.δ.12) The cell wall has a typical Gram-negative structure in ultrathin sections.

The cell membrane and cytoplasmic fraction contain *c*-type cytochromes with absorption maxima at 552, 521.8, and 417.8 nm.

Sulfate and sulfite serve as electron acceptors. Sulfur, fumarate, and nitrate are not reduced. Thiosulfate may be disproportionated: equimolar quantities of sulfate and sulfide have been observed to form from 10 mmol of thiosulfate. Sulfide is the only product of catabolism.

The fatty acid profile of type strain *D. hydrogenovorans* contains compounds that are typical for bacterial membranes. Saturated fatty acids account for 66.7% of the total fatty acids, with $C_{16:0}$ and $C_{18:0}$ acids predominating. Branched saturated fatty acids account for only 11% of the total fatty acids. The following monounsaturated fatty acids, which account for 12% of the total fatty acids, are also present: $C_{16:1}$, $C_{18:1\ \omega 9}$, $C_{18:1\ \omega 11}$, and $C_{19:1}$.

D. hydrogenovorans was first isolated from bottom deposits of the equatorial soda-depositing Lake Magadi. In central Asia, it is ubiquitous in alkaline lakes south of Baikal in the cryoarid steppe zone (Pikuta et al., 1997).

As a H_2-scavenging alkaliphile, *D. hydrogenovorans* may act as a hydrogen sink in an anaerobic, alkaliphilic community decomposing organic matter (Zavarzin et al., 1996). For instance, it develops in co-culture with alkaliphilic fermentative spirochetes growing on carbohydrates and produces an acetogenic shift in their metabolism (Pikuta et al., 1998b). As an extremely alkaliphilic sulfate-reducer, *Desulfonatronovibrio* participates in the alkalinization of soda lakes where sulfate reduction was for a long time considered to be an important process for the development of alkalinity. However, sulfate reducers capable of growing at pH values near 10 were previously unknown.

Enrichment and Isolation Procedures

Strains of *Desulfonatronovibrio* can be enriched and isolated from the alkaline soda lakes under strictly anaerobic conditions in the selective alkaline mineral medium II[1] of Zhilina and Zavarzin (1994), which has a high sodium carbonate content. Incubation is under an atmosphere of H_2. N_2 can substitute for the H_2 if Na-formate (5 g/l) is added as the electron donor.

Isolation is by serial dilution in liquid medium II with H_2 as

1. Medium II has the following composition (g/l distilled water): $NaHCO_3$, 15.0; Na_2CO_3, 10.0; NaCl, 10.0; Na_2SO_4, 3.0; NH_4Cl, 0.5; KCl, 0.2; K_2HPO_4, 0.2; $Na_2S \cdot 9H_2O$, 0.5; yeast extract, 0.5; and 1 ml trace element solution (Whitman et al., 1982).

FIGURE BXII.δ.11. Negatively stained cell of *Desulfonatronovibrio hydrogenovorans* Z-7952 isolated from Lake Shara-Nur (Tuva) showing the monopolar flagellum. Bar = 1 μm.

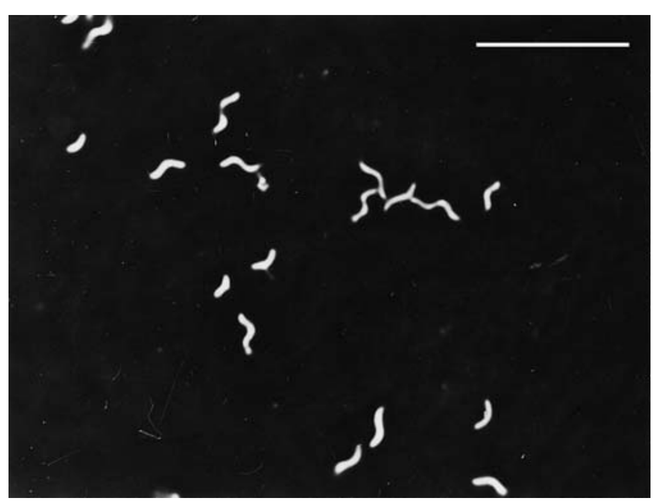

FIGURE BXII.δ.12. Cells of *Desulfonatronovibrio hydrogenovorans* Z-7935 as viewed with the anoptral microscope. Bar = 10 μm.

the substrate, followed by cloning by single colony isolation in roll tubes. For roll tube cultivation, 2% (w/v) agar (Difco) is added to 4-ml portions of carbonate-free medium II with sodium formate as the substrate. The carbonate solution is injected into the Hungate tubes along with melted agar after sterilization. Colonies are yellowish, translucent, lens shaped, and less than 0.2 mm in diameter.

Maintenance Procedures

Desulfonatronovibrio is maintained by regular subculturing in liquid medium and can be stored in a refrigerator at 6°C. Stock cultures are transferred every 2–3 months, but lysis of cells may occur. Strains of *Desulfonatronovibrio* may be stored indefinitely in liquid nitrogen.

Differentiation of the genus *Desulfonatronovibrio* from other genera

Genus *Desulfonatronovibrio* is differentiated from other genera of sulfate-reducing bacteria by its extreme alkaliphily and its obligate dependence on sodium and carbonate ions. The strains are morphologically and nutritionally similar to lithotrophic species of *Desulfovibrio* type but lack desulfoviridin. The fatty acid profile of *Desulfonatronovibrio* contains compounds that are associated with sulfate-reducing species; however, based on its fatty acid profile, *Desulfonatronovibrio* resembles only *Desulfohalobium* and *Desulfomicrobium* (correlation coefficient, 0.23). It lacks $C_{17:1\ iso}$ fatty acid, which is a biomarker of *Desulfovibrio*. *Desulfonatronovibrio* differs from halophilic *Desulfohalobium* (Ollivier et al., 1991) by its lower salinity range, substrate specificity, morphology, 8.5% lower mol% G + C content, and 16S rDNA sequence phylogenetic position. *Desulfonatronovibrio* also has an unusually narrow range of electron donors. Another alkaliphilic sulfate reducer *Desulfonatronum* (Pikuta et al., 1998b) utilizes a number of organic compounds, such as ethanol and lactate, that are not used by *Desulfonatronovibrio*. It also differs from *Desulfonatronovibrio* by a 9% higher mol% G + C content, 16S rDNA sequence positioning, and cell size and shape.

Taxonomic Comments

The phylogenetic position of *Desulfonatronovibrio* was determined by F. Rainey based on 16S rDNA sequence analysis (Fig. BXII.δ.13). *Desulfonatronovibrio* belongs to the cluster of sulfate-

FIGURE BXII.δ.13. Phylogenetic dendrogram indicating the position of *Desulfonatronovibrio* and *Desulfonatronum* within the radiation of sulfate-reducing bacteria of the *Deltaproteobacteria*. The position of the root was determined by including *Escherichia coli* as an outgroup organism. Strain TD3 is proposed in this chapter as the type strain of *Desulfothermus naphthae* gen. nov., sp. nov. Bar = 5 inferred substitutions per 100 nucleotides.

reducing eubacteria within the *Deltaproteobacteria*. It represents a distinct lineage, clustering with extremely halophilic *Desulfohalobium retbaense* (Ollivier et al., 1991) and hydrocarbon-utilizing strain TD3 (Rueter et al., 1994), with 16S rDNA sequence similarities of 88.7% and 86.6%, respectively. Its status as a separate genus is based on its distinct branch point and its 16S rDNA sequence difference of >11% compared with its nearest relative, as well as its distinct phenotypic characteristics.

List of species of the genus Desulfonatronovibrio

1. **Desulfonatronovibrio hydrogenovorans** Zhilina, Zavarzin and Rainey *in* Zhilina, Zavarzin, Rainey, Pikuta, Osipov and Kostrikina 1997, 149^{VP}
hy.dro.ge.no.vo′ rans. M.L. n. *hydrogen* hydrogen; M.L. part. adj. *vorans* devouring, utilizing; M.L. part. adj. *hydrogenovorans* hydrogen utilizing.

The characteristics are as given for the genus and under Further Descriptive Information. The following are additional characteristics. The pH range for growth is 8.0–10.2, and the pH optima for different strains lie in the range 9.0– 9.7 (that of the type strain is 9.5–9.7). Sodium and carbonate ions are required for growth. The optimal NaCl concentration is 3% (w/v); growth of the type strain occurs within the range 1–12%. No growth is evident in the type strain without NaCl, whereas other strains need only sodium carbonates.

Other strains of *D. hydrogenovorans* are Z-7952, Z-7953 (DSM 10321), and Z-7954, which were isolated from soda lakes in Tuva, Central Asia. These are similar to the type strain *D. hydrogenovorans*, with small differences in pH and temperature optima as well as mol% G + C content. Strains have a high degree of DNA–DNA hybridization similarity (90–100% with the type strain *D. hydrogenovorans* from Lake Magadi), despite their remote geographic habitats. All the Tuva strains differ from the type strain by their ability to grow in the absence of NaCl, instead requiring only sodium carbonates (Zavarzin et al., 1996 Pikuta et al., 1997).

The optimal temperature for the type strain is 37°C; maximum, 43°C.

The mol% G + C of the DNA is: 47.9–48.5 (T_m).

Type strain: Z-7935, DSM 9292.

GenBank accession number (16S rRNA): X99234.

Genus III. Desulfothermus *gen. nov.*

Jan Kuever, Fred A. Rainey and Friedrich Widdel

De.sul.fo.ther′ mus. L. pref. *de* from; L. n. *sulfur* sulfur; Gr. adj. *thermus* hot; M.L. masc. n. *Desulfothermus* sulfate reducer living in hot places.

Rod-shaped to slightly curved cells, 0.8–1.0 × 2.0–3.5 µm. Occur singly or in pairs. May grow as individual cells or as compact clumps. Cells tend to stick to hydrophobic surfaces. Spore formation is not observed. Gram negative. Slow motility may occur. Strict anaerobe with a respiratory type of metabolism. **Chemoorganotroph**, using alkanes (C_6–C_{14}), and long-chain fatty acids (C_4–C_{18}) **as electron donors and as carbon sources**; these compounds are completely oxidized to CO_2 via the anaerobic C_1-pathway (carbon monoxide dehydrogenase [CO-DH] pathway, Wood pathway) as indicated by CO–DH activity. **Sulfate and thiosulfate serve as terminal electron acceptors and are reduced to H_2S.** The optimal pH range for growth is 6.5–6.8. The optimal temperature range for growth is 60–65°C. Mesophilic species have not been described. Anoxic media containing a reductant (usually sulfide), NaCl, and $MgCl_2$ are necessary for growth. Vitamins are not required. Occur in anoxic marine sediment rich in aliphatic hydrocarbons.

The mol% G + C of the DNA is: 37.4.

Type species: **Desulfothermus naphthae** *sp. nov.*

Further descriptive information

The type strain of *D. naphthae* has rod-shaped to slightly curved cells which may be slightly motile, and stains Gram-negative. The temperature range for growth is between 50 and 69°C; the optimal is 60–65°C. The pH range for growth is 6.1–7.1, with optimal growth between 6.5 and 6.8.

D. naphthae reduces sulfate and thiosulfate to H_2S. Nitrate cannot serve as an electron acceptor. Alkanes (C_6–C_{14}), and long-chain fatty acids (C_4–C_{18}) are utilized as electron donors and organic carbon sources. Pentadecane and hexadecane are utilized very slowly. No growth on sugars, amino acids, dicarboxylic acids, aromatic compounds, and complex substrates such as yeast extract or peptone. 1-Alkenes, primary alcohols, and aldehydes, which are regarded as possible intermediates during growth on alkanes, are not used. All organic substrates are completely oxidized to CO_2 via the anaerobic C_1-pathway (carbon monoxide dehydrogenase [CO-DH] pathway, Wood pathway) as indicated by CO–DH activity (Ehrenreich, 1996). Ammonium ions are used as the nitrogen source. Vitamins are not required as growth factors. Desulfoviridin is not present (Rueter et al., 1994). Growth cannot be monitored by increase in turbidity, as even after production of 20 mM sulfide only a slight increase in turbidity has been observed.

Desulfothermus naphthae strains occur in anoxic marine sediments rich in aliphatic hydrocarbons.

D. naphthae may be cultured in a defined medium (e.g., as indicated for *Desulfobacter*) with sulfate as electron acceptor and alkanes as the electron donor and carbon source. The type strain is dependent on an elevated salt concentration; best growth is obtained in a medium containing 25 mM Mg^{2+}. The presence of 380 mM Cl^- ions is essential. This corresponds to 21 g/l NaCl and 5 g/l $MgCl_2 \cdot H_2O$.

Enrichment and Isolation Procedures

For the selective enrichment of *Desulfothermus* spp., the defined marine sulfate medium described for the isolation of *Desulfobacter*

spp. may be used. Instead of acetate, the medium is covered with *n*-decane (10% in 2,3,4,4,6,8,8-heptamethylnonane as inert carrier phase) or crude oil. Bottles of 100-ml capacity are inoculated with marine sediment slurry (approximately 5 ml) and kept anoxic by flushing with a mixture of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. Enrichment cultures are incubated at 60°C. Cultures should not be shaken, because the type strain shows better growth without shaking. After intense formation of H_2S has occurred (approximately three weeks), transfers to fresh medium are made. The enrichments should be mixed well before subculturing.

Pure cultures of *Desulfothermus* strains are obtained by repeated application of the agar dilution method, using a short-chain fatty acid as substrate. The type strain was isolated using caproate. The choice of substrate should depend on whether it was used by the enrichment culture. The method is similar to that described for the genus *Desulfobacter*, except that caproate medium is added to the molten concentrated agar solution.

Maintenance Procedures

Stock cultures are transferred every 2–3 months. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 2–5°C in the dark. *Desulfothermus* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen.

Differentiation of the genus *Desulfothermus* from other genera

A distinctive characteristic of *Desulfothermus* is the capacity for growth with *n*-alkanes as the only organic substrate at temperatures around 60°C. However, a definite differentiation requires comparative 16S rDNA sequence analysis and DNA–DNA hybridization.

Taxonomic Comments

Based on 16S rRNA gene sequence data, *Desulfothermus naphthae* forms a distinct lineage within the *Deltaproteobacteria*, but clusters with members of the family *Desulfovibrionaceae*. The closest relatives are members of the genera *Desulfohalobium* and *Desulfonatronovibrio*.

Cells are vibrios 0.7–0.9 × 2.0–3.0 μm, occurring singly or sigmoid in pairs. Cells may be spirilloid under suboptimal conditions. Asporogenous. Gram negative. Motile by a single polar flagellum. **Anaerobic. Possess a strictly respiratory type of metabolism with sulfate and other oxidized sulfur compounds serving as terminal electron acceptors** and being reduced to H_2S. **Extremely alkaliphilic.** No growth at pH values below 8; pH optimum, 9.5; pH maximum, 10. **Obligately dependent on sodium and carbonates. Lithoheterotrophic.** Utilizes H_2, formate, ethanol, or lactate for reduction of sulfur compounds. Utilizes acetate plus vitamin or yeast extract for anabolism. Desulfoviridin is not present. Cells contain *c*-type cytochromes. The habitat is bottom sediments of alkaline lakes. The genus presently includes only a single species.

The mol% G + C of the DNA is: 56–57.

Type species: **Desulfonatronum lacustre** Pikuta, Zhilina and

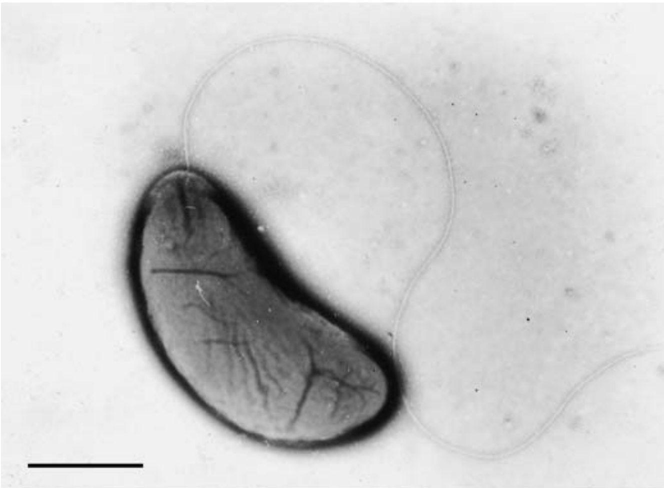

FIGURE BXII.δ.14. Negatively-stained cell of *Desulfonatronum lacustre* Z-7951 with monopolar flagellum. Bar = 1 μm.

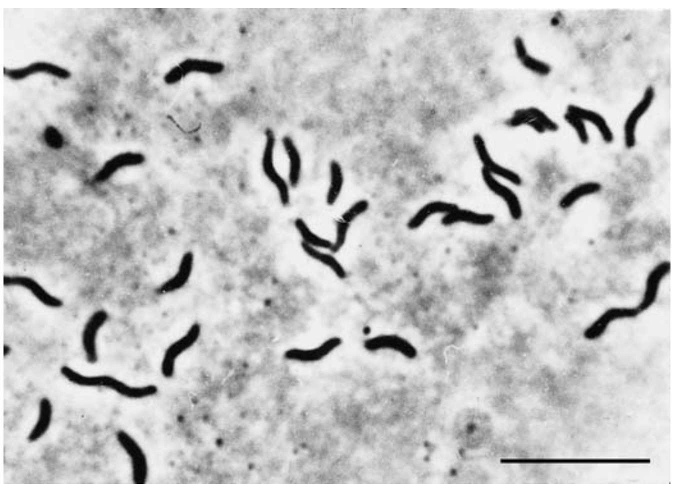

FIGURE BXII.δ.15. Cells of *Desulfonatronum lacustre* Z-7951 as viewed by phase-contrast microscopy. Bar = 10 μm.

Rainey 1998a, 631 (Effective publication: Pikuta, Zhilina and Rainey *in* Pikuta, Zhilina, Zavarzin, Kostrikina, Osipov and Rainey 1998b, 112.)

Further descriptive information

The cells are vibrioid with one polar flagellum (Fig. BXII.δ.14). Multiplication is by binary fission (Fig. BXII.δ.15). The cell wall has a typical Gram-negative structure in ultrathin section. The wall is resistant to enzymatic disintegration methods but not to ultrasound.

The cells contain *c*-type cytochromes with maxima at 552, 521.8, and 417.8 nm.

The type strain utilizes hydrogen, formate, and ethanol as electron donors. Some strains, such as Z-7955 from Lake Khylganta, Burjatia, also utilize lactate. Acetate is produced from ethanol or lactate. Sulfate, sulfite, and thiosulfate serve as electron acceptors. Fumarate, nitrate, DMSO, $Fe(OH)_3$, and S^0 are not reduced. Thiosulfate or sulfite may be disproportionated. Sulfide is the only product of catabolic reduction of sulfur compounds. Acetate or yeast extract is utilized for anabolism.

The prevailing fatty acids of *D. lacustre* are unsaturated fatty acids (about 60%), with major ones $C_{16:1}$ and $C_{18:1}$.

D. lacustre was first isolated from the sandy bottom deposits of low mineralized alkaline Lake Khadyn, Central Asia, south of Baikal in the cryoarid steppe zone. As an H_2-scavenging alkaliphile, *D. lacustre* might function as a hydrogen sink in an anaerobic, alkaliphilic community decomposing organic matter. For instance, it develops in coculture with alkaliphilic fermentative spirochetes growing on carbohydrates and produces an acetogenic shift in their metabolism (Pikuta et al., 1998b). As an extremely alkaliphilic sulfate-reducer, *Desulfonatronum* might participate in the alkalinization of soda lakes.

Enrichment and Isolation Procedures

Strains of *Desulfonatronum* can be enriched from alkaline soda lakes under strictly anaerobic conditions in the selective alkaline mineral medium no. 1[1] (Zavarzin et al., 1996), which has a high sodium carbonate content. Incubation is under an atmosphere of H_2. N_2 can substitute for H_2 if Na-formate or ethanol is added as the electron donor. Isolation is by serial dilution in liquid medium no. 1 where yeast extract is replaced by 2 mM sodium acetate with subsequent cloning by single colony isolation in roll tubes. For roll tube cultivation, 2% (w/v) agar (Difco) is added to 4-ml portions of carbonate-free medium no. 1. The carbonate solution is injected into Hungate tubes after sterilization. Colonies are isolated by the capillary technique under a dissecting microscope. Colonies are lenticular, yellowish, translucent, with even edges.

Maintenance Procedures

Desulfonatronum is maintained by regular subculturing in liquid medium and storage in the refrigerator at 6°C. Stock cultures are transferred every 2–3 months but lysis of cells may occur. Strains of *Desulfonatronum* may be stored indefinitely in liquid nitrogen.

Differentiation of the genus *Desulfonatronum* from other genera

The genus *Desulfonatronum* is differentiated from other genera of sulfate-reducing bacteria by its extreme alkaliphily. It differs from the genus *Desulfonatronovibrio* (which also includes true alkaliphiles) by its larger cell size, substrate specificity, utilization of thiosulfate as electron acceptor, lipid profile, 10% higher G + C content of the DNA, and almost twofold larger genome size (Pikuta et al., 1997). Few sulfate reducers have mol% G + C values similar to *Desulfonatronum*; however, *Desulfohalobium* (Ollivier et al., 1991) and *Desulfomicrobium* (Rozanova et al., 1988) are among them. *Desulfonatronum* differs from halophilic *Desulfohalobium* species by its independence from NaCl for growth, substrate specificity, lipid profile, and 16S rDNA sequence-based phylogenetic position. It differs from *Desulfomicrobium* by its cell morphology, substrate specificity, lipid profile, and 16S rDNA sequence-based phylogenetic position (see Table BXII.δ.13). The $C_{17:1\ iso}$ typical of *Desulfovibrio* species is found in only minor amounts in *Desulfonatronum*. The predominance of unsaturated fatty acids in *Desulfonatronum* distinguishes it from *Desulfonatronovibrio*.

1. Medium no.1 has the following composition (per liter of distilled water): Na_2CO_3, 2.76 g; NaCl, 10.0 g; Na_2SO_4, 3.0 g; NH_4Cl, 0.5 g; KCl, 0.2 g; K_2HPO_4, 0.2 g; $Na_2S \cdot 9H_2O$, 0.5 g; yeast extract, 0.5 g; substrate (electron donor), 5.0 g; and 1 ml of trace element solution (Whitman et al., 1982).

[h]Some strains utilize lactate.

Taxonomic Comments

The phylogenetic position of *Desulfonatronum* was determined based on 16S rDNA sequence analysis. The genus belongs to the cluster of sulfate-reducing bacteria within the *Deltaproteobacteria* (see Fig. BXII.δ.13). It represents a distinct lineage, with 16S rDNA sequence similarity between *Desulfonatronum* and other taxa within this group in the range of 83.4–89.7%. Its status as a separate genus is based on phenotypic and phylogenetic analysis, including a distinct branching point, 16S rDNA sequence difference of >10% from the nearest relative, and lipid composition. When the fatty acid profile of *Desulfonatronum* was compared with the lipid profiles of *Desulfomicrobium baculatum*, *Desulfohalobium retbaense*, and *Desulfonatronovibrio hydrogenovorans*, computer-assisted analysis revealed no correlation with any of these species or with strains of other genera of sulfate-reducing bacteria in the database.

List of species of the genus Desulfonatronum

1. **Desulfonatronum lacustre** Pikuta, Zhilina and Rainey 1998a, 631[VP] (Effective publication: Pikuta, Zhilina and Rainey in Pikuta, Zhilina, Zavarzin, Kostrikina, Osipov and Rainey 1998b, 112.)
la.cus'tre. F. or Ital. *lacustre* lacustrine, of lakes; from L. *lacus* basin, lake; probably influenced by L. masc. *paluster, palustris* marshy; M.L. adj. *lacustre* inhabiting lakes.

The characteristics are as given for the genus and under Further Descriptive Information. The following are additional characteristics. Optimal temperature, 37–40°C; range, 20–45°C. No growth below pH 8; maximum pH for growth, ~10; optimal pH, 9.5. Sodium and carbonate ions are required for growth. NaCl is not required but up to 10% (w/ v) NaCl can be tolerated.

The mol% G + C of the DNA is: 57.3 (T_m).

Type strain: Strain Z-7951, DSM 10312.

GenBank accession number (16S rRNA): Y14594.

Order III. **Desulfobacterales** *ord. nov.*

JAN KUEVER, FRED A. RAINEY AND FRIEDRICH WIDDEL

De.sul.fo.bac.ter.a′les. M.L. masc. n. *Desulfobacter* type genus of family; suffix *-ales* denotes order; M.L. fem. pl. n. *Desulfobacterales* the order that comprises *Desulfobacteraceae* and other families.

The order comprises **morphologically diverse sulfate-reducing bacteria** including cocci, oval, rod-shaped, and curved cells; some may form sarcina-like cell aggregates or multicellular, uniseriately arranged filaments. Many forms are motile by means of single polar flagella; multicellular filaments exhibit gliding motility. **Strictly anaerobic chemoorganotrophs, chemolithoheterotrophs, or chemolithoautotrophs with respiratory metabolism**; in addition, fermentative abilities are found in some members. With the exception of one isolate (*Desulfocapsa sulfexigens*), **the common electron acceptor is sulfate, which is reduced to sulfide**. Sulfite or thiosulfate may be used in addition; a few members also reduce elemental sulfur (or polysulfide) to sulfide, or nitrate to ammonia. Simple organic compounds such as long-chain fatty acids, alcohols, polar aromatic compounds, and in some cases even aliphatic or aromatic hydrocarbons, serve as electron donors and carbon sources. Most members of the family *Desulfobacteraceae* perform a complete oxidation of organic substrates. Most members of the family *Desulfobulbaceae* are incomplete oxidizers that form acetate as an end product. Some members can grow chemolithoautotrophically with H_2 and sulfate as the source of energy and CO_2 as the source of carbon for cell synthesis. Growth by disproportionation of sulfur, thiosulfate, and sulfite may occur. Members are mesophilic or psychrophilic; thermophiles have not been isolated in this order. Cells contain various cytochromes, other redox proteins, and menaquinones. Mesophilic species have been isolated from various aquatic environments, including marine, brackish water, and freshwater habitats.

The order comprises the families *Desulfobacteraceae* and *Desulfobulbaceae* (see Fig. BXII.δ.16).

Type genus: **Desulfobacter** Widdel 1981, 382 (Effective publication: Widdel 1980, 376.)

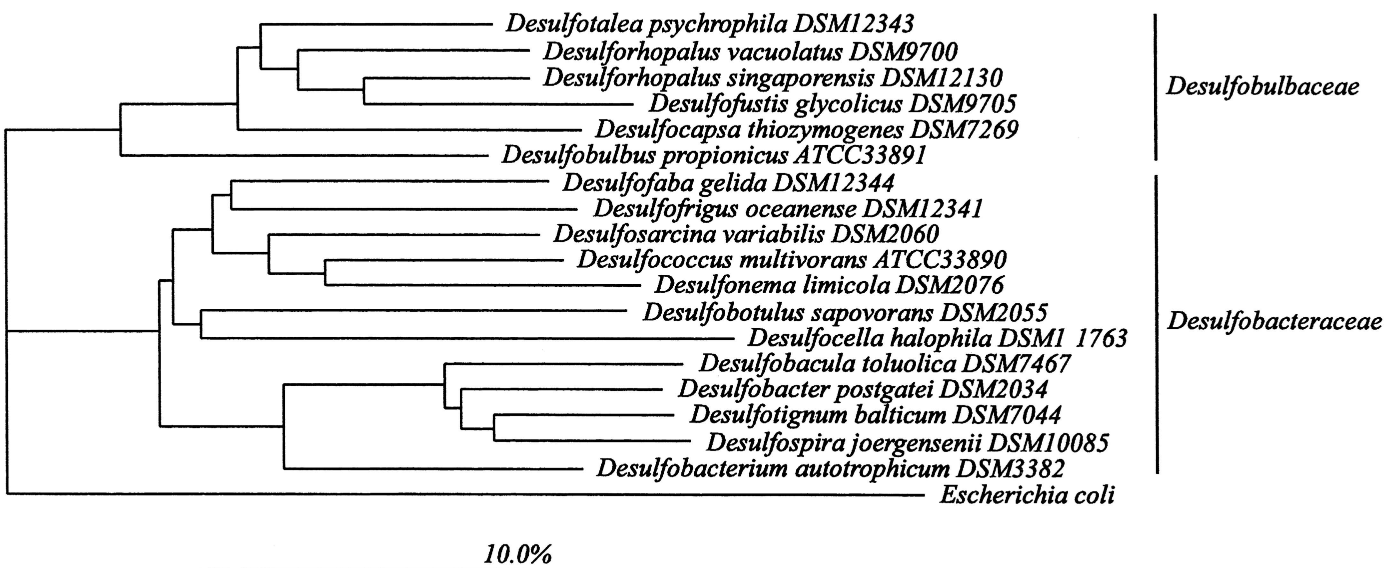

FIGURE BXII.δ.16. Phylogenetic relationships based on 16S rRNA gene sequence analyses of the genera within the order *Desulfobacterales*. The scale bar represents 10 inferred nucleotide substitutions per 100 nucleotides. The dendrogram was reconstructed from distance matrices using the neighbor-joining method.

Family I. **Desulfobacteraceae** *fam. nov.*

JAN KUEVER, FRED A. RAINEY AND FRIEDRICH WIDDEL

De.sul.fo.bac.ter.a.ce′ae. M.L. masc. n. *Desulfobacter* type genus of the family; suff. *ceae* denotes family; M.L. fem. pl. n. *Desulfobacteraceae* the family that comprises the genus *Desulfobacter* and other genera.

The family comprises morphologically diverse sulfate-reducing bacteria including cocci, oval, rod-shaped, and curved cells; some may form sarcina-like cell aggregates or multicellular, uniseriately arranged filaments. Many forms are motile by means of a single polar flagellum; multicellular filaments exhibit gliding motility. Strictly anaerobic chemoorganotrophs or chemolithoautotrophs

with respiratory metabolism; fermentative abilities are found in some members. The common electron acceptor is sulfate, which is reduced to sulfide. Sulfite or thiosulfate may also be used. Simple organic compounds such as long-chain fatty acids, alcohols, polar aromatic compounds, and in some cases even aliphatic or aromatic hydrocarbons, serve as electron donors and carbon sources. Most members of the family *Desulfobacteraceae* perform a complete oxidation of organic substrates. Some members can grow chemolithoautotrophically with H_2 and sulfate as the source of energy and CO_2 as the source of carbon for cell synthesis. Members are mesophilic or psychrophilic; thermophiles have not been isolated. Cells contain various cytochromes, other redox proteins, and menaquinones. Mesophilic species have been isolated from various aquatic environments, including marine, brackish water, and freshwater habitats.

The family comprises 14 described genera, *Desulfobacter*, *Desulfobacterium*, *Desulfobacula*, *Desulfobotulus* (proposed below), *Desulfocella*, *Desulfococcus*, *Desulfofaba*, *Desulfofrigus*, *Desulfomusa*, *Desulfonema*, *Desulforegula*, *Desulfosarcina*, *Desulfospira*, and *Desulfotignum*. Properties of genera are given in Table BXII.δ.14. Detailed properties of described species of each genus are given in the genus description. *Desulfomusa* and *Desulforegula* were validly published after the cut-off date for inclusion in this edition of the *Manual* (June 30, 2001).

Type genus: **Desulfobacter** Widdel 1981, 382 (Effective publication: Widdel 1980, 376.)

Genus I. **Desulfobacter** Widdel 1981, 382[VP] (Effective publication: Widdel 1980, 376)

Jan Kuever, Fred A. Rainey and Friedrich Widdel

De.sul.fo.bac′ter. L. pref. *de* from L. n. *sulfur* sulfur; M.L. n. *bacter* masc. equivalent of Gr. fem. n. *bacteria* rod or staff; M.L. masc. n. *Desulfobacter* a rod-shaped sulfate-reducing bacterium.

Oval to rod-shaped or slightly curved to vibrio-shaped cells, 0.5–2.5 × 1.5–8 μm. Occur singly or in pairs. Spore formation is not observed. Gram negative. Cells are motile by single polar flagella or nonmotile, but motility can be lost during cultivation. Strict anaerobe with a respiratory type of metabolism. **Chemoorganotrophs or chemoautotrophs. Acetate is the preferred general electron donor and carbon source,** and is completely oxidized to CO_2. Some species also use ethanol, and a few species use H_2/CO_2 or pyruvate. H_2-utilizing *Desulfobacter hydrogenophilus* grows autotrophically with CO_2 as the sole carbon source. **Sulfate, and usually sulfite and thiosulfate, serve as terminal electron acceptors and are reduced to H_2S. Sulfur and nitrate are not used as terminal electron acceptors.** Fermentative growth has not been observed. Desulfoviridin is absent, but desulforubidin is present in some species. The major menaquinone is MK-7. Growth occurs in simple defined media containing sulfide as a reductant. Most species require vitamins. Many members of this genus can fix N_2. The addition of ≥7 g NaCl and ≥1 g $MgCl_2 \cdot 6H_2O$ per liter medium is usually stimulatory or required for growth. The optimal temperature range for growth is 28–34°C. Thermophilic species have not been described. The optimal pH range for growth is 6.5–7.4. Carbon monoxide dehydrogenase activity is absent. Acetyl-CoA oxidation and CO_2 fixation with H_2 as electron donor in *D. hydrogenophilus* is accomplished via a modified TCA cycle. *Desulfobacter* species are most common in anoxic brackish or marine sediments, but some types may be found in anoxic freshwater sediments or in activated sludge.

The mol% G + C of the DNA is: 45–49.

Type species: **Desulfobacter postgatei** Widdel 1981, 382 (Effective publication: Widdel 1980, 373.)

Further descriptive information

Many *Desulfobacter* species have ellipsoidal to short, rod-shaped cells with rounded ends (Figs. BXII.δ.17, BXII.δ.18, BXII.δ.19, and BXII.δ.20); some strains form longer rods or curved cells;

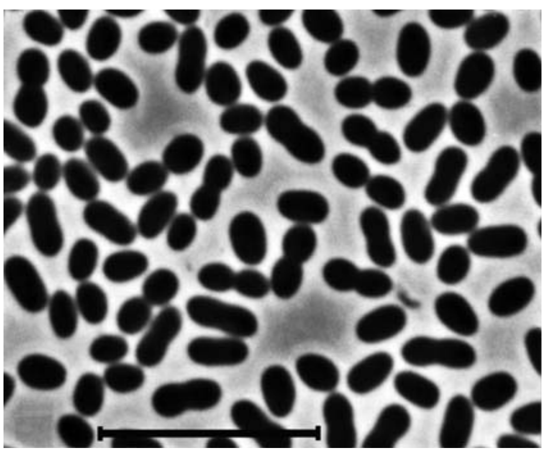

FIGURE BXII.δ.17. Phase-contrast micrograph of *Desulfobacter postgatei* (viable cells). Bar = 10 μm.

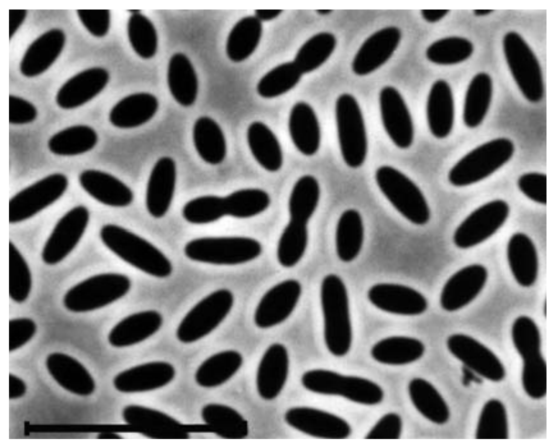

FIGURE BXII.δ.19. Phase-contrast micrograph of *Desulfobacter hydrogenophilus* (viable cells). Bar = 10 μm.

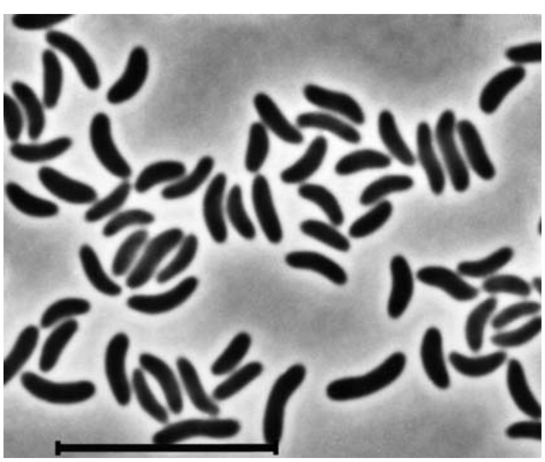

FIGURE BXII.δ.18. Phase-contrast micrograph of *Desulfobacter curvatus* (viable cells). Bar = 10 μm.

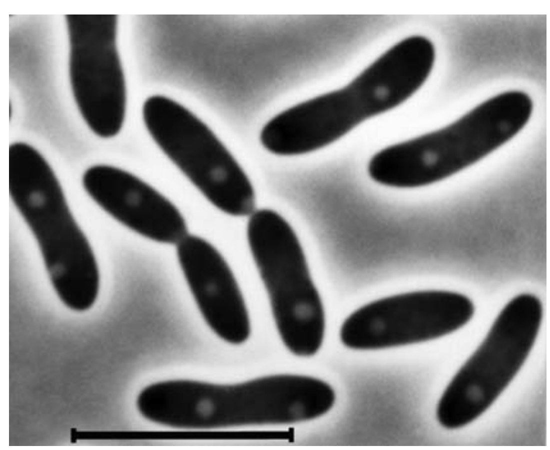

FIGURE BXII.δ.20. Phase-contrast micrograph of *Desulfobacter latus* (viable cells). Bar = 10 μm.

a few strains tend to form pleomorphic cells. The cells are often in pairs. Cells of marine strains or species have the tendency to stick together in clumps, which settle to the bottom of culturing vessels. In the first few enrichment passages on acetate and sulfate, motile cells can often be seen; after isolation most strains become nonmotile.

The optimal growth temperature is usually 28–32°C; the maximum is 37°C and the minimum usually 10°C; however, growth at 0°C has been observed in *D. hydrogenophilus*. The pH range for growth is 6.2–8.5, with an optimal at 7.3.

Growth occurs only in the presence of sulfate, sulfite, or thiosulfate as electron acceptors. Nitrate, fumarate, and malate are not reduced. Elemental sulfur inhibits growth. The type strain of *D. postgatei* uses only acetate as the electron donor and carbon source; however, other species may also use ethanol, pyruvate, or lactate (see Table BXII.δ.15). *D. hydrogenophilus* can grow autotrophically with H_2 as electron donor and CO_2 as carbon source. Sugar, pyruvate, and fumarate are not fermented. *Desulfobacter curvatus* can disproportionate sulfite and thiosulfate to sulfate and sulfide (Bak and Pfennig, 1987). Carbon monoxide dehydrogenase activity is absent. Acetyl-CoA oxidation (and CO_2 fixation with H_2 as electron donor in *D. hydrogenophilus*) is accomplished via a modified TCA cycle, as indicated by 2-oxoglutarate dehydrogenase activity (Brandis-Heep et al., 1983; Gebhardt et al., 1983; Schauder et al., 1986; Lien and Beeder, 1997).

D. postgatei contains membrane-bound and soluble cytochromes of the *b* and *c* type. The sulfite reductase desulforubidin is present in the type strain and in *D. vibrioformis*; other species were not investigated. All members of the genus *Desulfobacter* investigated so far contain MK-7 or MK-7(H_2) as the major menaquinone (Collins and Widdel, 1986). Major cellular fatty acids of the *Desulfobacter* strains are $C_{14:0}$, $C_{16:0}$, $C_{16:0\ 10CH_3}$, $C_{16:1\ \omega7c}$ and $C_{17:0\ cyclo}$ (Vainshtein et al., 1992; Kohring et al., 1994).

Desulfobacter strains occur in black anoxic sediments from brackish water and marine habitats. Occurrence in anoxic freshwater habitats (ditches, activated sludge) has also been shown by use of enrichment cultures prepared with brackish water media.

[b]Autotrophic growth.

Strains of *Desulfobacter* may be cultured in a defined medium[1] with sulfate as the electron acceptor and acetate as the electron donor and carbon source. Sulfide is added as reductant. Marine strains often require 20.0 g/l NaCl and 3.0 g/l $MgCl_2 \cdot 6H_2O$; brackish water strains tolerate lower levels of these salts. *p*-Aminobenzoic acid and biotin are required as growth factors by some species. Initiation of growth is favored, especially when inoculation is done from old cultures, by the addition of 10–30 mg/l of fresh sodium dithionite as a further strong reductant.

Enrichment and Isolation Procedures

For the selective enrichment of *Desulfobacter* strains, acetate-sulfate medium is used. Bottles or tubes (100-, 50-, or 20-ml capacity) can serve as culture vessels and are kept anoxic with tight screw caps (only if completely filled), or under a head space containing a mixture of N_2/CO_2 (90:10) and sealed with butyl rubber stoppers. The medium is inoculated with black anoxic mud from brackish water or marine habitats; 2–5% of the total volume should be added. *Desulfobacter* species may also be enriched and isolated via direct serial dilution of anoxic environmental samples in liquid medium (according to the most-probable-number method) or agar medium (see next paragraph) with propionate as organic substrate. The NaCl concentration of the medium should correspond approximately to the salinity of the natural source. The amount of $MgCl_2 \cdot 6H_2O$ added need not be greater than 3 g/l. Brackish water medium containing 7 g NaCl and 1.2 g $MgCl_2 \cdot 6H_2O$ per liter should be used for enrichment of *Desulfobacter* strains from anoxic freshwater habitats; typical freshwater media containing only 1 g NaCl and 0.5 g $MgCl_2 \cdot 6H_2O$ (or less) per liter are not suitable for such enrichment, but once strains grow well in brackish water medium they may subsequently be cultured at lower salinities. Addition of dithionite to enrichment cultures is recommended. Enrichment cultures are incubated at 25–30°C and are mixed by brief shaking every second day. After intense formation of H_2S has occurred (generally after 8–20 d), transfers to fresh medium are made. Because cells of *Desulfobacter* often attach to sediment particles or many form aggregates that sediment to the bottom of culture vessels, the cultures should be mixed well before subculturing.

Pure cultures are obtained by repeated application of the agar dilution method. A 3.3% (w/v) solution of agar is prepared in distilled water; the agar should be washed several times in cold distilled water before preparing the solution. The agar solution is dispensed in 3-ml amounts into test tubes, which are closed with aluminum caps and autoclaved. Agar tubes may be stored for 2–4 months. The agar tubes are kept molten (or remelted at 100°C) and placed in a water bath at 55°C. Defined culture medium is prewarmed to 41°C and 6-ml amounts are added to the tubes of liquefied agar; exposure to air is minimized by dipping the tip of the pipette into the agar medium. To compensate for the diluting effect of the aqueous agar, it is recommended to increase the amounts of NaCl and $MgCl_2 \cdot 6H_2O$ to 30 and 4.5 g, respectively, per liter of medium (e.g., by addition of sterile salt concentrate) before this is added to the agar. Addition of salts to the agar before autoclaving is not recommended as an alternative because this may promote hydrolysis of agar. Starting with 0.1–0.5 ml of an enrichment culture as inoculum, serial dilutions of approx. 1:10 are made using 6–8 tubes. Before the agar medium solidifies, dithionite solution is added aseptically to each tube from a 0.1-ml pipette which is at the same time used for gently mixing, starting at the highest dilution. All agar tubes are then hardened in cold water and immediately sealed with butyl rubber stoppers under a mixture of N_2/CO_2 (90:10) (v/v). The tubes are incubated in the dark for 2–4 weeks at 25–30°C. Well-separated colonies that occur in the higher dilutions can be removed with sterile Pasteur pipettes (thinned upon heating in a flame); the cells are used as inoculum for subsequent agar dilution cultures. The process is repeated until the cultures are pure, as indicated by homogenous colonies and homogenous cells.

Maintenance Procedures

Stock cultures are transferred every 3–5 months. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 2–5°C in the dark. *Desulfobacter* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen.

Differentiation of the genus *Desulfobacter* from other genera

In addition to standard 16S rRNA gene sequence analysis (see next section) and DNA–DNA hybridization, methods testing physiological characteristics may also be included in the differentiation of *Desulfobacter* from other morphologically similar sulfate-reducing bacteria (Widdel and Pfennig, 1981). *Desulfobacter* strains grow well (with a 15–20 h doubling time) in seawater or brackish water media containing acetate and sulfate. Sulfide concentrations of 20 mM, or sometimes even higher, may be produced. In contrast to *Desulfotomaculum acetoxidans*, which also grows on acetate and sulfate, *Desulfobacter* cells have rounded ends or are vibrio-shaped and do not form spores; moreover, they have a lower optimal growth temperature and they utilize only a few organic substrates beside acetate. A unique feature of all *Desulfobacter* strains is the presence of 2-oxoglutarate dehydrogenase, indicating the operation of a complete tricarboxylic acid cycle for oxidation of acetyl-CoA. All other completely oxidizing sulfate-reducing bacteria investigated so far use the anaerobic C_1 pathway (carbon monoxide dehydrogenase pathway, Wood pathway) for oxidation of acetyl-CoA.

Some *Desulfobacter* species resemble cells of *Desulfococcus multivorans* and *Desulfosarcina variabilis*; however, strains of the latter two species develop only slowly on acetate. They are capable of

1. The defined medium has the following composition (g/l of distilled water): Na_2SO_4, 3.0; KH_2PO_4, 0.2; NH_4Cl, 0.3; NaCl, 7.0 (for brackish water strains) or 20.0 (for marine strains); $MgCl_2 \cdot 6H_2O$, 1.2 (for brackish water strains) or 3.0 (for marine strains); KCl, 0.5; $CaCl_2 \cdot 2H_2O$, 0.15. After the medium has been autoclaved and cooled under an atmosphere of N_2/CO_2 (90:10), the following components are added per liter of medium from sterile stock solutions, while access of air is prevented by continuous flushing with a mixture of N_2/CO_2 (90:10): acetate solution ($CH_3COONa \cdot 3H_2O$, 280 g/l), 10.0 ml; trace element solution (see below), 1.0 ml; bicarbonate solution ($NaHCO_3$, 84 g/l, saturated with CO_2 and autoclaved under a CO_2 atmosphere), 30.0 ml; sulfide solution ($Na_2S \cdot 9H_2O$, 120 g/l, autoclaved under an N_2 atmosphere), 3.0 ml; vitamin solution (*p*-aminobenzoic acid, 40 mg/l, and biotin, 10 mg/l), 1.0 ml. Trace element solution (without chelating agent) contains (per liter): HCl (25% solution), 10 ml; $FeSO_4 \cdot 7H_2O$, 2.1 g; $CoCl_2 \cdot 6H_2O$, 190 mg; $ZnSO_4$, 144 mg; $MnCl_2 \cdot 4H_2O$, 100 mg; $Na_2MoO_4 \cdot 2H_2O$, 36 mg; $NiCl_2 \cdot 6H_2O$, 24 mg; H_3BO_3, 6 mg; $CuCl_2 \cdot 2H_2O$, 2 mg. The $FeSO_4$ is initially dissolved in the HCl solution and distilled water is added, followed by the other components. The pH of the complete defined medium is adjusted to 7.0–7.3. After the medium is inoculated, sodium dithionite (10–30 mg/l) is added from a freshly prepared 5% solution sterilized by filtration under anaerobic conditions; alternatively, dry crystals can be added with a sterile spatula.

utilizing a larger variety of organic compounds, such as 1-propanol, 1-butanol, higher fatty acids, and benzoate.

Taxonomic Comments

Based on 16S rRNA gene sequence data, *Desulfobacter* strains form one cluster within the *Deltaproteobacteria* and cluster with members of the family *Desulfobacteraceae*. The closest relatives are members of the genus *Desulfobacterium*, *Desulfobacula toluolica*, and *Desulfospira joergensenii*. A signature sequence for all described *Desulfobacter* species and other closely related sulfate-reducing bacteria is 5′-CACAGGATGTCAAACCCAG-3′ (oligonucleotide probe DSB985), which binds to the 16S rRNA at *E. coli* position 5′-985–1004-3′ (Devereux et al., 1992; Manz et al., 1998).

Widdel, F. and N. Pfennig. 1981. Studies on dissimilatory sulfate-reducing bacteria that decompose fatty acids. I. Isolation of new sulfate-reducing bacteria with acetate from saline environments. Description of *Desulfobacter postgatei* gen. nov., sp. nov. Arch. Microbiol. *129*: 395–400.

List of species of the genus Desulfobacter

1. **Desulfobacter postgatei** Widdel 1981, 382^{VP} (Effective publication: Widdel 1980, 373.)
post.ga′ te.i. M.L. gen. n. *postgatei* of Postgate; in honor of J.R. Postgate, an English microbiologist.

The morphology is as described in Table BXII.δ.15 and as depicted in Fig. BXII.δ.17. Characteristics are as described for the genus and summarized in Table BXII.δ.15. Cells contain desulforubidin as sulfite reductase. Occur in anoxic parts of brackish water and marine habitats; may also be enriched from freshwater mud by use of saltwater media.

The mol% G + C of the DNA is: 49 (HPLC).
Type strain: 2ac9, DSM 2034.
GenBank accession number (16S rRNA): M26633.

2. **Desulfobacter curvatus** Widdel 1988b, 328^{VP} (Effective publication: Widdel 1987, 290.)
cur.va′ tus. L. part. *curvatus* curved, bent.

The morphology is as described in Table BXII.δ.15 and as depicted in Fig. BXII.δ.18. Characteristics are summarized in Table BXII.δ.15. Growth requires 0.7 g/l NaCl and 0.13 g/l $MgCl_2 \cdot 6H_2O$. The type strain was isolated from marine mud from Venice (Italy) using acetate; however, vibrio-shaped, acetate-oxidizing, sulfate-reducing bacteria may also be found in freshwater sediments.

The mol% G + C of the DNA is: 46 (T_m).
Type strain: AcRM3, ATCC 43919, DSM 3379.
GenBank accession number (16S rRNA): M34413.

3. **Desulfobacter halotolerans** Brandt and Ingvorsen 1998, 327^{VP} (Effective publication: Brandt and Ingvorsen 1997, 371.)
ha.lo′ to.le.rans. Gr. n. *halos* salt; L. v. *tolerare* tolerate; M.L. adj. *halotolerans* salt-tolerating.

Characteristics are summarized in Table BXII.δ.15. An unusual characteristic of this species is the ability to grow even at an NaCl concentration of 130 g/l, all other *Desulfobacter* spp. can grow up to an NaCl concentration of only 60 g/l. The type strain was isolated from moderately hypersaline, thalassohaline sediment of the Great Salt Lake (Utah, USA).

The mol% G + C of the DNA is: 49 (HPLC).
Type strain: GSL-Ac1, DSM 11383.
GenBank accession number (16S rRNA): Y14745.

4. **Desulfobacter hydrogenophilus** Widdel 1988b, 328^{VP} (Effective publication: Widdel 1987, 290.)
hy.dro.ge.no′ phi.lus. M.L. n. *hydrogenum* hydrogen, from Gr. n. *hydro* water, and Gr. v. *genein* form or constitute; Gr. v. *philein*-like, love; M.L. adj. *hydrogenophilus* that likes hydrogen.

The morphology is as described in Table BXII.δ.15 and as depicted in Fig. BXII.δ.19. Characteristics are summarized in Table BXII.δ.15. This is the only described species of the genus *Desulfobacter* that can grow chemolithoautotrophically with H_2 and CO_2. The type strain was isolated from marine mud from Venice (Italy) using acetate.

The mol% G + C of the DNA is: 45 (T_m).
Type strain: AcRS1, ATCC 43915, DSM 3380.
GenBank accession number (16S rRNA): M34412.

5. **Desulfobacter latus** Widdel 1988b, 328^{VP} (Effective publication: Widdel 1987, 290.)
la′ tus. L. adj. *latus* large, wide.

The morphology is as described in Table BXII.δ.15 and as depicted in Fig. BXII.δ.20. Characteristics are summarized in Table BXII.δ.15. The type strain was isolated from marine mud from Venice (Italy) using acetate.

The mol% G + C of the DNA is: 44 (HPLC).
Type strain: AcRS2, ATCC 43918, DSM 3381.
GenBank accession number (16S rRNA): M34414.

6. **Desulfobacter vibrioformis** Lien and Beeder 1997, 1127^{VP}
vi.bri.o.for′ mis. L. v. *vibrio* vibrate; M.L. n. *vibrio* that which vibrates, a generic name; L. adj. suff. *formis*-like, of the shape of; *vibrioformis* vibrio shaped.

Characteristics are summarized in Table BXII.δ.15. Cells of *D. vibrioformis* contain desulforubidin as sulfite reductase. *D. vibrioformis* is able to grow without supplementation of vitamins. The type strain was isolated from a water-oil separation system on the deck of an oil field platform in the North Sea, with acetate as the only substrate.

The mol% G + C of the DNA is: 47 (HPLC).
Type strain: B54, DSM 8776.
GenBank accession number (16S rRNA): U12254.

Genus II. **Desulfobacterium** *Bak and Widdel 1988, 136^{VP} (Effective publication: Bak and Widdel 1986, 175)*

JAN KUEVER, FRED A. RAINEY AND FRIEDRICH WIDDEL

De.sul.fo.bac.te' ri.um. L. pref. *de* from L. n. *sulfur* sulfur; Gr. dim. n. *bakterion* a small rod; M.L. neut. n. *Desulfobacterium* a rod-shaped sulfate reducer.

Oval to rod-shaped, or spherical cells, 0.9–2 × 1.5–3 μm. Occur singly or in pairs; sometimes also in loose chains. Spore formation is not observed. Gram negative. Some species are motile, but motility may be lost during cultivation. Strict anaerobes with a respiratory and a fermentative type of metabolism. **Chemoorganotrophs or chemoautotrophs**, using formate, butyrate, higher fatty acids, other organic acids, alcohols, and $H_2 + CO_2$ **as electron donors and as carbon sources**; these compounds are completely oxidized to CO_2. One species can use nicotinate as sole electron donor and carbon source. Growth on acetate and propionate is usually very slow. **Sulfate and other oxidized sulfur compounds serve as terminal electron acceptors and are reduced to H_2S. Sulfur and nitrate are not used as terminal electron acceptors. Some species may grow slowly in the absence of an external electron acceptor by fermentation of lactate, pyruvate, malate, and fumarate.** Optimal growth temperature, 26–29°C. Anoxic media (with sulfide as a reductant) and vitamins are required for growth. *Desulfobacterium* species require brackish or marine concentrations of NaCl and $MgCl_2$. Cells contain cytochromes of the *b*- and *c*-type. Carbon monoxide dehydrogenase activity is commonly observed, indicating the operation of the anaerobic C_1 pathway (carbon monoxide dehydrogenase pathway, Wood pathway) for complete oxidation of acetyl-CoA, or for CO_2 fixation during autotrophic growth. *Desulfobacterium* species are widespread in brackish or marine sediments, but occur less frequently in freshwater habitats.

The mol% G + C of the DNA is: 45–48.

Type species: **Desulfobacterium autotrophicum*** Brysch, Schneider, Fuchs and Widdel 1988, 328 (Effective publication: Brysch, Schneider, Fuchs and Widdel 1987, 272.)

FURTHER DESCRIPTIVE INFORMATION

D. autotrophicum uses sulfate, thiosulfate, or fumarate as electron acceptor, whereas sulfite, sulfur, and nitrate are not used. Formate, butyrate, long chain fatty acids, other organic acids, and alcohols serve as electron donors and as carbon sources; these compounds are oxidized completely to CO_2 via the anaerobic C_1 pathway (carbon monoxide dehydrogenase pathway, Wood pathway) (Schauder et al., 1986). Despite the capacity for complete oxidation, high substrate concentrations can lead to an excretion of acetate, implying an incomplete oxidation; the acetate may be slowly utilized again.

D. niacini can grow with nicotinate as electron donor and carbon source. Phenylpropionate is oxidized to benzoate, which is not degraded. Chemolithoautotrophic growth occurs with H_2 as the electron donor and CO_2 as the carbon source. Growth on acetate and propionate is very slow. *D. vacuolatum* is able to grow on several amino acids as electron donor and the sole carbon and nitrogen source (Rees et al., 1998). In the absence of an external electron acceptor, some species grow slowly by fermentation of lactate, pyruvate, malate, and fumarate. Ammonium ions are used as the nitrogen source. Some strains require vitamins (Table BXII.δ.16). All members of the genus *Desulfobacterium* contain MK-7(H_2) or MK-7 as the major menaquinone (Collins and Widdel, 1986). Desulfoviridin is not present. Major cellular fatty acids of the *Desulfobacterium* strains are $C_{16:0}$, $C_{16:1\ \omega7c}$, and $C_{17:1\ \omega6c}$ (Vainshtein et al., 1992; Kohring et al., 1994).

Desulfobacterium species are abundant in anoxic marine sediments, especially those rich in organic compounds.

All described strains require NaCl and $MgCl_2$ for growth; best growth is obtained with 15–20 g NaCl and 3 g $MgCl_2 \cdot 6H_2O$ per liter.

ENRICHMENT AND ISOLATION PROCEDURES

For the selective enrichment of *Desulfobacterium*, the same defined marine sulfate medium described for the isolation of *Desulfobacter* spp. may be used. *D. autotrophicum* may be enriched with H_2 and CO_2 or with formate as electron donors and carbon sources. To avoid the development of mixed cultures of acetate-producing *Acetobacterium* spp. and lithoheterotrophic *Desulfovibrio* spp., which will also become established using these enrichment substrates, marine sediment samples should be diluted in anoxic liquid or agar medium under H_2/CO_2 (90:10) (v/v) (Brysch et al., 1987). Autotrophic growth of *D. autotrophicum* with H_2 and CO_2 occurs with a doubling time of around 16.5 h. *D. vacuolatum* may be enriched with isobutyrate (5 mM), whereas *D. niacini* is usually enriched with nicotinate (5 mM).

Bottles or tubes (100-, 50-, or 20-ml capacity) can serve as culture vessels and are kept anoxic with tight screw caps (if completely filled), or by providing an anoxic head space of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated (2–5% of the total volume) with dark anoxic sediment or sludge from sewage digesters. Enrichment cultures are incubated at 28–30°C. Cultures should be briefly mixed every day. After intense formation of H_2S has occurred, transfers to fresh medium are made. Enrichment cultures should be mixed well before subculturing. Pure cultures of *Desulfobacterium* strains are obtained by repeated application of the agar dilution method (as described for *Desulfobacter* in this edition of the *Manual*). The same substrates used for the enrichment cultures may be used to obtain pure cultures.

MAINTENANCE PROCEDURES

Stock cultures are transferred every 2–3 months. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 2–5°C in the dark. *Desulfobacterium* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen.

DIFFERENTIATION OF THE GENUS *DESULFOBACTERIUM* FROM OTHER GENERA

Strains of *Desulfobacterium* can be distinguished from other mesophilic sulfate-reducing bacteria by physiological and morphological properties. All *Desulfobacterium* strains known so far can grow lithoautotrophically with H_2/CO_2 (or with formate), or orga-

**Editorial Note:* The type species of the genus is *Desulfobacterium autotrophicum* and not *Desulfobacterium indolicum*, as indicated in List No. 24 in *International Journal of Systematic Bacteriology* (1988).

TABLE BXII.δ.16. Morphological and physiological characteristics of all described species of the genus *Desulfobacterium*[a]

Species	*Desulfobacterium autotrophicum*	*Desulfobacterium niacini*	*Desulfobacterium vacuolatum*
Morphology	Oval-shaped	Oval to irregular-shaped	Oval-shaped or spherical
Cell size (μm)	0.9–1.3 × 1.5–3	1.5–3	1.5–2 × 2–2.5

[b]Autotrophic growth.

noheterotrophically with long chain fatty acids, but are not able to grow with homocyclic aromatic compounds. *Desulfosarcina* and *Desulfococcus* strains can also use long chain fatty acids, but differ morphologically from *Desulfobacterium* species. Unambiguous differentiation requires 16S rDNA sequence analysis and DNA–DNA hybridization.

Taxonomic Comments

Based on 16S rRNA gene sequence data, all members of the genus *Desulfobacterium* form one cluster within the *Deltaproteobacteria* and cluster with members of the family *Desulfobacteraceae*. The closest relatives of *Desulfobacterium* species are members of the genera *Desulfobacter* and *Desulfobacula*. A signature sequence for all described *Desulfobacterium* species and other closely related sulfate-reducing bacteria is 5′-TGCGCGGACTCATCTTCAAA-3′ (oligonucleotide probe 221), which binds to the 16S rRNA at *E. coli* position 5′-221–240-3′ (Devereux et al., 1992; Manz et al., 1998).

The following organisms are no longer included in the genus, because 16S rDNA sequence analysis performed after the original description revealed the need for reclassification as members of other genera or new genera: *Desulfobacterium anilini* (new genus within the *Desulfobacteraceae*), *Desulfobacterium catecholicum* (new genus within the *Desulfobulbaceae*), *Desulfobacterium cetonicum* (see

genus *Desulfosarcina*), *Desulfobacterium indolicum* (new genus within the *Desulfobacteraceae*), *Desulfobacterium macestii* (see genus *Desulfomicrobium*), *"Desulfobacterium oleovorans"* (new genus), and *Desulfobacterium phenolicum* (see genus *Desulfobacula*).

De.sul.fo.ba'cu.la. L. pref. *de* from; L. n. *sulfur* sulfur; L. n. dem. *bacula* of baca, berry, olive-like fruit; *Desulfobacula* sulfate-reducing small berry.

Oval to sometimes coccoid or slightly curved cells, 1.2–1.5 × 1.2–3.0 μm. Occur singly or in pairs. Spore formation is not observed. Gram negative. Motility may occur. Strict anaerobes with a respiratory type of metabolism. **Chemoorganotrophs**, using toluene, other aromatic compounds, and a number of low-molecular mass aliphatic acids and alcohols **as electron donors and also as carbon sources**; these compounds are completely oxidized to CO_2 via the anaerobic C_1 pathway (carbon monoxide dehydrogenase [CO-DH] pathway, Wood pathway) as indicated by CO-DH activity. **Sulfate and other oxidized sulfur compounds serve as terminal electron acceptors and are reduced to H_2S.** Optimal growth temperature, 28°C. Anoxic media (with sulfide as a reductant) containing NaCl, $MgCl_2$, and vitamins are necessary for growth of the type species. Colonies in anoxic agar media are ochre to yellowish brown. Occur in anoxic marine sediments that are rich in organic compounds.

The mol% G + C of the DNA is: 41–42.

Type species: **Desulfobacula toluolica** Rabus, Nordhaus, Ludwig and Widdel 2000b, 1415 (Effective publication: Rabus, Nordhaus, Ludwig and Widdel 1993, 1450.)

Further descriptive information

The type strain of *D. toluolica* has oval-to-coccoid cells, which may be motile and stain Gram negative. The cells occasionally adhere to glass surfaces and are surrounded by slime capsules. In contrast, cells of *D. phenolica* are more curved and have a subpolar flagellum.

The type species has an optimal growth temperature of 28°C. The pH optimal for growth is between 7.0 and 7.1.

Desulfobacula reduces sulfate; other electron acceptors have not been tested. *D. phenolica* can also reduce thiosulfate, whereas sulfite, elemental sulfur, and nitrate cannot serve as electron acceptors. Butyrate, pyruvate, dicarboxylic acids, alcohols, and aromatic compounds including toluene serve as electron donors and organic carbon sources. *D. phenolica* can grow on toluene (Rabus et al., 1993). All organic substrates are completely oxidized to CO_2 via the anaerobic C_1 pathway (carbon monoxide dehydrogenase pathway, Wood pathway) (Rabus et al., 1993). The major menaquinone in the type strain of *D. phenolica* is MK-7(H_2) (Collins and Widdel, 1986). Major cellular fatty acids of *Desulfobacula* strains are $C_{16:0}$, $C_{16:1\ \omega7c}$, and $C_{16:0\ 10CH_3}$ (Kuever et al., 2001). Desulfoviridin is not present.

Desulfobacula species occur in anoxic marine sediments rich in organic material.

Desulfobacula species may be cultured in a defined medium with sulfate as electron acceptor and toluene or benzoate as the electron donor and carbon source. Both described species are dependent on an increased salt concentration; best growth is obtained with 20 g NaCl and 3 g $MgCl_2 \cdot 6H_2O$ per liter. Ammonium ions are used as the nitrogen source. The type strain of *D. toluolica* requires vitamins.

Enrichment and Isolation Procedures

For the selective enrichment of *Desulfobacula*, the same marine sulfate medium described for the isolation of *Desulfobacter* spp. may be used. For *D. toluolica*, the anoxic medium is overlaid with mineral oil or 2,2,4,4,6,8,8-heptamethynonane as carrier phase containing 2–5% (v/v) toluene (higher concentrations might be toxic). For *D. phenolica*, the medium is supplemented with 2 mM phenol.

Bottles or tubes (100-, 50-, or 20-ml capacity) can serve as culture vessels and are kept anoxic with tight screw caps (if completely filled), or by providing an anoxic head space of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated (2–5% of the total volume) with dark anoxic sediment. Enrichment cultures are incubated at 28–30°C. Cultures should be briefly mixed once a week. After intense formation of H_2S has occurred (approximately 8 weeks), transfers to fresh media are made. Enrichment cultures should be mixed well before subculturing.

Pure cultures of *Desulfobacula* species are obtained by repeated application of the agar dilution method. The method is similar to that described for the genus *Desulfobacter*. The same organic substrates as in the enrichment cultures may be used in agar medium; in the case of *D. toluolica*, the agar is overlaid with toluene in the carrier phase. Cells developing next to the toluene-containing carrier phase are largest in size. Alternatively, benzoate (2–3 mM) may be added as a soluble, almost non-toxic substrate to the agar for both species.

Maintenance Procedures

Stock cultures are transferred every 3–5 months. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 2–5°C in the dark. *Desulfobacula* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen.

Differentiation of the genus *Desulfobacula* from other genera

The ability to readily utilize toluene and phenol distinguishes *D. toluolica* and *D. phenolica* from most sulfate-reducing bacteria. However, a definite differentiation requires comparative 16S rDNA sequence analysis and DNA–DNA hybridization.

Taxonomic Comments

Based on 16S rRNA gene sequence data, *Desulfobacula* species cluster with members of the family *Desulfobacteraceae*. The closest relatives of members of the genus *Desulfobacula* are *Desulfospira joergensenii*, *Desulfotignum balticum*, and members of the genus *Desulfobacter*. A signature sequence for all described *Desulfobacula* species, *Desulfobacter* species, and other closely related sulfate-reducing bacteria is 5′-CACAGGATGTCAAACCCAG-3′ (oligonucleotide probe DSB985), which binds to the 16S rRNA at *E. coli* position 5′-985–1004-3′ (Devereux et al., 1992; Manz et al., 1998).

List of species of the genus Desulfobacula

1. **Desulfobacula toluolica** Rabus, Nordhaus, Ludwig and Widdel 2000b, 1415[VP] (Effective publication: Rabus, Nordhaus, Ludwig and Widdel 1993, 1450.)
tol.u.o′li.ca. L. adj. *toluolica* pertaining to toluene.

Characteristics are described in Table BXII.δ.17. Occurs in anoxic marine sediments that are rich in organic compounds. Isolated with toluene as the sole electron donor and carbon source.

The mol% G + C of the DNA is: 42 (T_m).

Type strain: Tol2, DSM 7467.

GenBank accession number (16S rRNA): X70953, AJ237606.

2. **Desulfobacula phenolica** (Bak and Widdel 1988) Kuever, Könneke, Galushko and Drzyzga 2001, 176[VP] (*Desulfobacterium phenolicum* Bak and Widdel 1988, 136.)
phe.no′li.ca. L. adj. *phenolica* pertaining to phenol.

Characteristics are described in Table BXII.δ.17. Occurs in anoxic marine sediments that are rich in organic compounds. The type strain was isolated from marine mud (Venice, Italy) using phenol. It shows rapid growth on benzoate and glutarate. Pleomorphism may be observed, depending on the growth substrate.

The mol% G + C of the DNA is: 40.6 (T_m).

Type strain: Ph01, ATCC 43956, DSM 3384.

GenBank accession number (16S rRNA): AJ237606.

Genus IV. **Desulfobotulus** *gen. nov.*

JAN KUEVER, FRED A. RAINEY AND FRIEDRICH WIDDEL

De.sul.fo.bo'tu.lus. L pref. *de* from; L. n. *sulfur* sulfur; M.L. masc. n. *botulus* sausage; M.L. masc. n. *Desulfobotulus* a sausage-shaped sulfate reducer.

Vibrio-shaped cells, 1.5 × 3–5.5 μm. Occur singly or in pairs. Sigmoid or spirilloid cells sometimes occur. Spore formation is not observed. Gram negative. The type species is motile. Strict anaerobe with a respiratory type of metabolism. **Chemoorganotrophic**, using butyrate, 2-methylbutyrate, higher fatty acids up to 18 carbon atoms, lactate, and pyruvate as electron donors and as carbon sources; **carbon sources are incompletely oxidized to acetate as an end product. Sulfate and sulfite serve as terminal electron acceptors and are reduced to H_2S. Thiosulfate, sulfur, fumarate, and nitrate are not used as terminal electron acceptors. Growth in the absence of an external electron acceptor is only possible with pyruvate.** Optimal temperature, 34°C. Anoxic medium, with sulfide as a reductant, is necessary for growth. Vitamins are not required. Cells contain cytochromes of the *b*- and *c*-type. Storage granules of poly-β-hydroxybutyrate occur. *Desulfobotulus* species are widespread in freshwater mud, but might occur in brackish or marine sediments as well.

The mol% G + C of the DNA is: 53.

Type species: **Desulfobotulus sapovorans** *comb. nov.* (*Desulfovibrio sapovorans* Widdel 1981, 382.)

FURTHER DESCRIPTIVE INFORMATION

The type strain of *D. sapovorans* has large vibrio-shaped cells under all growth conditions (Fig. BXII.δ.24). The cells are motile and stain Gram negative. The flagellum is sheathed. Sigmoid or spirilloid cells sometimes occur. The temperature range for growth is 15–38°C. The type strain has an optimal growth temperature of 34°C. The pH range for growth is 6.5–9.3, with an optimal pH of 7.7.

Desulfobotulus sapovorans, the only species of the genus described so far, is one of the relatively few members of the *Desulfobacteraceae* that cannot perform a complete oxidation of organic compounds, but rather form acetate as an end product. Fatty acids with an odd number of C-atoms are oxidized to acetate and propionate, in accordance with a β-oxidation pathway. A striking, although not unique, feature is the utilization of long-chain fatty acids. Good growth occurs with fatty acids up to 16 C-atoms (palmitate), whereas stearate (18 C-atoms) is utilized very slowly. H_2, formate, propionate, isobutyrate, 3-methylbutyrate (isovalerate), cyclohexanecarboxylate, succinate, fumarate, monovalent alcohols, and sugars are not utilized. *D. sapovorans* reduces only sulfate and sulfite to H_2S. Thiosulfate, elemental sulfur, fumarate, nitrate, and oxygen cannot serve as electron acceptors.

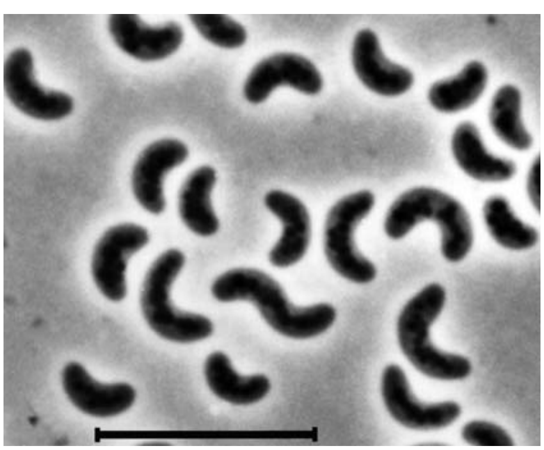

FIGURE BXII.δ.24. Phase-contrast micrograph of *Desulfobotulus sapovorans* with granules of poly-β-hydroxyalkanoic acid (viable cells). Bar = 10 μm.

The membrane fraction and cytoplasmic fraction contain *b*- and *c*-type cytochromes, the former being extractable with acetone plus HCl. Desulfoviridin is not present. The major menaquinone is MK-7 (Collins and Widdel, 1986). Major cellular fatty acids of the *Desulfobotulus* strains are $C_{15:0\ anteiso}$, $C_{16:1\ \omega7c}$, $C_{18:1\ \omega9c}$, and $C_{18:1\ \omega7c}$ (Vainshtein et al., 1992; Kohring et al., 1994).

Desulfobotulus strains occur in anoxic mud of freshwater environments. Enrichment can be accomplished with palmitate (see below). However enrichment is not highly specific.

Strains of *Desulfobotulus* may be cultured in a defined medium with sulfate as electron acceptor and fatty acids as the electron donors and carbon sources. Growth requires anoxic mineral media; sulfide is usually added as reductant. Vitamins are not required. Ammonium ions are used as the nitrogen source.

ENRICHMENT AND ISOLATION PROCEDURES

For the enrichment of *Desulfobotulus* strains, palmitate-sulfate medium[1] may be used. However, a highly selective medium for *D. sapovorans* has not been reported. Palmitate may also support growth of other sulfate-reducing bacteria, which may also have vibrio-shaped cells (but often smaller than *D. sapovorans*); oxidation of palmitate by such bacteria is usually also incomplete.

Bottles or tubes (100-, 50-, or 20-ml) can serve as culture vessels and are kept anoxic with tight screw caps (if completely filled), or by providing an anoxic head space of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated (2–5% of the total volume) with dark anoxic sediment or sludge from sewage digesters. Enrichment cultures are incubated at 34–37°C. Cultures should be briefly mixed every day. After intense formation of H_2S has occurred, transfers to fresh medium are made. Enrichment cultures should be mixed well before subculturing. Pure cultures of *Desulfobotulus* strains are obtained by repeated application of the agar dilution method (as described for *Desulfobacter* in this edition of the *Manual*). In the agar cultures, the insoluble fatty acid palmitate should be replaced by the butyrate–caproate–caprylate mixture (see footnote).

1. For cultivation of *D. sapovorans*, the mineral medium described in the *Desulfobacter* section (this *Manual*) is first prepared without NaCl and $MgCl_2$. The sodium salt of palmitic acid is added from a stock solution (26 g/l of palmitic acid plus 4 g/l NaOH, heated in a boiling water bath until the solution is clear; sterilized by autoclaving. The solutions must be remelted by heating before use; prewarmed pipettes should be used to take aliquots). Added volumes per liter of medium: 10–20 ml palmitate solution, followed by 1.0 ml of $MgCl_2$ solution (400 g/l $MgCl_2 \cdot 6H_2O$) and 4.0 ml of NaCl solution (300 g/l). Pure cultures can be alternatively grown on soluble monocarboxylic acids. For instance, 5–10 ml of a butyrate–caproate–caprylate mixture (containing per liter: 6.0, 2.5, and 1.0 g, respectively, of acids neutralized with NaOH) may be added per liter of medium.

Maintenance Procedures

Stock cultures are transferred every 3–5 months. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 2–5°C in the dark. *Desulfobotulus* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen.

Differentiation of the genus *Desulfobotulus* from other genera

Together with members of the genera *Desulfocella* and *Desulfarculus*, *Desulfobotulus* strains can be distinguished by their vibrio-shaped cells from other sulfate-reducing bacteria (except *Desulfocella*, *Desulfarculus*, and some unnamed types) that are able to grow on long-chain fatty acids. *Desulfarculus* strains perform complete substrate oxidation and autotrophic growth on formate, whereas members of the genera *Desulfocella* and *Desulfobotulus* oxidize substrates only incompletely to acetate and are not capable of autotrophic growth. The mol% G + C content of DNA from *Desulfocella halophila* is much lower than from *D. sapovorans* (35 vs. 53). However, a definite differentiation requires comparative 16S rDNA sequence analysis and DNA–DNA hybridization.

Taxonomic Comments

Based on 16S rRNA gene sequence data, *D. sapovorans* clusters with members of the family *Desulfobacteraceae*. The closest relatives of *D. sapovorans* are *Desulfocella halophila* and *Desulfococcus* species. A signature sequence for *D. sapovorans* is 5′-GGGACGCGGACT-CATCCTC-3′ (oligonucleotide probe DSBO 224), which binds to the 16S rRNA at *E. coli* position 5′-224–240-3′ (Manz et al., 1998).

List of species of the genus Desulfobotulus

1. **Desulfobotulus sapovorans** *comb. nov.* (*Desulfovibrio sapovorans* Widdel 1981, 382[VP])
sa.po′vo.rans. L. n. *sapo* soap; L. *voro* to devour; M.L. part. adj. *sapovorans* devouring soap (i.e., higher fatty acids).

The morphology is as depicted in Fig. BXII.δ.24. The characteristics are as described for the genus.

The mol% G + C of the DNA is: 53 (T_m).

Type strain: 1pa3, Lindhorst, ATCC 33892, DSM 2055.

GenBank accession number (16S rRNA): M34402.

Genus V. Desulfocella *Brandt, Patel and Ingvorsen 1999, 198[VP]*

Kristian K. Brandt, Kjeld Ingvorsen and Bharat K.C. Patel

De.sul.fo.cel′la. L. pref. *de* from; L. n. *sulfur* sulfur; L. n. *cella* small room, cell; M.L. fem. n. *Desulfocella* sulfate-reducing cell.

Vibrio-shaped cells, 0.5–0.7 × 2–4 μm. Motile by means of a single polar flagellum. Gram negative. Do not form spores. **Anaerobic, having a respiratory type of metabolism with sulfate as the terminal electron acceptor and producing H_2S. Chemoorganotrophic. A range of fatty acids (C_4–C_{16}) serve as electron donors and are incompletely oxidized. No fermentative growth.** Mesophilic. Neutrophilic. **NaCl is required for growth.** Vitamins are not required, but growth is stimulated by yeast extract. The genus belongs to the family *Desulfobacteraceae* within the *Deltaproteobacteria*. Isolated from hypersaline, thalassohaline sediments of the Great Salt Lake (Utah, USA).

The mol% G + C of the DNA is: 35.

Type species: **Desulfocella halophila** Brandt, Patel and Ingvorsen 1999, 199.

Further descriptive information

Desulfocella halophila strain GSL-But2 is capable of growth in a defined medium containing up to ~20% (w/v) NaCl and 620 mM Mg^{2+}. It may thus be active in its natural habitat, which has an *in situ* salinity of approximately 13% NaCl and 185 mM Mg^{2+}. However, like all other sulfate reducers described from hypersaline environments, it exhibits a salinity optimal for growth significantly below the *in situ* salinity of the environment from which it was isolated. Recently, direct evidence for the presence of slightly to moderately halophilic and extremely halotolerant, sulfate-reducing bacteria was obtained from a study of Great Salt Lake sediments (Brandt et al., 2001). *Desulfocella halophila* strain GSL-But2 so far represents the only described sulfate reducer isolated from a hypersaline environment that is able to grow by oxidation of butyrate and long-chain fatty acids. Long-chain fatty acids are abundant in cell membranes, and butyrate is an important fermentation product during anaerobic breakdown of organic matter. *Desulfocella halophila* and similar organisms might thus occupy important niches within the anaerobic degrader community in hypersaline sediments. In a recent study, addition of butyrate to Great Salt Lake sediments was found to significantly stimulate bacterial sulfate reduction activity (Brandt et al., 2001).

Enrichment and Isolation Procedures

Desulfocella halophila strain GSL-But2 was isolated from hypersaline surface sediment collected from the deepest part of the southern arm of the Great Salt Lake (Station AS2, Utah Geological Survey station code). Enrichment was performed in anaerobic, bicarbonate-buffered, dithionite-reduced liquid medium containing 10% (w/v) NaCl, with a mixture of volatile fatty acids (acetate, propionate, and butyrate) as electron donors and sulfate as electron acceptor. After 4 weeks, the enrichment culture contained cells of different morphologies and showed high sulfide production. The enrichment culture was subsequently transferred (5% v/v) to a similar medium with butyrate as the sole electron donor. After 2–3 transfers in butyrate medium, strain GSL-But2 was isolated using the deep agar dilution technique (Widdel and Bak, 1992).

Differentiation of the genus *Desulfocella* from other genera

Desulfocella halophila strain GSL-But2 is the only known truly halophilic and halotolerant sulfate reducer able to grow with butyrate and long-chain fatty acids (C_4–C_{16}) as electron donors. With the exception of *Desulfobotulus sapovorans* and *Desulforegula conservatrix* (Rees and Patel, 2001), *Desulfocella halophila* strain GSL-But2 can also be differentiated from all known mesophilic dissimilatory sulfate-reducing bacteria by its ability to incompletely oxidize long-chain fatty acids (C_4–C_{16}), with acetate as the major degradation product.

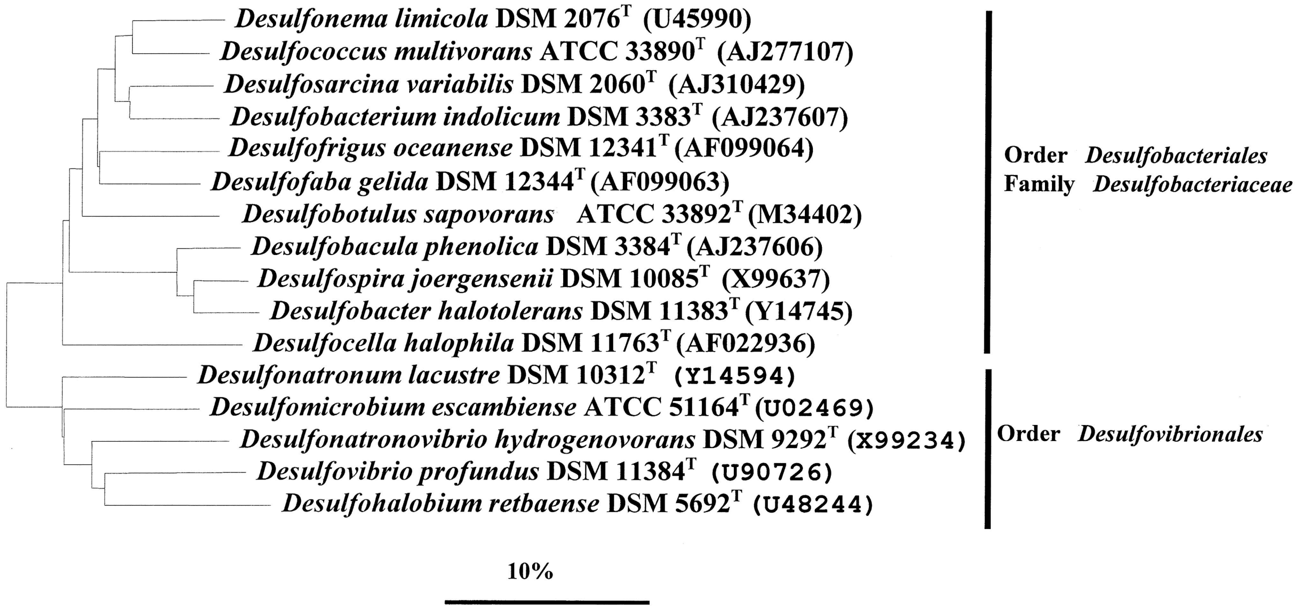

FIGURE BXII.δ.25. Dendrogram showing the phylogenetic position of *Desulfocella halophila* strain GSL-But2^T amongst members of the family *Desulfobacteraceae* in the order *Desulfobacterales* of the class *Deltaproteobacteria* of the phylum *Proteobacteria*. The strains used in the analysis, their culture collection numbers, and corresponding 16S rRNA gene sequences which were extracted from GenBank/EMBL (in parenthesis) are shown. Phylogenetic analysis was performed on 1130 unambiguous nucleotides using dnadist and neighbor-joining programs which form part of the PHYLIP suite of software. Bar indicates 10 nucleotide changes per 100 nucleotides. The following abbreviations have been used: T, type culture; ATCC, American Type Culture Collection; DSM, Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH.

Taxonomic Comments

Genetically, *Desulfocella halophila* differs from all known described organisms by virtue of its unique 16S rDNA sequence (Fig. BXII.δ.25), showing 87.5% similarity to its closest known relatives, and by its low DNA mol% G + C content of 35.

List of species of the genus Desulfocella

1. **Desulfocella halophila** Brandt, Patel and Ingvorsen 1999, 199^{VP}

ha.lo'phi.la. Gr. n. *hals* salt; Gr. adj. *philos* friendly to; M.L. fem. adj. *halophila* salt-loving.

The characteristics are as described for the genus, with the following additional features. Does not reduce thiosulfate, sulfite, S^0, ferric iron, nitrate, or fumarate. The following compounds are used as electron donors: pyruvate, L-alanine, 2-methylbutyrate, and many straight-chain saturated fatty acids with 4–16 carbons. Lactate is not utilized. Does not grow by fermentation of pyruvate, L-alanine, or butyrate when sulfate is absent.

Temperature range for growth, 14–37°C; optimal, ~34°C. Optimal salinity 4–5% NaCl; halotolerance 2–20% NaCl. Optimal growth occurs in the presence of 2–100 mM Mg^{2+}; growth occurs at up to 620 mM Mg^{2+}. pH Range for growth, 5.8–7.6; optimal, 6.5–7.3. Isolated from hypersaline, thalassohaline sediment of the Great Salt Lake (Utah, USA).

The mol% G + C of the DNA is: 35 (HPLC).

Type strain: GSL-But2, ATCC 700426, DSM 11763.

GenBank accession number (16S rRNA): AF022936.

Genus VI. **Desulfococcus** *Widdel 1981, 382^{VP} (Effective publication: Widdel 1980, 376)*

Jan Kuever, Fred A. Rainey and Friedrich Widdel

De.sul.fo.coc'cus. L. pref. *de* from L. n. *sulfur* sulfur; M.L. masc. n. *coccus* equivalent of Gr. masc. n. *kokkos* grain, berry; M.L. masc. n. *Desulfococcus* a berry shaped (spherical) sulfate-reducer.

Cells are spherical or lemon-shaped, 1.4–2.3 µm in diameter. Occur singly or in pairs. Spore formation is not observed. Cells stain Gram negative and often contain granules of poly-β-hydroxybutyrate. The cells are motile by a single polar flagellum, or are nonmotile. Slime capsules may occur. Strict anaerobes with a respiratory and fermentative type of metabolism. Nutritionally versatile. **Many species use formate and higher monocarboxylic acids up to C_{16}, lactate, pyruvate, and alcohols as electron donors and as carbon sources.** Acetone and phenyl-substituted organic acids may be utilized. These compounds are completely oxidized to CO_2 via the anaerobic C_1 pathway (carbon monoxide dehydrogenase pathway, Wood pathway). **Sulfate and other oxidized sulfur compounds serve as terminal electron acceptors and are reduced to H_2S.** In the absence of an external electron acceptor, slow growth occurs by fermentation of lactate or pyruvate to acetate and propionate. The optimal temperature range for growth is 28–35°C. The optimal pH range for growth is 6.7–7.6. Growth occurs in simple, defined media containing a re-

ductant (usually sulfide) and vitamins. Colonies in anoxic agar media are whitish to yellowish (with sometimes grayish appearance) and tend to be slimy. Desulfoviridin is present in all species. Thermophilic species have not been described. Occur in anoxic mud of freshwater, brackish water, and marine habitats; also occur in sludge of anaerobic sewage digestors.

The mol% G + C of the DNA is: 56–57.

Type species: **Desulfococcus multivorans** Widdel 1981, 382 (Effective publication: Widdel 1980, 377.)

Further descriptive information

The type strain of *D. multivorans* has spherical cells under all growth conditions (Fig. BXII.δ.26). Cells of other strains may sometimes be irregular. The type strain stains Gram negative, but a morphologically and nutritionally similar strain that stains Gram positive has been described; nevertheless, cells of this strain exhibited an ultrastructure characteristic of Gram-negative bacteria.

The type strain of *D. multivorans* is nonmotile, but cells from other strains and from enrichment cultures may exhibit a slow motility.

The optimal growth temperature for the type strain of *D. multivorans* is 35°C. Slow growth has been observed at 15°C.

D. multivorans reduces sulfate, sulfite, or thiosulfate to H_2S. Elemental sulfur, fumarate, malate, and nitrate cannot serve as electron acceptors. The following compounds are utilized as electron donors and organic carbon sources: formate, acetate, propionate, butyrate, isobutyrate, valerate, 2-methylbutyrate, 3-methylbutyrate, higher fatty acids up to 16 carbon atoms, lactate, pyruvate, ethanol, 1-propanol, and 1-butanol. Growth also occurs with aromatic compounds such as benzoate, phenylacetate, 3-phenylpropionate, 2-hydroxybenzoate, and with cyclohexanecarboxylate. All organic substrates are completely oxidized to CO_2 via the anaerobic C_1 pathway (carbon monoxide dehydrogenase pathway, Wood pathway) (Schauder et al., 1986). Growth on formate requires no additional organic carbon source.

In the absence of an external electron acceptor, slow growth is possible with pyruvate or lactate, which are fermented to acetate and propionate. Sugars are not fermented.

Cytochromes of the *b* and *c* type were shown to be present mainly in the membrane fraction. The sulfite reductase desulfoviridin has been identified in the cytoplasm of *D. multivorans.* The major menaquinone is MK-7 (Collins and Widdel, 1986).

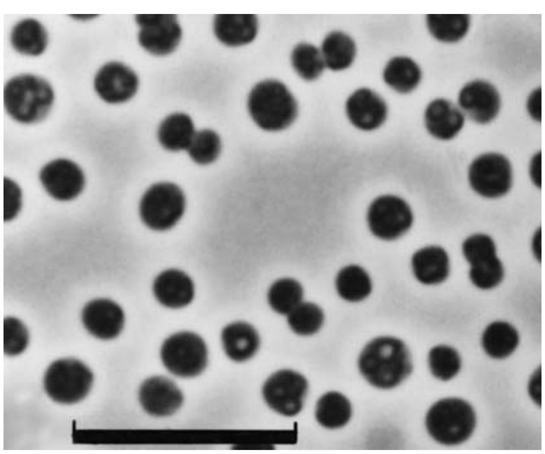

FIGURE BXII.δ.26. Phase-contrast micrograph of *Desulfococcus multivorans* viable cells, with granules of poly-β-hydroxyalkanoic acid. Bar = 10 μm.

Major cellular fatty acids of the *Desulfococcus* strains are $C_{15:0\ anteiso}$, $C_{16:0}$, and $C_{17:1\ anteiso\ \omega 8c}$ (Kohring et al., 1994).

Strains of *Desulfococcus* may be cultured in a defined medium[1] with sulfate as electron acceptor and benzoate or another carbon compound as the electron donor and carbon source. The best growth is obtained with 5–20 g/l NaCl and 1–3 g/l $MgCl_2{\cdot}6H_2O$, although growth also occurs with lower concentrations of these salts. Ammonium ions are used as the nitrogen source. When *D. multivorans* is cultured on benzoate or phenyl-substituted fatty acids, selenite and molybdate are required as trace compounds. Growth on benzoate is stimulated by low levels of fatty acids, especially those having an odd number of carbon atoms; with such supplementation the doubling time on benzoate is around 24 h. *p*-Aminobenzoate, biotin, and thiamin are required as growth factors. Sulfide may serve as a reductant. When inoculation is done from old cultures, initiation of growth is favored by the addition of 10–30 mg of sodium dithionite per liter of medium as a further strong reductant.

Enrichment and Isolation Procedures

For the selective enrichment of *Desulfococcus multivorans* strains, the sulfate medium described for *Desulfobacter* (see *Desulfobacter* section), but with the addition of benzoate (2–3 mM) as electron donor and carbon source, may be used. For *D. biacutus* acetone should be used instead of benzoate.

Bottles or tubes (100-, 50-, or 20-ml) can serve as culture vessels and are kept anoxic with tight screw caps (if completely filled), or by providing an anoxic head space of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated (2–5% of the total volume) with dark anoxic mud from ditches, brackish water, or marine habitats, or with sludge from anaerobic sewage digesters. Enrichment cultures are incubated at 30–35°C. Cultures should be briefly mixed every day. After intense formation of H_2S has occurred (generally after 2–4 weeks), transfers to fresh medium are made. Enrichment cultures should be mixed well before subculturing.

Pure cultures of *Desulfococcus* strains are obtained by repeated application of the agar dilution method (as described for *Desulfobacter* in this edition of the *Manual*).

Maintenance Procedures

Stock cultures are transferred every 3–5 months. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 2–5°C in the dark. *Desulfococcus* strains may be preserved indefinitely by suspending the cells in anaerobic medium containing 5% dimethylsulfoxide and storing in liquid nitrogen.

Differentiation of the genus *Desulfococcus* from other genera

Typical phenotypic characteristics of *Desulfococcus* species are spherical or lemon-shaped cells and the ability to grow well with

1. The defined medium is prepared as described in the *Desulfobacter* section (this *Manual*), with the following additions (g/l): NaCl, 7.0; $MgCl_2{\cdot}6H_2O$, 1.2. After autoclaving, the following components are added aseptically from sterile stock solutions (per liter of medium): sodium benzoate solution (150 g/l), 5.0 ml; vitamin solution (*p*-aminobenzoate, 40 mg/l; biotin, 10 mg/l; thiamine hydrochloride, 100 mg/l; solution sterilized by filtration), 1.0 ml; sodium selenite solution ($Na_2SeO_3{\cdot}5H_2O$, 3 mg/l; NaOH, 0.5 g/l), 1.0 ml. The pH of the medium is adjusted to 7.2–7.4. For stimulation of growth on benzoate, 50–200 μM *n*-valerate (or a mixture of propionate, *n*-butyrate, isobutyrate, *n*-valerate, 2-methylbutyrate, 3-methylbutyrate and *n*-caproate; approximately 50 μM each) may be added from a sterile stock solution.

benzoate, other phenyl-substituted fatty acids, or acetone as electron donors for sulfate reduction. However, these properties are insufficient for unequivocal taxonomic assignment. Several oval-shaped sulfate-reducing bacteria may also occasionally form spherical cells, and the number of isolates with oval cells that grow on aromatic compounds has been increasing. *Desulfosarcina*, the sulfate-reducing bacterium with the highest phenotypic and phylogenetic similarity to *Desulfococcus* species, also utilizes benzoate and tends to form free-living spherical cells; however, unlike *Desulfococcus*, *Desulfosarcina* also forms cell aggregates, which are especially favored in colonies growing on agar media. A clear differentiation of *Desulfococcus* from other species is only possible by analysis of 16S rRNA genes and DNA–DNA hybridization.

Taxonomic Comments

Based on 16S rRNA gene sequence data, members of the genus *Desulfococcus* cluster with other members of the family *Desulfobacteraceae*. The closest relatives are *Desulfosarcina variabilis*, *Desulfonema magnum*, *Desulfonema limicola*, and *Desulfonema ishimotonii*. A signature sequence for all described *Desulfococcus* species is 5′-CCCAAACGGTAGCTTCCT-3′ (oligonucleotide probe DCC209), which binds to the 16S rRNA corresponding to *E. coli* position 5′-209–226-3′ (Ravenschlag et al., 2000).

Cells are large rods, 3.1 × 5.4–6.2 μm, which form aggregates. Motile cells may occur in old cultures. Cells stain Gram negative and do not form spores. Strict anaerobe with a respiratory and fermentative type of metabolism. Chemoorganotroph, using formate, propionate, butyrate, lactate, pyruvate, other organic acids, alcohols, and alanine as electron donors and also as carbon sources; organic compounds are incompletely oxidized to acetate and CO_2. Sulfate, thiosulfate, and sulfite serve as terminal electron acceptors and are reduced to sulfide. Fermentative growth on pyruvate or other carbon substrates is possible. Obligately psychrophilic. The temperature optimal for growth is 7°C; growth still occurs at −1.8°C. The optimal pH for growth is between 7.1 and 7.6. Mesophilic and thermophilic species are not known. Sodium chloride and magnesium chloride are required, and optimal growth occurs at marine concentrations of these salts. Anoxic media containing a reductant (usually sulfide) are necessary for growth. Vitamins are not required. Desulfoviridin is absent. Occur in permanently cold marine sediments.

The mol% G + C of the DNA is: 52.5.

Type species: **Desulfofaba gelida** Knoblauch, Sahm and Jørgensen 1999, 1641.

Further descriptive information

Desulfofaba gelida, the only known species of the genus, is one of the first obligately psychrophilic sulfate-reducing bacteria that has been described (Knoblauch et al., 1999). *D. gelida* is nutritionally relatively versatile. Formate, propionate, butyrate, lactate, pyruvate, malate, succinate, fumarate, ethanol, 1-propanol, 1-butanol, glycerol, glycine, and alanine serve as carbon sources and electron donors. No growth on fructose and glucose. As electron acceptor *D. gelida* uses sulfate, thiosulfate, and sulfite, which are reduced to sulfide. Elemental sulfur, nitrate, nitrite, Fe(III)-oxyhydroxide, and Fe(III)-citrate are not reduced. Fermentative growth occurs on pyruvate and fumarate. Sulfur and thiosulfate are not disproportionated.

Cells contain phosphatidylethanolamine and phosphatidylglycerol as lipids; MK-8 is the sole menaquinone. Major cellular fatty acids are odd numbered and unbranched, $C_{15:0}$ and $C_{15:1\ \omega6c}$. The only described species contains no desulfoviridin.

D. gelida is cultivated in defined, synthetic, marine medium (see chapter on *Desulfobacter*) with propionate or another organic substrate and sulfide as reductant.

Enrichment and Isolation Procedures

For specific enrichment, synthetic marine mineral medium reduced with sulfide should be used (see chapter on *Desulfobacter*). *D. gelida* may be especially enriched with propionate (5 mM) that is added from sterile stock solutions. Bottles or tubes (100-, 50-, or 20-ml) can serve as culture vessels and are kept anoxic with tight screw caps (if completely filled), or by providing an anoxic head space of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated (2–5% of the total volume) with dark anoxic sediment. *Desulfofaba* species may be also enriched and isolated via direct serial dilution of anoxic environmental samples in liquid medium (according to most-probable-number method) or agar medium (see next paragraph) with propionate as organic substrate. Enrichment cultures are incubated at 4°C. After intense formation of H_2S has occurred (~8–10 weeks), transfers to fresh medium are made. Enrichment cultures should be mixed well before subculturing. Pure cultures of *Desulfofaba* strains are obtained by repeated application of the agar dilution method (as described for *Desulfobacter* in this edition of the *Manual*, but modified after Isaksen and Teske, 1996).

Maintenance Procedures

Stock cultures are transferred every 6 weeks. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 2–5°C in the dark. *Desulfofaba* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen.

Differentiation of the genus *Desulfofaba* from other genera

Desulfofaba gelida can be phenotypically distinguished from other sulfate-reducing bacteria by physiological and morphological properties. Distinctive features are optimal growth at low temperature, large cells, and utilization of propionate. Apart from low growth temperature and large cells, incomplete substrate oxidation and the inability to grow on long-chain fatty acids or aromatic compounds allows differentiation from completely oxidizing members of the genera *Desulfococcus* and *Desulfosarcina*. In contrast to other incomplete oxidizers able to grow with propionate, like *Desulfobulbus* and *Desulforhopalus* strains, *Desulfofaba gelida* is able to grow on butyrate. However, a clear identification can only be done by comparative analysis of 16S rDNA sequences and DNA–DNA hybridization.

Taxonomic Comments

Based on 16S rRNA gene sequence data, *Desulfofaba gelida* clusters with other members of the family *Desulfobacteraceae*. The closest relatives of *D. gelida* are members of the genus *Desulfofrigus* and *Desulfosarcina variabilis*. A signature sequence for described *Desulfofaba* species and *Desulfofrigus* species is 5′-CCTCTACACA-CCTGGAATTCC-3′ (oligonucleotide probe DSf672), which binds to the 16S rRNA corresponding to *E. coli* position 5′-672–690-3′ (Ravenschlag et al., 2000).

1. **Desulfofaba gelida** Knoblauch, Sahm and Jørgensen 1999, 1641[VP]
ge′li.da. L. adj. *gelide* ice-cold; referring to the low temperature optimal for growth.

Characteristics are as indicated for the genus. Isolated from anoxic sediment from Hornsund (Svalbard) with propionate as electron donor and carbon source and sulfate as electron acceptor.

The mol% G + C of the DNA is: 52.5 (HPLC).

Type strain: PSv29, DSM 12344.

GenBank accession number (16S rRNA): AF099063.

Genus VIII. Desulfofrigus *Knoblauch, Sahm and Jørgensen 1999, 1640[VP]*

JAN KUEVER, FRED A. RAINEY AND FRIEDRICH WIDDEL

De.sul.fo.fri′gus. L. pref. *de* from; L. n. *sulfur* sulfur; L. neut. n. *frigus* cold; M.L. neut. n. *Desulfofrigus* sulfate reducer living in the cold.

Cells are large, straight or slightly curved rods, 0.8–2.1 × 3.2–6.1 µm. Motile cells may be observed in old cultures. Cells stain Gram negative and do not form spores. Strict anaerobe with a respiratory and fermentative type of metabolism. **Chemoorganotroph**, using fatty acids, other carboxylic acids including amino acids, and alcohols as electron donors and also as carbon sources. No growth on fructose and glucose. **Organic substrates completely oxidized to CO_2 or incompletely oxidized to acetate. Sulfate serves as terminal electron acceptor and is reduced to sulfide.** Ferric citrate may also serve as electron acceptor. The type strain can also use thiosulfate and sulfite as electron acceptor. Elemental sulfur, Fe (III)-oxohydroxide, nitrate, and nitrite are not used as electron acceptors. Fermentative growth on pyruvate, malate, or other carbon substrates is possible. Sulfur and thiosulfate are not disproportionated. Only the type species is obligately psychrophilic. The temperature optimal for growth is 10–18°C, but growth still occurs at −1.8°C. Thermophilic species are not known. The optimal pH for growth is between 7.0 and 7.5. *Desulfofrigus* species require sodium chloride and magnesium chloride, and optimal growth occurs at marine salt concentrations. Media containing a reductant are necessary for growth. Occur in permanently cold marine sediments.

The mol% G + C of the DNA is: 52–53.

Type species: **Desulfofrigus oceanense** Knoblauch, Sahm and Jørgensen 1999, 1640.

Further descriptive information

Desulfofrigus species were among sulfate-reducing bacteria isolated during a microbiological study of permanently cold, Arctic sediment. Special adaptation to conditions in such sediments are indicated by the ability to grow at −1.8°C, viz. near the freezing point of seawater. Whereas *D. oceanense* may be regarded as a true psychrophile, *D. fragile* is psychrotolerant and characterized by a relatively wide temperature range for growth, up to 27°C. In *D. oceanense*, the capacity for complete oxidation of organic substrates to CO_2 is evident from utilization of acetate as growth substrate. The mode of substrate oxidation (complete versus incomplete) in *D. fragile* has not been unequivocally proven. Acetate added to cultures is not utilized.

Cells contain the polar lipids phosphatidylethanolamine and phosphatidylglycerol, and MK-9 is the sole menaquinone. Major cellular fatty acids are $C_{16:1\ \omega7c}$ and $C_{18:1\ \omega7c}$. The only described species contains no desulfoviridin. Obligate or facultatively psychrophilic, although *Desulfofrigus fragile* can grow up to 27°C.

Desulfofrigus species are cultivated in defined synthetic marine media (see chapter on *Desulfobacter*) with lactate, acetate, or another organic substrate and sulfide as reductant.

Enrichment and Isolation Procedures

For specific enrichment, synthetic marine mineral medium reduced with sulfide should be used (see chapter on *Desulfobacter*). *Desulfofrigus* species may be especially enriched with lactate (10 mM) or acetate (10 mM) that is added from sterile stock solutions. Bottles or tubes (100-, 50-, or 20-ml) can serve as culture vessels and are kept anoxic with tight screw caps (if completely filled), or by providing an anoxic head space of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated (2–5% of the total volume) with dark anoxic sediment. *Desulfofrigus* species may also be enriched and isolated via direct serial dilution of anoxic environmental samples in liquid medium (according to most-probable-number method) or agar medium with lactate or acetate as organic substrates. Enrichment cultures are incubated at 4°C. After intense formation of H_2S has occurred (~8–10 weeks), transfers to fresh medium are made. Enrichment cultures should be mixed well before subculturing. Pure cultures of *Desulfofrigus* strains are obtained by repeated application of the agar dilution method (as described for *Desulfobacter* in this edition of the *Manual*).

Maintenance Procedures

Stock cultures are transferred every 6 weeks. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 2–5°C in the dark. *Desulfofrigus* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen.

Differentiation of the genus *Desulfofrigus* from other genera

Desulfofrigus species can be phenotypically distinguished from other sulfate-reducing bacteria by physiological properties. A distinctive feature is optimal growth at low temperature. The inability to grow with propionate is one characteristic that allows differentiation from other psychrophilic or mesophilic sulfate reducers, such as *Desulfobulbus*, *Desulfofaba*, and *Desulforhopalus* species. However, a clear identification can only be done by comparative analysis of 16S rDNA sequences and DNA–DNA hybridization.

Taxonomic Comments

Based on 16S rRNA gene sequence data, *Desulfofrigus* species cluster with other members of the family *Desulfobacteraceae*. The closest relatives of *Desulfofrigus* species are members of the genus *Desulfofaba* and *Desulfosarcina variabilis*. A signature sequence for

described *Desulfofaba* species and *Desulfofrigus* species is 5′-CCTCTACACACCTGGAATTCC-3′ (oligonucleotide probe DSf672), which binds to the 16S rRNA corresponding to *E. coli* position 5′-672–690-3′ (Ravenschlag et al., 2000).

Genus IX. Desulfonema *Widdel 1981, 382*[VP] *(Effective publication: Widdel 1980, 378)*

Jan Kuever, Fred A. Rainey and Friedrich Widdel

De.sul.fo.ne′ma. L. pref. *de* from; L. n. *sulfur* sulfur; L. n. *nema* thread; M.L. neut. n. *Desulfonema* thread-forming sulfate reducer.

Cells arranged in uniseriately multicellular, flexible filaments with gliding motility. Filaments are 2.5–8 μm in diameter and sometimes about 2 mm in length; the nearly cylindrical cells are 2.5–13 μm long. Cross-walls are visible (Figs. BXII.δ.27 and BXII.δ.28C). Granules of poly-β-hydroxyalkanoic acid are commonly stored. Filaments are always attached to surfaces that serve as substrata for gliding motility. Cell walls characteristic of Gram-negative bacteria have been revealed by electron microscopy of ultrathin sections, even though Gram stain may be positive in some instances (unequally stained). The outer membrane has a wavy structure. Strictly anaerobic, having a respiratory type of metabolism. **Chemoorganotrophs or chemoautotrophs**, using acetate and higher monocarboxylic acids up to C_{14}, fumarate, and succinate **as electron donors and carbon sources**. Lactate or benzoate may also serve as organic substrates. Organic substrates are completely oxidized to CO_2 via the anaerobic C_1 pathway (carbon monoxide dehydrogenase [CO-DH], Wood pathway) as indicated by CO-DH activity. For chemoautotrophic growth of

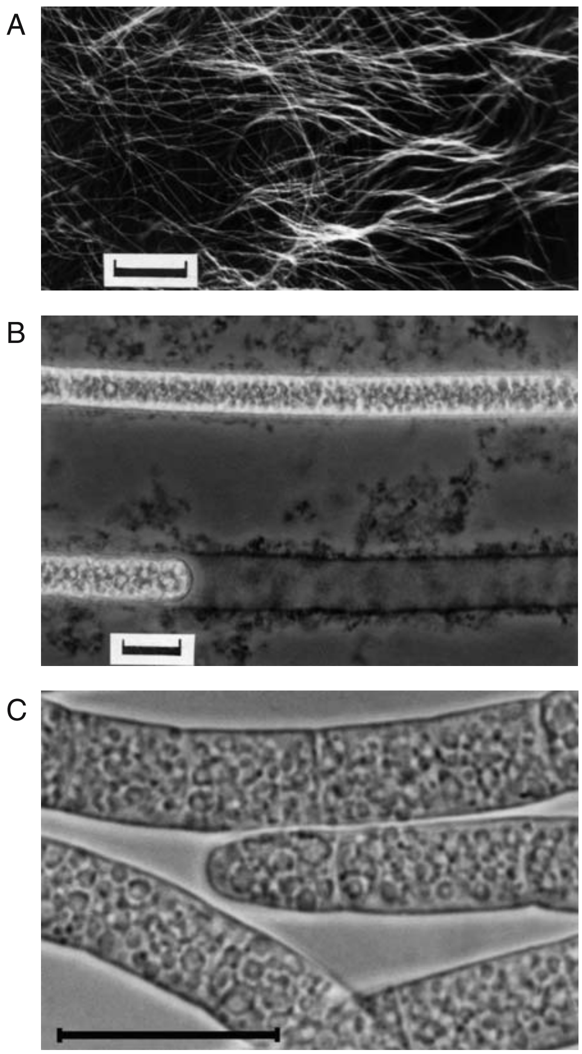

FIGURE BXII.δ.28. (*A*) *Desulfonema magnum*, layer of filaments at the wall of a culture bottle (viable cells). Bar = 1 mm. (*B*) Phase-contrast micrograph of *Desulfonema magnum* with granules of poly-β-hydroxyalkanoic acid; filaments glide in synthetic sediment of aluminum phosphate which makes slime trails visible (viable cells). Bar = 10 μm. (*C*) Phase-contrast micrograph of *Desulfonema magnum* with granules of poly-β-hydroxyalkanoic acid (viable cells). Bar = 10 μm.

some species, **H_2 can serve as the electron donor and CO_2 as the carbon source. Sulfate serves as terminal electron acceptor and is reduced to H_2S; sulfite and thiosulfate may or may not be used.** Elemental sulfur does not serve as electron acceptor but is inhibitory. **Growth does not occur by fermentation in the absence of an external electron acceptor.**

All species are able to grow in simple defined media containing a reductant. Vitamins are required for growth. The optimal pH range for growth is 7.0–7.6. The optimal temperature range for growth is 28–32°C. Thermophilic species are not known. The addition of >15 g NaCl and >2 g $MgCl_2 \cdot 6H_2O$ is required for growth. Gliding movement and growth are promoted by addition of insoluble substrata such as agar or inorganic precipitates. Desulfoviridin is present or absent. Cytochromes are present.

Occur in organic-compound-rich, anoxic sediments. Only marine species have been isolated so far. *Desulfonema* species also occur in freshwater habitats, but have never been obtained in pure culture.

The mol% G + C of the DNA is: 35–55.

Type species: **Desulfonema limicola** Widdel 1981, 382 (Effective publication: Widdel 1980, 379.)

Further descriptive information

The multicellular filaments of *Desulfonema* species are not sheathed; however, remnants of lysed cells within a filament can simulate a sheath. Filaments of *D. limicola* and *D. ishimotonii* do not glide regularly; the most conspicuous motility characteristic of this species is a slow twitching or jerky swinging of the filaments when they creep out of sediment particles. The gliding movement of *D. magnum* is more regular, and a speed of about 4 μm/s is reached. Gliding filaments reverse the direction of movement if they meet obstacles; a reversion of the gliding direction may also occur without obvious reason. Gliding filaments often form trails from sediment particles, probably by slime excretion.

The ultrastructure of *D. limicola* and *D. magnum* has been examined (Widdel et al., 1983). Ultrathin sections of both species exhibited intracytoplasmic membranes and a wavy outer membrane. The wavy structure was more regular in *D. magnum* than in *D. limicola*.

Desulfonema species are nutritionally versatile sulfate-reducing bacteria that oxidize a range of fatty acids and dicarboxylic acids; hydrogen, lactate, benzoate, or higher phenyl-substituted organic acids may also be oxidized. Sulfate is used as an external electron acceptor; alternatively sulfite or thiosulfate may be reduced. All organic substrates are completely oxidized to CO_2 via the anaerobic C_1 pathway (carbon monoxide dehydrogenase pathway, Wood pathway) (Fukui et al., 1999). Nitrate, fumarate, or malate do not serve as electron acceptors. Sugars, pyruvate, or fumarate are not fermented. Elemental sulfur inhibits growth, probably by increasing the redox potential. Filaments are damaged by oxygen.

Desulfonema species occur in anoxic sediments, especially those rich in decomposing algal material. In samples taken from such habitats, the filaments may be observed under the microscope without a preceding enrichment in the laboratory. Only marine, salt-requiring *Desulfonema* species have been isolated so far in pure culture. However, observation of morphologically similar, sometimes thinner filaments grown in anaerobic enrichments from pond and ditch sediments and application of 16S rRNA-targeted fluorescent probes (Fukui et al., 1999) suggest that freshwater forms may also occur.

Even though some organic acids (e.g., isobutyrate, benzoate) may promote growth of *Desulfonema* species in natural samples, none of the electron donors known to be oxidized by *Desulfonema* species allows a reliable selective enrichment. Since the filamentous, gliding, sulfate reducers grow relatively slowly (doubling

times around 14–30 h or longer), they are often outcompeted in enrichment cultures by unicellular sulfate reducers, after some transfers. A selective advantage of *Desulfonema* in nature is probably the capacity for gliding movement that allows filaments to spread in sediments and exploit favorable growth conditions. Moreover, the long filaments resist grazing by protozoa (Widdel, 1983).

Desulfonema species may be cultivated under strictly anoxic conditions in reduced synthetic media[1] with sulfate as the electron acceptor and acetate, propionate, higher fatty acids, succinate, lactate, or benzoate as electron donors. Good growth may be obtained using combinations of organic substrates. Growth on acetate as sole organic substrate is very slow but can be stimulated by low concentrations (~50 mg/l) of additional electron donors, e.g., formate, fatty acids, or succinate. Previously sterilized extracts from anaerobically digested complex organic matter (sludge extracts) have been used to promote growth on organic substrates (Widdel, 1983; Widdel et al., 1983). Ammonium ions are used as nitrogen source. *D. limicola* and *D. ishimotonii* are routinely grown with 20 g NaCl and 3 g $MgCl_2 \cdot 6H_2O$ per liter medium. The standard medium contains biotin or a vitamin mixture. For optimal growth of *D. magnum*, 20 g NaCl, 5 g $MgCl_2 \cdot 6H_2O$, and at least 0.8 g $CaCl_2 \cdot 6H_2O$ per liter medium are necessary; biotin, 4-aminobenzoic acid, and vitamin B_{12} are required as growth factors. The high requirement for calcium ions has not been reported for any other sulfate-reducing bacterium. Gliding movement and growth are supported by addition of artificial sediments such as precipitated aluminum phosphate or sloppy agar (2 g/l).

1. Defined medium has the following composition (in g/l distilled water): Na_2SO_4, 4.0; KH_2PO_4, 0.2; NH_4Cl, 0.2; NaCl, 20; KCl, 0.5; $MgCl_2 \cdot 6H_2O$, 3.0 for *D. limicola* and 5.0 for *D. magnum*; and $CaCl_2 \cdot 2H_2O$, 0.15 for *D. limicola* and 1.4 for *D. magnum*. The dissolved salts are autoclaved. For the preparation of soft agar medium that supports homogeneous growth and gliding movement, 2 g of repeatedly washed (with cold H_2O), separately autoclaved agar in 70 ml H_2O are added per liter (final volume) of the hot autoclaved medium and mixed immediately; agar is omitted if artificial sediment is added later (see below). After the medium is cooled under an anaerobic atmosphere, the following volumes from separately sterilized stock solutions are added per liter medium while access of air is prevented by flushing with a mixture of N_2/CO_2 (CO_2 content: 5–20%, depending on the desired pH): solution of 84 g/l $NaHCO_3$ (autoclaved under CO_2 atmosphere), 30 ml; trace element solution (see below), 1 ml; solution of 3 mg/l $Na_2SeO_3 \cdot 5H_2O$ + 0.5 g/l NaOH, 1 ml; solution of 120 g/l $Na_2S \cdot 9H_2O$ (autoclaved under N_2 atmosphere), 3 ml; filter-sterilized vitamin mixture (see below), 1 ml; filter-sterilized thiamin solution (100 mg/l of 25 mM NaH_2PO_4/H_3PO_4 buffer, pH 3.4), 1 ml; and filter-sterilized B_{12} solution (50 mg/l), 1 ml. The pH of the mixed medium is adjusted with sterile HCl or Na_2CO_3 solution to 7.6 for *D. limicola* and to 7.0 for *D. ishimotonii* and *D. magnum*. The medium may be dispensed into tubes (10ml) or culture bottles (50 or 100 ml); bottles are completely filled and tightly sealed with screw caps or are provided with an anaerobic gas phase and sealed with butyl rubber stoppers. The desired organic substrates are added from sterile stock solutions. For *D. limicola*, 5–10 ml from a solution of 280 g/l sodium acetate trihydrate are added per liter of medium. Growth on acetate is stimulated by the addition of 1 ml from a mixture of organic acids (see below) per liter of culture medium. For *D. ishimotonii*, 5–10 ml from a solution of 140 g/l sodium acetate trihydrate and 22 g/l sodium isobutyrate are added per liter of medium. The substrates for *D. limicola* are also suitable for *D. ishimotonii*, and vice versa. For *D. magnum*, 3–5 ml from a solution of 150 g/l sodium benzoate are added per liter of medium. A sediment of aluminum phosphate per liter of medium is precipitated before inoculation: 5 ml of an autoclaved solution of 48 g/l $AlCl_3 \cdot 6H_2O$ are added, and the pH is readjusted with 1.6 ml from a solution of 106 g/l Na_2CO_2.

Trace element solution (without complexing agent) as described for *Desulfobacter* should be used.

Vitamin mixture contains per liter 10 mM Na_2HPO_4/NaH_2PO_4 buffer (pH 7.1): 4-aminobenzoic acid, 40 mg; D(+)-biotin, 10 mg; nicotinic acid, 100 mg; calcium D(+)-pantothenate, 50 mg; pyridoxine hydrochloride, 150 mg.

Mixture of organic acids (modified after Bryant, 1973) contains (per l): isobutyric acid, 5 g; valeric acid, 5 g; isovaleric acid, 5 g; 2-methylbutyric acid, 5 g; caproic acid, 2 g; heptanoic acid, 2 g; octanoic acid, 2 g; and succinic acid, 45 g. The acids are neutralized with NaOH.

Enrichment and Isolation Procedures

Filamentous, gliding, sulfate-reducing bacteria can be enriched in raw cultures if anoxic sediment samples from sulfate-rich freshwater or marine habitats are mixed with algal material or cellulose powder. In case of low sulfate concentrations, $CaSO_4$ should be added. Enrichments are incubated under an anoxic gas phase in a sealed bottle in the dark at room temperature. After 1–2 weeks, cell filaments may form dense silky layers covering the sediment and the glass wall.

Of the defined substrates known for *D. ishimotonii* and *D. magnum*, isobutyrate (5 mmol/l) and benzoate (3 mmol/l), respectively, are most suitable for enrichment in synthetic media. Acetate and a fatty acid mixture (see footnote) may be used to enrich *D. limicola*, but the procedure has low selectivity and often leads to the growth of *Desulfobacter*-like sulfate-reducing bacteria. An inoculum of 2–5% (v/v) black marine mud should be used. No artificial substrata for gliding movement should be added to the enrichment subcultures, so that filaments are forced to grow at the glass wall. If possible, transfers should be made from the glass wall. Parts of the layers may be sucked into a Pasteur pipette. However, despite these precautions, unicellular sulfate reducers often become dominant. *Desulfonema* may be obtained in pure culture only if the number of these competitors is not significantly higher than the number of filaments. Before the enrichment medium becomes turbid due to spreading of unicellular competitors, tufts of filaments are taken from the glass wall into Pasteur pipettes and washed anaerobically to remove the bulk of other cells. For washing, a fine-mesh copper grid (as used in electron microscopy) fixed in a conically drawn glass tube by means of a thin resin layer (Widdel 1980, 1983) or a small cotton plug in such a glass tube (Fukui et al., 1999) may be used as a sieve (Widdel, 1980, 1983). Anoxic medium is kept above the grid or cotton plug by the level of an elevated, bent outlet tube. After addition of filament tufts, sterile medium passes through the grid or cotton plug; *Desulfonema* filaments are retained, whereas the bulk of unicellular competitors and commensals pass through. Growth of *D. ishimotonii* is affected if exclusive addition of the initial, selective substrate isobutyrate is continued (Fukui et al., 1999). Therefore, an acetate–isobutyrate mixture (see above) should be added to subcultures.

In the case of *D. magnum*, a pure culture may be finally obtained from the washed filaments by transferring one of the relatively thick, visible filaments through a series of small portions of sterile anoxic medium. *D. limicola* may be isolated from washed filaments in agar dilution series. A medium with agar at lower concentration (8 g/l) than is found in standard agar media is recommended. The agar is prepared as described for *Desulfobacter*. The same concentrations of NaCl, $MgCl_2$, and $CaCl_2$ as in the enrichment medium are added in concentrated form to the agar before mixing with medium. The dilution procedure is analogous to that for *Desulfobacter*.

Filamentous sulfate reducers may form fluffy colonies. If, however, the gliding filaments migrate through the agar (as in *D. magnum*), the described method is not useful for isolation, since separate colonies are not obtained. Colonies of filaments are picked with medium-containing Pasteur pipettes. These may previously be drawn in a flame to an appropriate diameter. If the filaments cannot be reached without touching colonies of other bacteria, a part of the soft agar is carefully sucked off with a Pasteur pipette connected to a vacuum pump; however, a min-

imum distance of 8 mm should be kept between filaments and agar surface. In order to prevent contamination by bacteria liberated from disrupted colonies, the agar surface is sterilized, e.g., by addition of bromine vapor to the head space of the agar tube. The slow penetration of bromine into the agar is visible by a yellow zone. After 1 min, the bromine is removed with a gas stream of N_2. The bromine dissolved in the upper agar zone is reduced by injection of 0.5 ml SO_2 gas (e.g., made from sodium bisulfite plus acid in a serum bottle) into the head space. Immediately after decolorization of the bromine zone, the SO_2 is removed with N_2.

A few isolated filaments often do not start to grow if transferred into large volumes (>20 ml) of liquid medium in common tubes or bottles. Such filaments should be transferred into media in special anaerobic glass tubes (15 ml) with pointed, conical bottoms. The filaments sink to this narrow part of the tube where they can establish a growth-favoring microenvironment and where growth can be observed under the dissecting microscope. Initiation of growth may be promoted by addition of sludge extract (supernatant from centrifuged sediment of the habitat; 10–20% [by volume] added to the medium and dithionite as strong reductant). In the beginning, tubes are incubated without shaking. If growth is visible as increasing numbers of filaments attached to the glass wall, the culture may be shaken twice a day.

Freshly isolated filamentous sulfate reducers usually spread on surfaces and form silky layers that may cover the whole inner wall of the culture vessel. After a number of subcultures, however, *Desulfonema* filaments tend to creep together and form irregular clumps; such cultures grow only poorly, and filaments in clumps may soon die off. Clump formation is avoided by providing an insoluble substratum (aluminum phosphate or sloppy agar; see above) for gliding movement and by shaking the culture once or twice a day.

Maintenance Procedures

Pure cultures are maintained in liquid medium with an added sediment in completely filled screw-capped bottles, or under an anaerobic gas phase in bottles sealed with butyl rubber stoppers. Filaments remain viable longest with substrates on which growth is relatively slow. The enrichment substrate isobutyrate usually affects *D. ishimotonii* after a number of transfers. Stock cultures of *D. limicola* may be kept on acetate plus low concentrations of other fatty acids, and those of *D. magnum* may be kept on benzoate. *D. limicola* is stored at 2–5°C. *D. magnum* is damaged at such low temperatures and, therefore, is stored at −20°C. Stock cultures are transferred every 2–4 months. Strains may also be preserved indefinitely by suspending the filaments in anaerobic medium containing 5% (v/v) dimethylsulfoxide and storing in liquid nitrogen.

Differentiation of the genus *Desulfonema* from other genera

Desulfonema species are most easily differentiated from all other genera of sulfate-reducing bacteria by their striking filamentous morphology. The filaments consist of regularly arranged, nearly cylindrical cells. Single cells are usually not observed but may be liberated by shearing forces.

Desulfonema is distinguished from *Beggiatoa* species that may be abundant at the oxic–anoxic interface in sediments by the absence of highly refractile sulfur globules. Granules of poly-β-hydroxyalkanoic acid that are often present in *Desulfonema* are less refractile than sulfur globules. In sediment samples kept under completely anoxic conditions, *Desulfonema* continues to move and to multiply, whereas *Beggiatoa* becomes nonmotile, loses the sulfur droplets, and dies off after some days. *Desulfonema* can be differentiated from filamentous gliding cyanobacteria and green bacteria by the absence of pigments. Layers of *Desulfonema* are whitish, and filaments appear colorless in the brightfield microscope.

In addition, 16S rRNA gene sequence analysis (see next section) and DNA–DNA hybridization, as well as physiological characteristics (Table BXII.δ.20), may allow differentiation from other genera.

Taxonomic Comments

The closest relatives of *Desulfonema* species are members of the genera *Desulfosarcina* and *Desulfococcus*. A signature sequence for *Desulfonema magnum* and *Desulfonema limicola* species is 5′-TAUGGGAGAGGGAAGCGGAA-3′ (oligonucleotide probe DNM 657), which binds to the 16S rRNA corresponding to position 5′-657–676-3′ of the *Escherichia coli* 16S rRNA sequence (Fukui et al., 1999). Despite one mismatch in the signature sequence of *Desulfonema ishimotonii*, good hybridization signals can be obtained with this species. Members of the genera *Desulfococcus* and *Desulfosarcina* have also only one mismatch and might result in positive signals, but are morphologically differentiated from *Desulfonema* (see above).

after Maoto Ishimoto, a Japanese biochemist and microbiologist.

Characteristics are summarized in Table BXII.δ.20. Optimal growth of the type strain requires 20 g/l NaCl, 3 g/l $MgCl_2 \cdot 6H_2O$, and at least 0.2 g/l $CaCl_2 \cdot 2H_2O$ in the culture medium. *D. ishimotonii* is morphologically indistinguishable from *D. limicola*, but exhibits faster growth (14–18 h doubling time in comparison to ~30 h in case of the latter). Isolated from marine mud from Tokyo Bay, Japan.

The mol% G + C of the DNA is: 55.0 (HPLC).
Type strain: Tokyo 01, DSM 9680.
GenBank accession number (16S rRNA): U45992.

3. **Desulfonema magnum** Widdel 1981, 382[VP] (Effective publication: Widdel 1980, 381.)
mag′ num. L. adj. *magnus* large, big.

The morphology is as depicted in Fig. BXII.δ.28. Characteristics are summarized in Table BXII.δ.20. Optimal growth of the type strain requires 20 g/l NaCl, 5 g/l $MgCl_2 \cdot 6H_2O$, and at least 0.8 g/l $CaCl_2 \cdot 2H_2O$ in the culture medium. Isolated from marine mud, Montpellier, France.

The mol% G + C of the DNA is: 41.6 (T_m).
Type strain: 4beI3, DSM 2077, ATCC 35288.
GenBank accession number (16S rRNA): U45989.

Genus X. **Desulfosarcina** *Widdel 1981, 382[VP] (Effective publication: Widdel 1980, 382)*

Jan Kuever, Fred A. Rainey and Friedrich Widdel

De.sul.fo.sar′ ci.na. L. pref. *de* from; L. n. *sulfur* sulfur; *sarcina, Desulfosarcina* sarcina-shaped sulfate reducer.

Irregularly shaped cells occurring singly and in large, sarcina-like packets. Cells are 0.8–1.5 × 1.5–7.0 μm, occurring singly or in pairs. Spore formation is not observed. Granules of poly-β-hydroxyalkanoic acid frequently occur within the cells. Gram negative. Usually nonmotile, but cells motile by means of a single polar flagellum may occur. Strictly anaerobic, having both a res-

piratory and a fermentative type of metabolism. **Chemoorganotrophs or chemoautotrophs**, using formate, acetate, propionate, butyrate, higher fatty acids, other organic acids, alcohols, and **benzoate or similar aromatic compounds as electron donors and also as carbon sources**; these compounds are completely oxidized to CO_2. Chemoautotrophic growth occurs with **H_2 as the electron donor and CO_2 as the carbon source**. **Sulfate and other oxidized sulfur compounds serve as terminal electron acceptors and are reduced to H_2S.** In the absence of an external electron acceptor, slow growth of the type species occurs by fermentation of lactate or pyruvate to acetate and propionate. Carbon monoxide dehydrogenase activity is commonly observed, indicating the operation of the anaerobic C_1 pathway (carbon monoxide dehydrogenase pathway, Wood pathway) for complete oxidation of acetyl-CoA, or for CO_2 fixation during autotrophic growth. Media containing a reductant and not less than 10 g/l NaCl and 2 g/l $MgCl_2 \cdot 6H_2O$ are necessary for growth. Optimal growth temperature, 28–33°C. Thermophilic species have not been described. The optimal pH range for growth is 7.2–7.6. Cells contain desulforubidin as sulfite reductase, and cytochromes of the *b* and *c* type. Colonies in anaerobic agar media are grayish to yellowish, compact, and irregular in shape. Occur in anoxic part of brackish water and marine habitats.

The mol% G + C of the DNA is: 51–59.

Type species: **Desulfosarcina variabilis** Widdel 1981, 382 (Effective publication: Widdel 1980, 383.)

Further descriptive information

D. variabilis forms large free-living cells (Fig. BXII.δ.29A) and sarcina-like packets with irregular arrangement of cells or distorted appearance (Fig. BXII.δ.29B). These packets form pellets in liquid media and layers at the glass wall. Cells liberated from the packets (e.g., by squeezing) are irregularly shaped. Repeated subculturing from the culture fluid favors the development of coccoidal or ellipsoidal cells which occur singly or in pairs (Fig. BXII.δ.29A). Single cells of the type strain are nonmotile, although some possess a single polar flagellum. Motile cells have been observed in enrichment cultures of *Desulfosarcina*.

The temperature range for growth is 15–38°C, with optimal growth occurring at 33°C. The pH range for growth is 6.7–9.0, with pH 7.4 being the optimal.

D. variabilis reduces sulfate, sulfite, or thiosulfate to H_2S. Elemental sulfur and nitrate cannot serve as electron acceptors. *D. cetonicum* can use sulfur as electron acceptor. Chemoautotrophic growth occurs with H_2 as the electron donor and CO_2 as the carbon source. The following compounds serve as both electron donors and organic carbon sources for chemoorganotrophic growth: formate, propionate, butyrate, valerate, 2-methylbutyrate, 3-methylbutyrate, higher fatty acids up to 14 carbon atoms, lactate, pyruvate, succinate, fumarate, ethanol, 1-propanol, 1-butanol, benzoate, and phenyl-substituted organic acids. Some species can additionally use acetone, toluene, *m*-cresol, or *o*-xylene. Growth on acetate alone is very slow. All organic substrates are completely oxidized to CO_2 via the anaerobic C_1 pathway (carbon monoxide dehydrogenase pathway, Wood pathway; Schauder et al., 1986; Janssen and Schink, 1995a, b; Harms et al. 1999b).

In the absence of an external electron acceptor, slow growth is possible with pyruvate or lactate, which are fermented to acetate and propionate. Fumarate can be slowly fermented to acetate, propionate, and succinate; it does not act as terminal electron acceptor for anaerobic respiration. Sugars are not fermented.

Membrane-bound and soluble cytochromes of the *b* and *c* type have been identified in *D. variabilis.* Cells contain desulforubidin as sulfite reductase (Arendsen et al., 1993) and menaquinone MK-7 as the predominant quinone (Collins and Widdel, 1986). Major cellular fatty acids of *Desulfococcus multivorans* strains are $C_{15:0\ anteiso}$ and $C_{16:0}$ (Kohring et al., 1994).

D. variabilis is sensitive toward light and has to be incubated in the dark. Diffuse daylight in the laboratory may inhibit growth completely.

Desulfosarcina occurs in anoxic black mud of brackish water and marine habitats.

Strains of *Desulfosarcina* may be cultured in a defined medium[1] with sulfate as electron acceptor and benzoate as the electron donor and carbon source. For *D. cetonicum*, brackish medium should be used. Ammonium ions are used as the nitrogen source. For growth on benzoate, addition of molybdate as a trace element is necessary. It is not yet known whether selenite is required, but

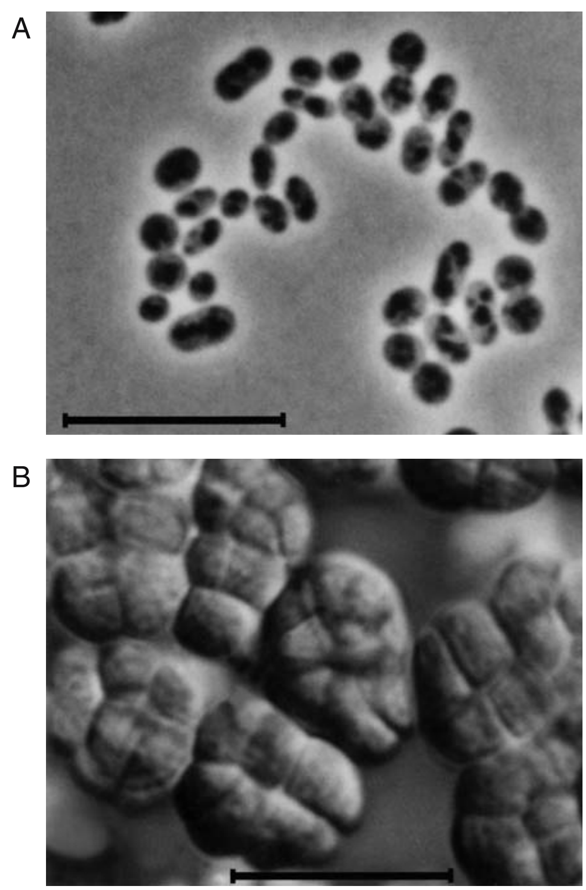

FIGURE BXII.δ.29. (*A*) Phase-contrast micrograph of *Desulfosarcina variabilis*, viable single cells from liquid medium. Bar = 10 µm; (*B*) phase-contrast micrograph of *Desulfosarcina variabilis*, cell packets from an agar colony. Bar = 10 µm.

1. The defined medium is prepared as described in the footnote of the section on the genus *Desulfobacter*. The following additions are recommended (g/l): NaCl, 13.0 and $MgCl_2 \cdot 6H_2O$, 2.0. After autoclaving of the medium, the following additional components are added aseptically from sterile stock solutions (per liter of medium): sodium benzoate solution (150 g/l), 5.0 ml; sodium selenite solution ($Na_2SeO_3 \cdot 5H_2O$, 3 mg/l and NaOH, 0.5 g/l), 1.0 ml. The pH of the medium is adjusted to 7.3–7.5.

selenite is added routinely to the medium. The type strains of *D. variabilis* and *D. cetonicum* do not require vitamins; other strains have not been studied in this regard. When inoculation is done from old cultures, initiation of growth is favored by the addition of 10–30 mg sodium dithionite per liter of medium as a further strong reductant, in addition to routinely added sodium sulfide.

Enrichment and Isolation Procedures

For the selective enrichment of *Desulfosarcina* strains, benzoate–sulfate medium is used. Other aromatic compounds or acetone will favor growth of species other than the type species, *D. variabilis*. Bottles or tubes (100-, 50-, or 20-ml capacity) can serve as culture vessels and are kept anoxic with tight screw caps (if completely filled), or by providing an anoxic headspace of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated with black anoxic mud from brackish or seawater sediments; 2–5% of the total volume should be added. Enrichment cultures are incubated at 25–30°C and mixed by shaking every second day. After intense formation of H_2S has occurred (generally after 10–20 d), transfers to fresh medium are made. Enrichment cultures should be mixed well before subculturing.

Pure cultures of *Desulfosarcina* strains are obtained by repeated application of the agar dilution method. The method is similar to that described for the genus *Desulfobacter*, except that benzoate medium is added to the molten concentrated agar solution. Before inoculation of the agar medium, cell packets of *Desulfosarcina* should be broken carefully with a homogenizer in medium under anoxic conditions. In agar media, *Desulfosarcina* forms irregularly shaped, compact colonies, which can be removed with a sterile Pasteur pipette.

Desulfosarcina ovata strains may be enriched and isolated with *o*-xylene as electron donor and carbon source. Pure cultures are obtained by repeated application of the agar dilution method. The method is similar to that described for *Desulfobacula toluolica* (see genus *Desulfobacula*), except that the overlying carrier phase contains 2% (v/v) *o*-xylene (Harms et al., 1999b).

Maintenance Procedures

Pure cultures are maintained in liquid medium in screw-capped bottles or in anoxically gassed, butyl rubber-sealed bottles, with storage at 2–5°C. Stock cultures are transferred every 2–3 months. *Desulfosarcina* strains may be preserved indefinitely by suspending the cells in anaerobic medium containing 5% dimethylsulfoxide and storing in liquid nitrogen.

Differentiation of the genus *Desulfosarcina* from other genera

Desulfosarcina differs from many other anaerobic sulfate-reducing bacteria by its formation of dense sarcina-like cell packets. A characteristic physiological property of *Desulfosarcina* is its growth with benzoate and phenyl-substituted fatty acids. This property is also shared by members of the genera *Desulfococcus* and *Desulfobacterium*; however, species of the latter genera are coccoid or small rods under all cultural conditions and never form cell packets.

Taxonomic Comments

The closest relatives of the genus *Desulfosarcina* are members of the genus *Desulfonema*, and *Desulfococcus multivorans*. A signature sequence for all described *Desulfosarcina* species except *D. cetonicum* is 5′-AGGCCACCCTTGATCCAA-3′ (oligonucleotide probe DSC193), which binds to the 16S rRNA corresponding to position 5′-193–210-3′ of the *Escherichia coli* 16S rRNA sequence (Ravenschlag et al., 2000).

Genus XI. **Desulfospira** *Finster, Liesack and Tindall 1997e, 1274*[VP] *(Effective publication: Finster, Liesack and Tindall 1997c, 207)*

WERNER LIESACK AND KAI FINSTER

De.sul.fo.spi′ra. L. pref. *de* from; L. n. *sulfur* sulfur; Gr. n. *spira* a coil; M.L. fem. n. *Desulfospira* a sulfate-reducing coil.

Curved, often spirilloid cells 0.7–0.8 × 1–2 μm. Nonmotile. Gram negative. Endospores not formed. Anaerobic, having a respiratory type of metabolism. Fermentative growth does not occur. Catalase positive. **Chemoorganotrophic or chemoautotrophic**, using a wide range of organic compounds as electron donors and also as carbon sources, e.g., fatty acids, dicarboxylic acids, oxoacids, hydroxyacids, or compatible solutes; **these substrates are completely oxidized to CO_2. Maleate and proline are used as electron donors.** Aromatic compounds and sugars are not utilized. **Sulfate, sulfite, thiosulfate, and S^0 serve as terminal electron acceptors** and are reduced to H_2S. Na^+ and Mg^{2+} are required for growth. Biotin is required for growth. Cells contain *c*-type cytochromes and menaquinones with seven isoprenoid units. Desulfoviridin is not present. Isolated from iron-rich, oxidized, marine surface sediment.

The mol% G + C of the DNA is: 50.

Type species: **Desulfospira joergensenii** Finster, Liesack and Tindall 1997e, 1274 (Effective publication: Finster, Liesack and Tindall 1997c, 207.)

Further descriptive information

Growth in the presence of Fe(III)-oxyhydroxide in nonreduced medium may be interpreted as an adaptation to oxidized conditions which prevail in the surface sediment from which *D. joergensenii* strain B331 was isolated. In the absence of Fe(III)-oxyhydroxide, substrate utilization ceased when sulfide concentrations reached 8–9 mM. This was probably due to the toxicity of hydrogen sulfide at higher concentrations. In the presence of Fe(III)-oxyhydroxide, larger amounts of substrate were utilized because hydrogen sulfide was continuously removed by chemical reoxidation to S^0 and/or precipitation as FeS.

Enrichment and Isolation Procedures

Desulfospira strains are selectively enriched in a sulfate-free, anaerobic mineral medium (Widdel and Bak, 1992; Finster and Bak, 1993) with highly purified S^0 (200 mg per 50 ml medium) as electron acceptor in the presence of large amounts of amorphous Fe(III)-oxyhydroxide (1 ml 0.3 M Fe(III)-oxyhydroxide per 10 ml medium). Reducing agents are omitted. Sodium butyrate (5 mM) is used as the electron donor. S^0 is prepared and added as described by Pfennig and Biebl (1976). Amorphous Fe(III)-oxyhydroxide is prepared by titration of an acidic $FeCl_3$ solution with NaOH to pH 7. Oxidized marine surface sediment serves as inoculum. The formation of black spots around small sulfur particles indicates the reduction of S^0 to H_2S, which results in the precipitation of FeS. Black particles can be dissolved by addition of a few drops of 1 M HCl solution to a subsample of the enrichment culture. The release of H_2S is indicated by its characteristic odor. Cells are primarily present in the precipitates and not in the supernatant.

Pure cultures are obtained by repeated application of the agar shake dilution method (Pfennig, 1978). A 3% (w/v) solution of agar is prepared in distilled water. The agar should be washed several times in distilled water before preparing the solution. The agar shakes consist of two different phases, one containing amorphous Fe(III)-oxyhydroxide in 3% agar, and a second containing substrates and inoculum. For preparation of the iron-containing phase, 1 ml of a 0.3 M Fe(III)-oxyhydroxide suspension is added to test tubes containing 3 ml of molten sterile agar. After mixing, the suspension is allowed to solidify while placed in a horizontal position. The solidified iron-containing phase should cover one half of the glass wall of the test tube.

The second phase contains an agar dilution series supplemented with sodium butyrate and S^0. The agar medium is kept molten after inoculation and then rapidly transferred to test tubes containing the iron-agar phase. The tubes are immediately transferred to a cold water bath, sealed with butyl rubber stoppers, and gassed with a mixture of N_2/CO_2 (90:10). The formation of black FeS in the iron-agar layer is indicative of the reduction of S^0 to H_2S. Well-separated colonies that occur in the higher dilutions can be removed with sterile Pasteur pipettes and used as the inoculum for subsequent agar shake cultures or liquid cultures containing butyrate, S^0, and Fe(III)-oxyhydroxide. Alternatively, *Desulfospira* strains can be grown in anaerobic, sulfide-reduced medium with sulfate as electron acceptor instead of S^0. Addition of Fe(III)-oxyhydroxide is then omitted.

Maintenance Procedures

Pure cultures are maintained in liquid culture medium in screw-capped bottles or in anaerobically gassed bottles sealed with butyl rubber stoppers, with storage at 2–5°C. Stock cultures are transferred every 1–3 months.

Differentiation of the genus *Desulfospira* from other genera

The genus *Desulfospira*, currently represented only by its type species *D. joergensenii*, is characterized by the ability to use both oxidized sulfur compounds and S^0 as terminal electron acceptors for anaerobic respiration. This phenotypic trait has only been observed for a few species belonging to the genera *Desulfovibrio* and *Desulfomicrobium* (Widdel and Pfennig, 1992), and for *Desulfofustis glycolicus* (Friedrich and Schink, 1995; Friedrich et al., 1996). A unique nutritional characteristic of *D. joergensenii* among known sulfate reducers is the utilization of maleate and proline. *D. joergensenii* and *Desulfobacula toluolica* (Rabus et al., 1993) differ in the pattern of utilized substrates (Table BXII.δ.22). The presence of two types of menaquinones with seven isoprenoid units (MK-7 and MK-7 [VII-H2]) and the absence of an internally branched hexadecyl fatty acid ($C_{16:0\ CH_3}$) distinguishes *D. joergensenii* from members of the genus *Desulfobacter* (Taylor and Parkes, 1983; Dowling et al., 1986; Vainshtein et al., 1992).

Taxonomic Comments

Based on comparative sequence analysis of the 16S rRNA-encoding gene, the genus *Desulfospira* belongs to the family *Desulfobacteraceae* in the *Deltaproteobacteria*. Common characteristics of all described members of this family are the complete oxidation of organic compounds to CO_2 (Widdel and Hansen, 1992) and the presence of menaquinones with seven isoprenoid units. Within the family *Desulfobacteraceae*, *D. joergensenii* forms a coherent line of descent with *D. toluolica* and members of the genus *Desulfobacter* (Fig. BXII.δ.30). The overall dissimilarity value(s) of the 16S rRNA gene sequence from *D. joergensenii* to that of *D. toluolica* is 4.6%, and to those of members of the genus *Desulfobacter* between 5.2% and 7.3%.

List of species of the genus Desulfospira

1. **Desulfospira joergensenii** Finster, Liesack and Tindall 1997e, 1274[VP] (Effective publication: Finster, Liesack and Tindall 1997c, 207.)
joer.gen.se′ ni.i. M.L. gen. n. *joergensenii* of Joergensen; named after B.B. Jørgensen, a Danish microbiologist who has made important contributions to our current knowledge of the sulfur cycle.

The description is based on the type strain B331 (Finster et al., 1997c). The morphology is as indicated in the generic description and as depicted in Fig. BXII.δ.31. The main characteristics are as listed in the generic description.

In liquid media, chains consisting of two or more cells often occur. Colonies in anaerobic agar media are lens-shaped with a faint orange-red color, whether grown with elemental sulfur as electron acceptor in the presence of Fe(III)-oxyhydroxide, or with sulfate as electron acceptor in the absence of Fe(III)-oxyhydroxide.

Formate and CO_2 can serve as the sole electron donor and carbon source, respectively, for chemoautotrophic

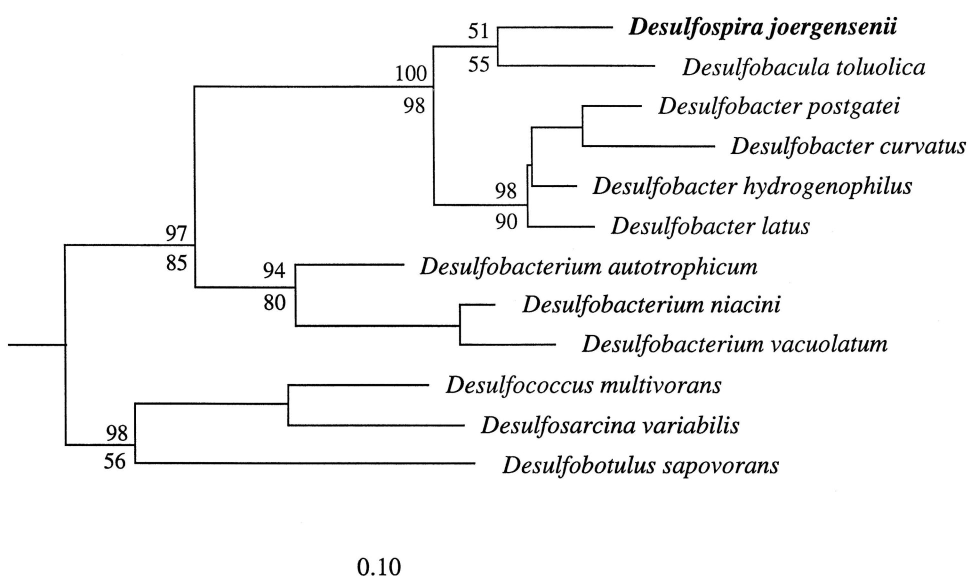

FIGURE BXII.δ.30. Dendrogram showing the phylogenetic position of *Desulfospira joergensenii* in relation to other members of the family *Desulfobacteraceae* in the *Deltaproteobacteria*. The rooting was inferred using the 16S rRNA gene sequence of *Escherichia coli* as an outgroup. The tree was constructed using a maximum likelihood method (FastDNAml), Maidak et al., 1997, and the ARB program package, Strunk and Ludwig, 1998. Bootstrap values were determined using maximum parsimony (PHYLIP), Felsenstein, 1993; 100 data resamplings) and neighbor-joining (ARB; 1000 data resamplings) methods. The values are given as percentage of outcome for the maximum parsimony test above, and for the neighbor-joining method below, the respective branches. The region of the 16S rRNA molecule between positions 28 and 1357 (International Union of Biochemistry of *Escherichia coli* 16S rRNA numbering) was used in the analysis. Bar = estimated number of base changes per nucleotide sequence position.

growth. The following substrates are utilized as electron donor for growth: hydrogen, formate, butyrate, caprylate, laurinate, myristinate, crotonate, α-ketoglutarate, glutarate, 3-oxoglutarate, fumarate, maleate, succinate, oxalacetate, pyruvate, lactate, glycolate, glycerol, choline chloride, betaine, DMSP, proline, and yeast extract.

The following substrates support sulfate reduction but not growth: valerate, palmitate, stearate, methanol, glycine, alanine, L-threonine, glutamate, acetone, ethylene-glycol, CE-broth, nicotinate, and benzoate.

The following substrates are not utilized: 1-propanol, 1-butanol, dimethylamine, trimethylamine, acetate, isobuty-

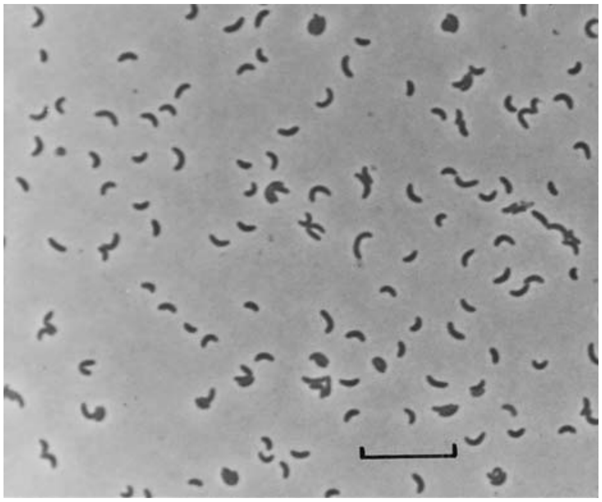

FIGURE BXII.δ.31. Phase-contrast photomicrograph showing cells of *Desulfospira joergensenii* strain B331 isolated from iron-rich, oxidized, marine surface sediment. Bar = 10 μm.

rate, 2-methylbutyrate, isovalerate, pelargonate, caprinate, oxamate, citrate, tartrate, malonate, malate, adipate, pimelate, aspartate, oxalate, glyoxylate, croton-aldehyde, glucose, fructose, mannitol, sorbitol, trehalose, methionine, tyrosine, L-arginine, tryptophan, phenylalanine, phenol, *p*-cresol, toluene, cyclohexanecarboxylate, vanillin, pyrimidine, pyridine, pyrogallol, and 3-phenylpropionate.

No fermentative type of metabolism occurs with lactate, pyruvate, fumarate, maleate, malate, glutamate, oxalacetate, and aspartate as substrates. Nitrate, nitrite, Fe(III)-oxyhydroxide, Fe(III)-citrate, trimethylamine oxide, dimethyl sulfoxide, and fumarate are not utilized as electron acceptors.

Optimal NaCl concentration, 1.2–2%; range for growth, 0.6–4%. Optimal $MgCl_2 \cdot 6H_2O$ concentration, 0.1–0.3%; minimum concentration for growth, 0.1%. Compared to growth obtained at the optimal concentration, only slight inhibition with 2.1% $MgCl_2 \cdot 6H_2O$. Optimal temperature, 26–30°C; range for growth, 8–30°C. Optimal pH, 7.4–7.6; range for growth, pH 6.5–7.9. Catalase positive.

MK-7 and MK-7 (VII-H_2) menaquinones are present. The fatty acid composition comprises mainly unbranched fatty acids. The major polar lipids are phosphatidyl glycerol and phosphatidyl ethanolamine.

Isolated from oxidized, iron-rich, surface sediment of a mud flat overgrown with *Zostera noltii*.

The mol% G + C of the DNA is: 49.9 (HPLC).

Type strain: Strain B331, DSM 10085.

GenBank accession number (16S rRNA): X99637.

Genus XII. **Desulfotignum** *Kuever, Könneke, Galushko and Drzyzga 2001, 176*[VP]

Jan Kuever, Fred A. Rainey and Friedrich Widdel

De.sul.fo.tig′ num. L. pref. *de* from; L. n. *sulfur* sulfur; M.L. n. *tignum* stick; M.L. neut. n. *Desulfotignum* sulfate-reducing stick.

Rod-shaped, sometimes slightly curved, cells, 0.5–0.7 × 1.5–3 μm. Occur singly or in pairs. Spore formation is not observed. Gram negative. Motile by a single polar flagellum. Strictly anaerobic, having both a respiratory and a fermentative type of metabolism. **Chemoorganotroph or chemoautotroph**, using formate, acetate, butyrate, higher fatty acids, other organic acids, alcohols, and **benzoate or similar aromatic compounds as carbon sources and also as electron donors for anaerobic respiration**; these compounds are completely oxidized to CO_2. Chemolithoautotrophic growth occurs with **H_2 as the electron donor and CO_2 as the carbon source. Sulfate, sulfite, and thiosulfate serve as terminal electron acceptors and are reduced to H_2S**. In the absence of an external electron acceptor, slow growth occurs by fermentation of pyruvate. Carbon monoxide dehydrogenase activity is commonly observed, indicating the operation of the anaerobic C_1 pathway (carbon monoxide dehydrogenase pathway, Wood pathway) for CO_2 fixation and complete oxidation of acetyl-CoA. Media containing vitamins, a reductant, and not less than 10 g NaCl/l are necessary for growth. The optimal growth temperature is 28–32°C, the temperature range 10–42°C. Thermophilic species have not been described. The optimal pH for growth is 7.3, the pH range 6.5–8.2. Cells contain no desulfoviridin, cytochromes of the *c* type are present. Occur in anoxic part of marine habitats.

The mol% G + C of the DNA is: 62.

Type species: **Desulfotignum balticum** Kuever, Könneke, Galushko and Drzyzga 2001, 176.

Further descriptive information

Formate, acetate, crotonate, C_4–C_{12} straight-chain fatty acids, pyruvate, lactate, fumarate, succinate, maleinate, malate, benzoate, 4-hydroxybenzoate, phenol, phenylalanine, and phenylacetate serve as electron donors and also as carbon sources; these compounds are completely oxidized to CO_2. *D. balticum* uses sulfate, sulfite, and thiosulfate as electron acceptors, whereas sulfur and nitrate are not used. Cells contain cytochrome *c* but no desulfoviridin. Major cellular fatty acids of the type strain are $C_{16:0}$, $C_{16:0\ 10CH_3}$, and $C_{17:0\ cyclo}$. Ammonium ions are used as the nitrogen source. *Desulfotignum* strains occur in anoxic marine sediments rich in organic material. Media containing a reductant such as sulfide and vitamins are necessary for growth.

Enrichment and Isolation Procedures

For the selective enrichment of *Desulfotignum*, the same defined marine sulfate medium described for the isolation of *Desulfobacter* spp. may be used. Instead of acetate, benzoate (2 mM) is added as electron donor and carbon source. Bottles or tubes (100-, 50- or 20-ml capacity) can serve as culture vessels and are kept anoxic with tight screw caps (if completely filled), or by providing an anoxic head space of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated (2–5% of the total volume) with dark anoxic sediment. Enrichment cultures are incubated at 30°C. Cultures should be briefly shaken once a week. After intense formation of H_2S has occurred, transfers to fresh medium are made. Enrichment cultures should be mixed well

before subculturing. Pure cultures of *Desulfotignum* strains are obtained by repeated application of the agar dilution method (as described for *Desulfobacter* in this edition of the *Manual*). The same substrates used for the enrichment cultures may be used for obtaining pure cultures.

Maintenance Procedures

Stock cultures are transferred every 3–5 months. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 2–5°C in the dark. *Desulfobacter* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen.

Differentiation of the genus *Desulfotignum* from other genera

From other sulfate-reducing bacteria that utilize benzoate (*Desulfobacula*, *Desulfococcus*, and *Desulfosarcina*), *Desulfotignum balticum* is easily distinguished by its pronounced rod-shaped, elongate cells. Unambiguous differentiation from these other sulfate-reducing bacteria requires comparative 16S rDNA sequence analysis and DNA–DNA hybridization.

Taxonomic Comments

The closest relatives of *Desulfotignum balticum* are members of the genera *Desulfobacula*, *Desulfobacter*, and *Desulfospira*. A signature sequence for *Desulfobacter*, *Desulfobacula*, *Desulfospira*, and *Desulfotignum* is 5′-CACAGGATGTCAAACCCAG-3′ (oligonucleotide probe DSB985), which binds to the 16S rRNA corresponding to *E. coli* position 5′-985–1003-3′ (Manz et al., 1998).

Family II. **Desulfobulbaceae** *fam. nov.*

Jan Kuever, Fred A. Rainey and Friedrich Widdel

De.sul.fo.bul.ba.ce′ ae. M.L. masc. n. *Desulfobulbus* type genus of the family; suffix *ceae* denotes family; M.L. fem. pl. n. *Desulfobulbaceae* the family that comprises the genus *Desulfobulbus* and other genera.

The order comprises morphologically diverse sulfate-reducing bacteria including cocci, oval, rod-shaped, and curved cells. Many forms are motile by means of single polar flagella. Some members contain gas vesicles. **Strictly anaerobic chemoorganotrophs, chemolithoheterotrophs, or chemolithoautotrophs with respiratory metabolism**; in addition, fermentative abilities are found in some members. With the exception of one isolate (*Desulfocapsa sulfexigens*), **the common electron acceptor is sulfate,** which is reduced to sulfide. **Sulfite or thiosulfate may also be used; some members may also reduce elemental sulfur (or polysulfide) or nitrate**; nitrate is reduced to ammonia. **Simple organic compounds, such as long-chain fatty acids and alcohols, serve as electron donors and carbon sources**. Most members of the family are incomplete oxidizers that form acetate as an end product. Growth by disproportionation of sulfur, thiosulfate, and sulfite may occur. Members are mesophilic or psychrophilic; thermophiles have not been isolated. Cells contain various cytochromes, other redox proteins, and menaquinones. Desulfoviridin is not present; desulforubidin has been detected in most species. Mesophilic species have been isolated from various aquatic environments, including marine, brackish water, and freshwater habitats.

The family comprises the genera *Desulfobulbus*, *Desulfocapsa*, *Desulfofustis*, *Desulforhopalus*, and *Desulfotalea*. Comparative properties of all described genera are given in Table BXII.δ.23. Detailed properties of described species of each genus are given in the genus descriptions.

be used as electron donor in the presence of acetate as organic carbon source (chemolithoheterotrophic growth). **Sulfate and often sulfite or thiosulfate serve as terminal electron acceptors and are reduced to H_2S.** Sulfur is never reduced. **In the absence of an external electron acceptor, growth may occur by fermentation of lactate, pyruvate, and ethanol (+ CO_2), malate, or fumarate.** The optimum pH range for growth is 6.6–7.5. The optimum temperature range for growth is 25–40°C. Thermophilic species are not known. Media containing a reductant and *p*-aminobenzoate are required for growth. Colonies in anaerobic agar media are whitish to grayish and smooth. All described species contain desulforubidin as sulfite reductase. Occur in anoxic parts of freshwater, brackish water, and marine habitats; also isolated from rumen contents, animal dung, and sewage sludge.

The mol% G + C of the DNA is: 50–60.

Type species: **Desulfobulbus propionicus** Widdel 1981, 382 (Effective publication: Widdel 1980, 374.)

Further descriptive information

Cells of *D. propionicus* are generally lemon or onion shaped (Fig. BXII.δ.32), other species have a more rod-like cell shape and less pointed ends. Cells are often in pairs and chains. Many strains are motile by a single polar flagellum. However, the type strain of *D. propionicus* is nonmotile; electron microscopy of this strain has shown the presence of pili but not of flagella.

The temperature range for growth is 10–43°C. *D. propionicus* has an optimum growth temperature of 39°C; other strains may have lower temperature optima of 28–31°C. The pH range for growth is 6.0–8.6, with an optimum pH of 7.2.

All members of the genus reduce sulfate, sulfite, and thiosulfate to H_2S. *D. propionicus* can also use nitrate and ferric iron

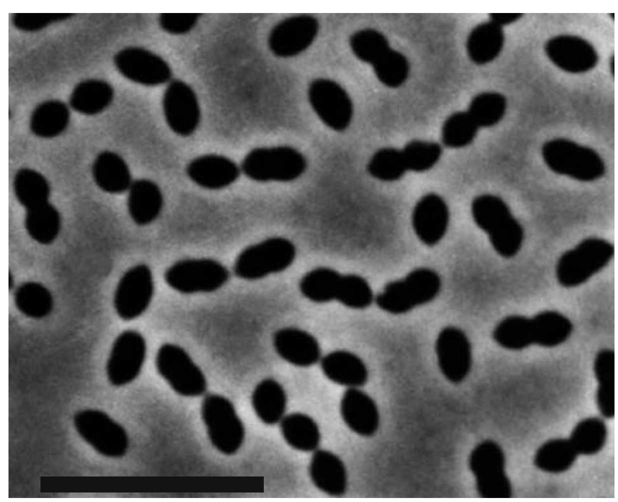

FIGURE BXII.δ.32. Phase-contrast micrograph of *Desulfobulbus propionicus* (viable cells). Bar = 10 μm.

as terminal electron acceptors, which are reduced to ammonia and ferrous iron, respectively (Widdel and Pfennig, 1982; Lovley et al., 1993b). Elemental sulfur, fumarate, and malate cannot serve as electron acceptors. Slow growth by disproportionation of sulfur was observed with *D. propionicus* if acetate was supplied as the carbon source (Lovley and Phillips, 1994a). This process was accelerated by the presence of Mn(IV). Propionate, lactate, pyruvate, ethanol, and 1-propanol are utilized as electron donors and organic carbon sources; *D. rhabdoformis* can also use malate, fumarate, and succinate. Oxidation of these substrates usually leads to the formation of acetate as an end product. *Desulfobulbus* spp. can grow with H_2 as an electron donor, but growth does not occur chemoautotrophically; acetate is necessary as a carbon source in the presence of bicarbonate (chemolithoheterotrophic growth; see also chapter *Desulfovibrionales*).

In the absence of a terminal electron acceptor, growth is possible with pyruvate or lactate, which are fermented to acetate and propionate. *D. propionicus* can also grow by fermentation of ethanol and CO_2 (Laanbroek and Pfennig, 1981; Tasaki et al., 1990), whereas *D. rhabdoformis* grows by fermentation of malate and fumarate (Lien et al., 1998). Sugars are not fermented.

Membrane-bound and soluble cytochromes of the *b* and *c* type have been identified in *D. propionicus* and other species. All described *Desulfobulbus* spp. contain desulforubidin as sulfite reductase and menaquinone-5(H_2) as the predominant quinone (Collins and Widdel, 1986). Major cellular fatty acids (PFLA) are $C_{17:1\ \omega6c}$ and $C_{18:1\ \omega7c}$ (Kohring et al., 1994).

Desulfobulbus occurs in the anoxic black mud of freshwater ditches and lakes, brackish water, and marine habitats. It also occurs in bovine rumen fluid, in the intestinal tract of animals, and in the anaerobic sludge of animal manure deposits and sewage plants (Tasaki et al., 1990).

Strains of *Desulfobulbus* may be cultured in a defined anoxic medium[1] with sulfate as electron acceptor and propionate, lactate, or 1-propanol as the electron donor and carbon source. For *D. rhabdoformis*, malate, fumarate, and succinate may be used as alternative electron donors and carbon sources. Ammonium ions serve as the nitrogen source. When inoculation is done from old cultures, initiation of growth is favored by the addition of 10–30 mg sodium dithionite per liter of medium as a further strong reductant, in addition to routinely added sodium sulfide.

Enrichment and Isolation Procedures

For the selective enrichment of *Desulfobulbus* strains, propionate–sulfate medium is used. Bottles or tubes (100-, 50-, or 20-ml capacity) can serve as culture vessels and are kept anoxic with tight screw caps, or by using a headspace of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated with black anoxic mud from freshwater ditches or ponds, brackish water, or marine habitats, manure deposits, sludge from sewage digestors, or rumen fluid; 3–5% of the total culture volume should be added. *Desulfobulbus* species may be also enriched and isolated via direct serial dilution of anoxic environmental samples in liquid medium (according to most-probable-number method) or agar medium (see next paragraph) with propionate as organic substrate. Furthermore, selective enrichment of *Desulfobulbus* species is possible under fermentative conditions without sulfate in anoxic bicarbonate-buffered medium in a chemostat, using ethanol as the growth-limiting substrate (Laanbroek et al., 1982); such cultures form propionate and acetate as fermentation products.

The NaCl concentration of the medium should correspond approximately to the salinity of the natural source, but the added amount of $MgCl_2 \cdot 6H_2O$ need not be higher than 3 g/l. Addition of dithionite to enrichment cultures is recommended. Enrichment cultures are incubated at 28–36°C and mixed by shaking every second day. When intense formation of H_2S has occurred (generally after 10 d), transfers to fresh medium are made. Enrichment cultures should be mixed well before subculturing.

Pure cultures of *Desulfobulbus* strains are obtained by repeated application of the agar dilution method. The method is similar to that described for the genus *Desulfobacter*, except that propionate medium is added to the molten concentrated agar solution.

In enrichment cultures with seawater or brackish water medium, cells of *Desulfobacter* spp. may develop on the acetate excreted by *Desulfobulbus* spp. In the highest dilutions of agar cultures, however, only *Desulfobulbus* develops into large colonies.

Maintenance Procedures

Stock cultures are transferred every 2–3 months. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 2–5°C in the dark. *Desulfobulbus* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen.

Differentiation of the genus *Desulfobulbus* from other genera

Desulfobulbus spp. grow well (with doubling times of ~10 h) with sulfate and propionate, and the latter substrate is a characteristic organic substrate for the genus. Other sulfate-reducing bacteria, like *Desulfococcus multivorans*, *Desulfosarcina variabilis*, or *Desulfobacterium* spp., can also utilize propionate; however, these organisms carry out complete oxidation of the propionate and also grow more slowly than does *Desulfobulbus*.

Taxonomic Comments

The closest relatives of *Desulfobulbus* species are member of the genera *Desulfocapsa* and *Desulforhopalus*. A signature sequence for all described *Desulfobulbus* species and other closely related sulfate-reducing bacteria is 5′-GAATTCCACTTTCCCCTCTG-3′ (oligonucleotide probe 660), which binds to the 16S rRNA corresponding to position 5′-660–679-3′ of the *Escherichia coli* 16S rRNA sequence (Devereux et al., 1992; Manz et al., 1998).

Further Reading

Widdel, F. and N. Pfennig. 1982. Studies on dissimilatory sulfate-reducing bacteria that decompose fatty-acids. II. Incomplete oxidation of propionate by *Desulfobulbus propionicus* gen. nov., sp. nov. Arch. Microbiol. *131*: 360–365.

1. The defined medium is prepared as described in the footnote on the genus *Desulfobacter*, with the following additions (g/l): NaCl, 1.0 (for freshwater strains) or 20.0 (for marine strains); $MgCl_2 \cdot 6H_2O$, 0.5 (for freshwater strains) or 3.0 (for marine strains). Sodium propionate (final concentration, 1.5 g/l) is added aseptically from a sterile stock solution to provide an organic substrate; however, the best growth occurs with sodium lactate (final concentration, 2.0–4.0 g/l) in the presence of sulfate. The only growth factor required by *Desulfobulbus* is *p*-aminobenzoic acid. The pH of the complete medium is adjusted to 7.3–7.4.

GenBank accession number (16S rRNA): X95180.

3. **Desulfobulbus marinus** *sp. nov.*
ma.ri'nus. synonym of L. adj. *maritimus* pertaining to the sea.

The morphology is as described in Table BXII.δ.24 and as depicted in Fig. BXII.δ.33. Characteristics are summarized in Table BXII.δ.24. Type strain isolated from an anoxic mud flat of the Jadebusen (Germany) with propionate as selective substrate.

The mol% G + C of the DNA is: 47.3 (HPLC).

TABLE BXII.δ.24. Morphological and physiological characteristics of described species of the genus *Desulfobulbus*[a]

Species	*Desulfobulbus propionicus*	*Desulfobulbus elongatus*	*Desulfobulbus marinus*	*Desulfobulbus rhabdoformis*

[b]Used as electron donor only in the presence of acetate as carbon source.

Deposited strain: 3pr10, DSM 2058.
GenBank accession number (16S rRNA): M34411.

4. **Desulfobulbus rhabdoformis** Lien, Madsen, Steen and Gjerdevik 1998, 473[VP]
rhab.do.for′ mis. Gr. fem. n. *rhabdos* rod; L. adj. suff. *formis*-like, of the shape; *rhabdoformis* rod-shaped.

Characteristics are summarized in Table BXII.δ.24. Isolated from a water-oil separation system (North Sea oil platform) with propionate as selective substrate.
The mol% G + C of the DNA is: 50.6 (HPLC).
Type strain: M16, DSM 8777.
GenBank accession number (16S rRNA): U12253.

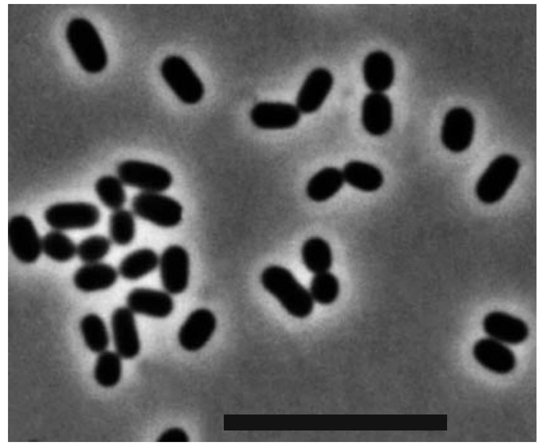

FIGURE BXII.δ.33. Phase-contrast micrograph of *Desulfobulbus marinus* (viable cells). Bar = 10 μm.

Genus II. **Desulfocapsa** *Janssen, Schuhmann, Bak and Liesack 1997, 601[VP] (Effective publication: Janssen, Schuhmann, Bak and Liesack 1996, 190)*

Jan Kuever, Fred A. Rainey and Friedrich Widdel

De.sul.fo.cap′ sa. L. pref. *de* from; L. n. *sulfur* sulfur; L. n. *capsa* box; M.L. fem. n. *Desulfocapsa* a sulfate-reducing box.

Cells are round-ended rods, or elongated rods with pointed ends, 0.5–0.9 × 2.0–4.0 μm. Cells are motile by means of single subpolarly inserted flagella, but motility can be limited to only a few cells in the population of some species. No spores are formed. Metabolism is strictly anaerobic. Simple organic compounds are incompletely oxidized, with sulfate as electron donor that is reduced to sulfide. One species of the genus, *D. sulfexigens*, is not able to use sulfate as electron acceptor. **Inorganic sulfur compounds are disproportionated to sulfate and sulfide** and support **chemolithoautotrophic growth with CO_2 as carbon source**. Fermentative growth with organic compounds is not possible. The optimal pH range for growth is 7.3–7.5. The optimal temperature range for growth is 20–30°C. Thermophilic species are not known. The NaCl requirement varies within the genus; growth of the type strain is inhibited at an NaCl concentration higher than 15 g/l. The genus comprises marine and freshwater strains. All described species contain cytochromes and no desulfoviridin. Occur in sediments of freshwater or marine habitats close to the anoxic/oxic interface.

The mol% G + C of the DNA is: 47–51.

Type species: **Desulfocapsa thiozymogenes** Janssen, Schuhmann, Bak and Liesack 1997, 601 (Effective publication: Janssen, Schuhmann, Bak and Liesack 1996, 190.)

Further descriptive information

Ethanol, 1-propanol, and butanol are used as electron donors with sulfate as electron acceptor and are oxidized to the respective fatty acids. *D. sulfexigens* is not able to grow with sulfate as the electron acceptor; only small amounts of sulfate were reduced to sulfide in the presence of formate and hydrogen, without growth (Finster et al., 1998).

Disproportionation of thiosulfate and sulfite added to media in concentrations of a few mmol/l is thermodynamically favorable with these compounds serving as the only sources to sustain growth. The energetically less favorable disproportionation of elemental sulfur to sulfide and sulfate allows growth only if products are scavenged, for instance by the addition of ferric hydroxide as a sulfide trap. Cell synthesis occurs autotrophically with CO_2 as carbon source; the pathway for CO_2 fixation is unknown.

The optimal pH range for growth of *D. thiozymogenes* is 7.3–7.5, whereas *D. sulfexigens* shows optimal growth between pH 6.7 and 7.3. The optimal temperature range for growth is 20–30°C. *D. sulfexigens* requires an NaCl concentration of 15 g/l, whereas growth of *D. thiozymogenes* is inhibited at this concentration. The genus contains marine and freshwater strains.

Enrichment and Isolation Procedures

For specific enrichment, a sulfate-free marine or freshwater mineral medium (e.g., as described for *Desulfobacter*) reduced with sulfide should be used. Thiosulfate at a concentration of 10 mM is added as the only substrate from sterile stock solution. Acetate may or may not be added at low concentration (1–2 mM) for enrichment of potential nonautotrophic (chemolithoheterotrophic) species, or autotrophic species that are stimulated by acetate. Bottles or tubes (100-, 50-, or 20-ml capacity) can serve as culture vessels and are kept anoxic with tight screw caps, or by using a headspace of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated with sediment from the anoxic/oxic interface; 3–5% of the total culture volume should be added. *Desulfocapsa* species may also be enriched and isolated via direct serial dilution of anoxic environmental samples in liquid medium (according to most-probable-number method) or agar medium with thiosulfate as the only substrate. Incubations should be done at 30°C. Pure cultures are obtained by repeated application of agar dilutions as described in the chapter for the genus *Desulfobacter*, using the combined substrates described above. Alternative substrates are sulfite (10mM) and sulfur. For specific enrichment of *D. sulfexigens*, sulfur in the presence of amorphous ferric hydroxide is used (Finster et al., 1998), followed by isolation of pure cultures with thiosulfate as electron donor. Ferric hydroxide is prepared as described by Lovley and

Phillips (1986). Stock solutions of thiosulfate and sulfite are filter sterilized, whereas amorphous ferric hydroxide is autoclaved. Sulfur is prepared as described in the chapter for the genus *Desulfuromonas*.

Maintenance Procedures

Maintenance procedures have not been described. Procedures described for other genera in this chapter may be attempted.

Differentiation of the genus *Desulfocapsa* from other genera

Members of the genus *Desulfocapsa* can be distinguished from other sulfate-reducing bacteria by the limited number of electron donors used for the reduction of sulfate or other sulfur compounds. A unique feature of this genus is the ability to grow autotrophically by disproportionation of thiosulfate, sulfite, or sulfur (in the presence of ferric iron); other sulfate-reducing bacteria may also be able to disproportionate these compounds, but have not been described to grow autotrophically. *Desulfovibrio sulfodismutans* and *Desulfobulbus propionicus* require acetate as carbon source for growth by disproportionation of reduced sulfur compounds. However, a clear differentiation can only be obtained by comparative analysis of 16S rDNA sequences.

Taxonomic Comments

D. thiozymogenes and *D. sulfexigens* fall into the *Desulfobulbaceae* of the *Deltaproteobacteria*. The closest relatives are *Desulfofustis glycolicus*, *Desulforhopalus vacuolatus*, and members of the genus *Desulfobulbus*.

Janssen, P.H., A. Schuhmann, F. Bak and W. Liesack. 1996. Disproportionation of inorganic sulfur compounds by the sulfate-reducing bacterium *Desulfocapsa thiozymogenes* gen. nov., sp. nov. Arch. Microbiol. *166*: 184–192.

List of species of the genus Desulfocapsa

1. **Desulfocapsa thiozymogenes** Janssen, Schuhmann, Bak and Liesack 1997, 601[VP] (Effective publication: Janssen, Schuhmann, Bak and Liesack 1996, 190.)
thi.o.zy.mo'ge.nes. Gr. n. *thios* sulfur; Gr. n. *zyme* leaven, ferment; Gr. v. *gennaio* to produce; M.L. adj. *thiozymogenes* causing a fermentation of sulfur.

Characteristics are summarized in Table BXII.δ.25. Ethanol, 1-propanol, and 1-butanol are used as electron donors with sulfate as electron acceptor and are oxidized to the respective fatty acids. Thiosulfate and sulfite are disproportionated to sulfate and sulfide with concomitant growth. Sulfur is disproportionated to sulfate and sulfide, but supports growth only in the presence of ferric iron. The type strain has been isolated from anoxic freshwater sediment from Lake Brabrand, Arhus (Denmark) with thiosulfate as the sole energy source and acetate to stimulate carbon assimilation.

The mol% G + C of the DNA is: 50.7 (HPLC).
Type strain: Bra2, DSM 7269.
GenBank accession number (16S rRNA): X95181.

2. **Desulfocapsa sulfexigens** Finster, Liesack and Thamdrup 2000, 1699[VP] (Effective publication: Finster, Liesack and Thamdrup 1998, 124.)
sulf.ex'i.gens. L. n. *sulfur* sulfur; L. v. *exigo* to demand; M.L. part. adj. *sulfexigens,* demanding sulfur for growth.

Characteristics are summarized in Table BXII.δ.25. Thiosulfate and sulfite are disproportionated to sulfate and sulfide with concomitant growth. Sulfur is disproportionated to sulfate and sulfide and supports growth only in the presence of ferric iron. The type strain was isolated from oxidized marine sediment of the basin of Arcachon (France) with sulfur as the electron donor and ferric iron as hydrogen sulfide scavenging agent. The isolate cannot grow with sulfate as the electron acceptor.

The mol% G + C of the DNA is: 47.2 (HPLC).
Type strain: SB164P1, DSM 10523.
GenBank accession number (16S rRNA): Y13672.

Genus III. **Desulfofustis** *Friedrich, Springer, Ludwig and Schink 1996, 1067*[VP]

Michael Friedrich and Bernhard Schink

De.sul.fo.fus′tis. L. pref. *de* from; L. n. *sulfur* sulfur; L. n. *fustis* club; M.L. masc. n. *Desulfofustis* a club-shaped sulfate reducer.

Straight or slightly curved rods, spore formation not observed. Gram negative. Metabolism anaerobic, respiratory. **Organic substrates oxidized incompletely to acetate (and CO_2); glycolate or glyoxylate completely oxidized to CO_2. Sulfate or sulfite used as electron acceptors and reduced to H_2S.** Grouped with *Deltaproteobacteria* based on 16S rDNA gene sequence analysis.

Type species: **Desulfofustis glycolicus** Friedrich, Springer, Ludwig and Schink 1996, 1067.

Further descriptive information

Desulfofustis glycolicus clusters with the *Deltaproteobacteria*, close to *Desulforhopalus vacuolatus* and *Desulfobulbus propionicus* (90.6% and 86.5% 16S rDNA sequence similarity, respectively). These microorganisms represent a subgroup within the *Deltaproteobacteria*.

D. glycolicus reduces sulfate, sulfite, and elemental sulfur to H_2S. Other terminal electron acceptors such as thiosulfate, nitrate, and fumarate cannot be reduced. The following compounds serve as electron donor and carbon sources: glycolate, glyoxylate, L-lactate, L-malate, fumarate, succinate, and yeast extract (0.1%). *D. glycolicus* oxidizes only glycolate and glyoxylate completely to CO_2. All other electron donors are oxidized neither completely to CO_2 nor incompletely to 1 mol acetate per mol of electron donor, as expected for incomplete oxidation stoichiometries. Reduced acetate formation is counterbalanced by increased H_2S formation. This unusual substrate degradation balance seen in the type strain may result from the presence of carbon monoxide dehydrogenase, which may be responsible for partial oxidation of acetate. However, the mechanism of acetate excretion and activation in *D. glycolicus* is still unknown, since phosphotransacetylase and acetate kinase are lacking. *D. glycolicus* grows with H_2 as electron donor but acetate is required for assimilatory metabolism.

Glycolate is oxidized by a membrane-associated methylene-blue-dependent glycolate dehydrogenase (E.C.1.1.99.14), but the further reaction sequence leading to complete oxidation is not known.

D. glycolicus strains may be cultured in defined medium[1] with sulfate as electron acceptor and glycolate, lactate, malate, fumarate, or succinate as electron donor and carbon source. Cells grown with glyoxylate as carbon source and electron donor exhibit long and unpredictable lag phases upon transfer on the same substrate. An inoculum size of 10% is recommended, especially with older cultures as inoculum source.

Cytochromes of *b*- and *c*-type are present in both the membranes and the cytoplasmic fraction, and a menaquinone-5 (H_2) as major quinone. *D. glycolicus* contains a sulfite reductase of

1. The defined medium is prepared as described for *Desulfobacter*, with the following additions (g/l): NaCl, 3.0; $MgCl_2 \cdot 2H_2O$, 3.0; vitamin solution (*p*-aminobenzoic acid, 40 mg/l; biotin, 10 mg/l; nicotinic acid, 100 mg/l; Ca-D(+) pantothenate, 50 mg/l; pyridoxamine HCl, 150 mg/l; thiamine dichloride, 100 mg/l; folic acid, 30 mg/l; DL-α-liponic acid; solutions sterilized by filtration), and cyanocobalamin (100 mg/l), 1 ml/liter each; sodium selenite-tungsten solution ($Na_2SeO_3 \cdot 2H_2O$, 3 mg/l; $Na_2WO_4 \cdot 2H_2O$, 4 mg/l; KOH, 0.7 g/l), 1 ml/l. Sodium glycolate (10 mM final concentration) is added from a filter-sterilized stock solution as organic substrate.

desulforubidin type, as identified by its characteristic absorption maxima (279, 396, 545, and 580 nm wavelength). The purified protein is a heteropolymer consisting of three subunits with molecular masses of 42.5 (α), 38.5 (β), and 13 (γ) kDa.

The ecological role of *D. glycolicus* in its natural habitat, a marine sediment, may be glycolate degradation. However, in nature glycolate is formed mainly as a result of photorespiration of photoautotrophs under conditions of high light intensity and low CO_2 availability, and this type of metabolism is rarely encountered in marine sediments. Therefore, other ecologically relevant habitats for glycolate-oxidizing sulfate-reducing bacteria may be mats of photoautotrophs, such as a cyanobacterial mat in a hypersaline pond system. In the upper, hyperoxic layer of this system, Fründ and Cohen (1992) found evidence for sulfate-dependent glycolate oxidation.

Enrichment and Isolation Procedures

D. glycolicus can be selectively enriched using glycolate-sulfate medium with NaCl concentrations corresponding to the salinity of the inoculum source. Anoxic black mud from marine habitats (2–5% of the culture volume) is used to inoculate medium in screw-capped bottles. Enrichments are incubated at 28°C with occasional mixing of the bottles. After strong H_2S formation (usually within 3 to 4 weeks) in glycolate enrichments as compared to controls without organic substrate added, enrichments can be transferred to fresh culture media. Subsequently, pure cultures can be obtained by the agar shake dilution method (for details see section on *Desulfobacter*). *D. glycolicus* forms disc-shaped brownish-to-black colonies in agar shake dilutions.

Maintenance Procedures

Pure cultures may be stored anaerobically in liquid medium at room temperature in the dark. Stock cultures should be transferred every 1–2 months.

For long-term preservation, a dense cell suspension of *D. glycolicus* may be suspended in anaerobic medium without bicarbonate containing DMSO (5% v/v), glycerol (10% v/v), and peptone (1% w/v), sealed in sterile glass capillaries, and stored in liquid nitrogen.

Differentiation of the genus *Desulfofustis* from other genera

The genus *Desulfofustis* can be differentiated from other genera mainly by 16S rDNA gene sequence comparison, and by its growth with glycolate as electron donor and carbon source. However, since only a single species has been described so far, it is not known whether glycolate is a unique electron donor and carbon source for other potential members of this genus.

Taxonomic Comments

Based on 16S rDNA sequence analysis, *D. glycolicus* forms a subgroup within the *Deltaproteobacteria*, together with *Desulforhopalus vacuolatus* and *Desulfobulbus propionicus* (90.6% and 86.5% 16S rDNA sequence similarity, respectively). Several cloned partial 16S rDNA sequences (clones A30, A36, A33; RDP tree), and partial sequences of *Desulfobulbus* spp. (Dbb.sp1 and Dbb.sp.2; RDP tree) are more closely related to *D. glycolicus* than *Desulforhopalus vacuolatus* and *Desulfobulbus propionicus*; however, only partial sequences are available for phylogenetic comparison.

List of species of the genus Desulfofustis

1. **Desulfofustis glycolicus** Friedrich, Springer, Ludwig and Schink 1996, 1067[VP]
gly.co' li.cus. M.L. n. *acidum glycolicum* glycolic acid; M.L. adj. *glycolicus* referring to glycolic acid as the key substrate of this species.

Straight or slightly curved rods, 0.55 × 2.0–4.5 µm. Motile by means of one subterminally inserted flagellum. Anaerobic, respiratory metabolism. Chemoorganotrophic, using glycolate, glyoxylate, L-lactate, L-malate, fumarate, succinate, yeast extract, or hydrogen (in the presence of CO_2 and acetate) as electron donors and carbon sources for anaerobic respiration; only glycolate and glyoxylate are completely oxidized to CO_2. Sulfate, sulfite, and S^0 used as electron acceptors and are reduced to H_2S. Thiosulfate or nitrate not reduced. Temperature range for growth is 15–37°C, optimal at 28°C. pH range 6.7–8.3, optimal at pH 7.4. Occur in anoxic sediments from brackish and marine water sources.

The mol% G + C of the DNA is: 56.2 ± 0.2 (HPLC).
Type strain: PerGlyS, DSM 9705.
GenBank accession number (16S rRNA): X99707.

Genus IV. **Desulforhopalus** *Isaksen and Teske 1999, 935[VP] (Effective publication: Isaksen and Teske 1996, 167)*

Jan Kuever, Fred A. Rainey and Friedrich Widdel

De.sul.fo.rho' pa.lus. L. pref. *de* from; L. n. *sulfur* sulfur; L. n. *rhopalus* cudgel; M.L. masc. n. *Desulforhopalus* cudgel-formed sulfate reducer.

Cells are oval to rod shaped with rounded ends, 1.5–1.8 × 3–5 µm. Longer cells occur in the stationary phase. Cells may contain gas vesicles. Occur singly, in pairs, or short chains. Spore formation is not observed. Gram negative and nonmotile. Strictly anaerobic, having both a respiratory and a fermentative type of metabolism. **Chemoorganotrophs**, using propionate, lactate, pyruvate, ethanol, and 1-propanol **as electron donors and carbon sources**. **Organic substrates are incompletely oxidized to acetate and CO_2. Chemolithoheterotrophic growth occurs with H_2 as the electron donor in the presence of acetate** as the organic carbon source. **Sulfate, sulfite, and thiosulfate serve as terminal electron acceptors and are reduced to H_2S.** Sulfur and oxygen are not reduced; nitrate is reduced to ammonia only by *D. singaporensis*. **In the absence of an external electron acceptor, growth occurs by fermentation of pyruvate and lactate.** *D. singaporensis* can grow by fermentation of 2-aminoethansulfonate (taurine) and by disproportionation of sulfite in the presence of acetate.

All species are able to grow in simple defined media containing a reductant. Some species require the vitamins pyridoxamine, nicotinate, and 4-aminobenzoate for growth. The optimal pH range for growth is 6.8–7.2. The optimal temperature range for growth is 20–30°C. Thermophilic species are not known. At least

5 g NaCl and 1 g $MgCl_2 \cdot 6H_2O$ per liter are required for growth. Desulfoviridin is absent. Occur in the upper part of anoxic marine or brackish sediment.

The mol% G + C of the DNA is: 48.4–50.6.

Type species: **Desulforhopalus vacuolatus** Isaksen and Teske 1999, 935 (Effective publication: Isaksen and Teske 1996, 167.)

Further descriptive information

The temperature range for growth of *D. vacuolatus* is 0–24°C, with an optimal growth temperature of 18–19°C. In contrast, *D. singaporensis* has a temperature range for growth between 20 and 35°C, with an optimal at 31°C.

Propionate, lactate, pyruvate, propanol, and ethanol are utilized as electron donors and organic carbon sources. Oxidation is incomplete and leads to formation of acetate as an organic end product. Disproportionation of sulfite allows growth only in the presence of acetate as carbon source.

Desulfoviridin is not present. Major cellular fatty acids of *D. vacuolatus* are $C_{15:1\ \omega6c}$ and $C_{17:1\ \omega6c}$ (Knoblauch et al., 1999). *Desulforhopalus* strains occur in the upper part of reduced marine or brackish sediments.

D. vacuolatus may be cultured in a defined medium (e.g., as described for *Desulfobacter*) with sulfate as electron acceptor and lactate or various other substrates as the electron donor and carbon source. The type strain requires at least 5 g NaCl and 1 g $MgCl_2 \cdot 6H_2O$ per liter for growth. Ammonium ions are used as the nitrogen source; *D. singaporensis* can also use taurine. The vitamins pyridoxamine, nicotinate, and 4-aminobenzoate are required as growth factors for *D. vacuolatus*.

Enrichment and Isolation Procedures

For the selective enrichment of *D. vacuolatus* strains, a marine medium (e.g., as described for *Desulfobacter*) with lactate or propionate as electron donor and thiosulfate as electron acceptor may be used. Bottles or tubes (100-, 50-, or 20-ml capacity) can serve as culture vessels and are kept anoxic with tight screw caps, or by using a headspace of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated with black anaerobic mud from a marine habitat; 2–5% of the total culture volume should be added. *D. vacuolatus* strains may also be enriched and isolated via direct serial dilution of anoxic environmental samples in liquid medium (according to most-probable-number method) or agar medium (see next paragraph) with lactate or propionate added as organic substrate. Enrichment cultures are incubated at 10°C. Occasional mixing may favor growth. After intense formation of H_2S has occurred, transfers to fresh medium are made. Enrichment cultures should be mixed before subculturing. Use of thiosulfate as electron acceptor under psychrophilic growth conditions (around 4–8°C) favors selection of *Desulforhopalus* strains over marine *Desulfobulbus* strains. For enrichment of *D. singaporensis*, a combination of malate and taurine (each 10 mM) in the absence of sulfate should be used. The NaCl concentration used should be the same as for sulfate-reducing bacteria from brackish water habitats (5–10 g/l).

Pure cultures of *Desulforhopalus* strains are obtained by repeated application of the agar dilution method. The method is similar to that described for the genus *Desulfobacter*, except that another electron donor (see above) is added to the molten concentrated agar solution.

Maintenance Procedures

Maintenance procedures have not been described. Procedures described for other genera in this chapter may be attempted.

Differentiation of the genus *Desulforhopalus* from other genera

Physiologically, *Desulforhopalus* species share many features with members of the genus *Desulfobulbus*. Both oxidize propionate incompletely to acetate and CO_2 and can grow by fermentation. Clear differentiation requires comparative 16S rDNA sequences analysis. A more or less reliable detection of *Desulforhopalus* cells in naturally enriched populations may be possible using the oligonucleotide probe described below.

Taxonomic Comments

The closest relatives of *Desulforhopalus* species are members of the genera *Desulfotalea*, *Desulfocapsa*, *Desulfobulbus*, and *Desulfofustis glycolicus*. A signature sequence for *Desulforhopalus* species, *Desulfofustis glycolicus*, *Desulfocapsa sulfexigens*, and other closely related sulfate-reducing bacteria is 5′-CCCCCTCCAGTACTCAAG-3′ (oligonucleotide probe DSR651), which binds to the 16S rRNA corresponding to position 5′-651–668-3′ of the *Escherichia coli* 16S rRNA sequence (Manz et al., 1998).

As indicated by its different physiological properties and phylogenetic distance, inclusion of *D. singaporensis* within the genus remains questionable. More detailed characterization in the future might justify the reclassification of *D. singaporensis* as a new genus within the *Desulfobulbaceae*.

Isaksen, M.F. and A. Teske. 1996. *Desulforhopalus vacuolatus* gen. nov., sp. nov., a new moderately psychrophilic sulfate-reducing bacterium with gas vacuoles isolated from a temperate estuary. Arch. Microbiol. *166*: 160–168.

List of species of the genus Desulforhopalus

1. **Desulforhopalus vacuolatus** Isaksen and Teske 1999, 935[VP] (Effective publication: Isaksen and Teske 1996, 167.)
va.cu.o.la′tus. M.L. n. *vacuolatus* vacuolated due to the morphology of the cells.

Characteristics are described in Table BXII.δ.26. The type strain was isolated from anoxic marine sediment, Kysing Fjord (Denmark), with lactate or propionate as only organic substrate and thiosulfate as electron acceptor.

The mol% G + C of the DNA is: 48.4 (HPLC).
Type strain: itk10, DSM 9700.
GenBank accession number (16S rRNA): L42613.

2. **Desulforhopalus singaporensis** Lie, Clawson, Godchaux and Leadbetter 2000, 1699[VP] (Effective publication: Lie, Clawson, Godchaux and Leadbetter 1999, 3333.)
sin.ga.po′ren.sis. M.L. n. *singaporensis* referring to the place of isolation, Republic of Singapore.

The characteristics are described in Table BXII.δ.26. Cells produce nonprosthecate structures called spinae. The type strain was isolated from anoxic sediment from a salt marsh (Singapore) using 10 mM malate and 10 mM taurine. Taurine allows growth in the absence of a nitrogen source.

The mol% G + C of the DNA is: 50.6 (HPLC).
Type strain: T1, DSM 12130.
GenBank accession number (16S rRNA): AF118453.

[a]Symbols: nr, not reported; +, present, observed in all species; −, not present, not observed; ±, variable; (+), poorly motile, poor growth; I, incomplete; py, pyrodoxine; ni, nicotinate; pa, *p*-aminobenzoate.

[b]Used as electron donor only in the presence of acetate as carbon source.

Genus V. **Desulfotalea** *Knoblauch, Sahm and Jørgensen 1999, 1641*[VP]

Jan Kuever, Fred A. Rainey and Friedrich Widdel

De.sul.fo.ta'le.a. L. pref. *de* from; L. n. *sulfur* sulfur; L. fem. n. *talea* a rod; M.L. fem. n. *Desulfotalea* a sulfate-reducing rod.

Cells are large rods of variable length, 0.6–0.7 × 1.6–7.4 μm. Cells may be motile, but motility may not be observed in cultures at the beginning of growth. Cells stain Gram negative. Spores are not formed. Strictly anaerobic, having a respiratory and fermentative type of metabolism. **Chemoorganotrophs**, using formate, carboxylic acids, amino acids, and alcohols **as electron donors and also as carbon sources**. **Oxidation is incomplete and leads to acetate. Sulfate and ferric citrate serve as terminal electron acceptors and are reduced to sulfide and ferrous citrate, respectively.** The type species can also use thiosulfate and sulfite as electron acceptors. Elemental sulfur, Fe(III)-oxohydroxide, nitrate, and nitrite are not used as electron acceptors. **Fermentative growth on pyruvate and fumarate is possible. Obligately or facultatively psychrophilic.** The temperature optimal for growth is 10–18°C, and growth still occurs in saltwater at −1.8°C. Thermophilic species are not known. The optimal pH for growth is between 7.2 and 7.9. The species require sodium chloride and magnesium chloride, and optimal growth occurs at brackish or marine salt concentrations, depending on the strain. Media containing a reductant are necessary for growth. Vitamins are not required. Desulfoviridin is absent. Occur in permanently cold marine sediments.

The mol% G + C of the DNA is: 42–47.

Type species: **Desulfotalea psychrophila** Knoblauch, Sahm and Jørgensen 1999, 1641.

Further descriptive information

Formate, lactate, pyruvate, fumarate, amino acids, and alcohols serve as electron donors and also as carbon sources for *Desulfotalea* species. Growth on H_2 requires low concentrations (1–2 mM) of acetate as an organic carbon source in addition to CO_2. No growth on fructose and glucose. The ability to use thiosulfate and sulfite instead of sulfate varies from species to species. *D. arctica* reduces sulfur without growth. Sulfur and thiosulfate are not disproportionated.

The temperature range for growth of *D. psychrophila* is −1.8–19°C, with an optimal growth temperature of 10°C. *D. arctica* has a temperature range for growth between −1.8 and 26°C; with an optimal at 18°C. Mesophilic and thermophilic species are not known.

Optimal growth of the type species requires an NaCl concentration of 10 g/l, whereas *D. arctica* needs 19 g/l. Vitamins are not required for growth. *Desulfotalea* species contain phosphatidylethanolamine, diphospatidylglycerol, and phosphatidylglycerol as lipids; MK-6 or MK-6(H_2) are the sole menaquinones. Major cellular fatty acids are $C_{16:1\ \omega 7c}$ and $C_{16:1\ \omega 5c}$. Described species do not contain desulfoviridin. Their habitat is permanently cold marine sediments.

Enrichment and Isolation Procedures

For specific enrichment, synthetic marine mineral medium (e.g., as described for *Desulfobacter*) reduced with sulfide should be used. As electron donor and carbon source, 10 mM lactate is added from sterile stock solutions. Bottles or tubes (100-, 50-, or 20-ml capacity) can serve as culture vessels and are kept anoxic with tight screw caps, or by using a headspace of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated with anoxic sediment from a marine habitat; 3–5% of the total culture volume should be added. *Desulfotalea* species may also be enriched and isolated via direct serial dilution of anoxic environmental samples in liquid medium (according to most-probable-number method) or agar medium (see next paragraph) with lactate as organic substrate. Incubations should be done at 4°C. Sulfide production after 8–10 weeks indicates development of sulfate-reducing bacteria. After some transfers, a stable enrichment is obtained. This can be used for isolation of pure cultures by the repeated application of agar dilutions, as described in the chapter for the genus *Desulfobacter* (modified after Isaksen and Teske, 1996), or by serial dilution in liquid media using lactate as electron donor.

Maintenance Procedures

Stock cultures are transferred every 4–6 weeks. *Desulfotalea* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen. Transfers should be done every six weeks. Incubation at 4°C and an inoculum size of 10% are recommended.

Differentiation of the genus *Desulfotalea* from other genera

Strains of *Desulfotalea* can be distinguished from other sulfate-reducing bacteria by physiological properties. The most important characteristic of *Desulfotalea* species for differentiation from other species is the requirement for a lower temperature for optimal growth, compared to mesophilic sulfate-reducers. The inability to grow with propionate allows a separation from other psychrophilic or mesophilic sulfate-reducers, like *Desulfobulbus* spp., *Desulfofaba gelida*, and *Desulforhopalus* spp. Growth by disproportionation of reduced sulfur compounds as observed in psychrotolerant *Desulfocapsa* spp. does not occur within the genus *Desulfotalea*. However, a clear differentiation can only be done by comparative analysis of 16S rDNA sequences.

Taxonomic Comments

The closest relatives of *Desulfotalea* species are *Desulforhopalus vacuolatus*, *Desulfofustis glycolicus*, and members of the genus *Desulfocapsa*. A signature sequence for *Desulfotalea* species, *Desulfofustis glycolicus*, and other closely related sulfate-reducing bacteria is 5′-CCATCTGACAGGATTTTAC-3′ (oligonucleotide probe Sval428), which binds to the 16S rRNA corresponding to position 5′-428–446-3′ of the *Escherichia coli* 16S rRNA sequence (Sahm et al., 1999).

Family III. **Nitrospinaceae** *fam. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Ni.tro.spi.na' ce.ae. M.L. masc. n. *Nitrospina* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Nitrospinaceae* the *Nitrospina* family.

The family *Nitrospinaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genus *Nitrospina* (type genus).

Description is the same as for the genus *Nitrospina*.

Type genus: **Nitrospina** Watson and Waterbury 1971, 225.

Genus I. **Nitrospina** *Watson and Waterbury 1971, 225*[AL]

Eva Spieck and Eberhard Bock

Ni.tro.spi' na. L. n. *nitrum* nitrate; L. n. *spina* spine; M.L. masc. n. *Nitrospina* nitrate sphere.

Rod-shaped cells 0.3–0.5 × 1.7–6.6 μm. Spherical forms 1.4–1.5 μm in diameter are found in old cultures. Cells reproduce by binary fission. **An intracytoplasmic membrane system is missing**, but occasionally invaginations of the cytoplasmic membrane occur. Gram negative. Nonmotile. **Aerobic**. The major source of energy and reducing power is from the **oxidation of nitrite to**

nitrate. **Obligate lithoautotrophs**. Optimal growth requires 70–100% seawater. Cells occur in marine environments.

The mol% G + C of the DNA is: 57.7.

Type species: **Nitrospina gracilis** Watson and Waterbury 1971, 225.

Further descriptive information

The two strains of *Nitrospina* are peripherally related to the *Deltaproteobacteria* (family *Desulfarculaceae*) (Teske et al. 1994), the class in which the genus *Nitrospina* was first placed. Since no phototrophic organisms are known so far in this class, it is questionable whether *Nitrospina* is derived from photosynthetic ancestry. Additional details and a comparison of the biochemical properties of *Nitrospina* to those of other nitrite-oxidizing genera can be found in the introductory chapter "Lithoautotrophic Nitrite-Oxidizing Bacteria." Detailed treatments of the ecology of nitrite-oxidizing bacteria and of the phylogeny of these organisms can be found in the introductory chapter "Nitrifying Bacteria."

Cells are straight, slender rods without intracytoplasmic membranes (Fig. BXII.δ.34). Resting forms are shown in Fig. BXII.δ.35. Several modes of electron microscopy reveal the presence of particles associated with the cell membrane (Figs. BXII.δ.36, BXII.δ.37, and BXII.δ.38). In negatively stained preparations, irregular particles with a diameter of 13–17 nm are bound to the outside of the cytoplasmic membrane (Fig. BXII.δ.36). In ultrathin sections, electron-dense material is visible in the periplasmic space (Watson and Waterbury, 1971). The most abundant proteins of crude extracts of *Nitrospina* have molecular masses of 130 and 47 kDa (Ehrich, personal communication). The β-subunit of the nitrite-oxidizing system (β-NOS) of *Nitrospina* has been shown to be located in the periplasmic space by labeling with monoclonal antibodies (MAbs) against the β-subunit of the nitrite oxidoreductase (β-NOR) of *Nitrobacter* (Fig. BXII.δ.37). This protein has a molecular mass of 48 kDa, which is similar to the β-NOS of *Nitrospira*. Cytochromes of the *c*-type but not of the *a*-type were detected. Cell suspensions show characteristic absorption peaks at 425, 532 and 553 nm. Glycogen-like inclusion bodies may represent storage material. No carboxysomes have been found in this organism. The temperature range for growth is 20–30°C and the pH range is 7.0–8.0. The two strains of *Nitrospina gracilis* have been isolated from Atlantic and Pacific seawater. 16S rDNAs with high similarities to *Nitrospina* were found in the microbial community of marine sponges (Hentschel et al., 2002). No terrestrial strains are known, although 16S rDNA clones related to *Nitrospina* were obtained recently from uranium waste piles (Selenska-Pobell, 2002). A further species, represented by strain 347 from the Black Sea, was separated by 16S rRNA sequence analysis (Ludwig, personal communication).

FIGURE BXII.δ.34. Negatively stained cell of *Nitrospina gracilis*. Bar = 500 nm.

Enrichment and Isolation Procedures

Nitrite oxidizers can be isolated using a mineral medium containing nitrite; the compositions of media for lithotrophic, mixotrophic, and heterotrophic growth are given in Table BXII.δ.28. Serial dilutions of enrichment cultures must be incubated for one to several months in the dark. Since nitrite oxidizers are sensitive to high partial pressures of oxygen, cell growth on agar surfaces is limited. Nitrite oxidizers can be separated from heterotrophic contaminants by Percoll gradient centrifugation and subsequent serial dilution (Ehrich et al., 1995).

Maintenance Procedures

Nitrifying organisms can survive starvation for more than one year when kept at 17°C in liquid medium. Nevertheless, cells should be transferred to fresh media every four months. Three different growth media for nitrite oxidizers are listed in Table

FIGURE BXII.δ.35. Resting forms of *Nitrospina gracilis*. Bar = 500 nm.

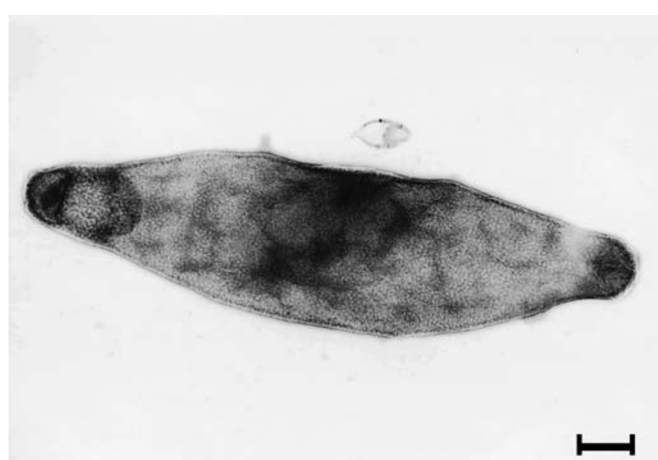

FIGURE BXII.δ.36. Electron micrograph of a partly destroyed cell of *Nitrospina gracilis* in negative contrast. Hexagonal particles are shining through the outer membrane. Bar = 250 nm.

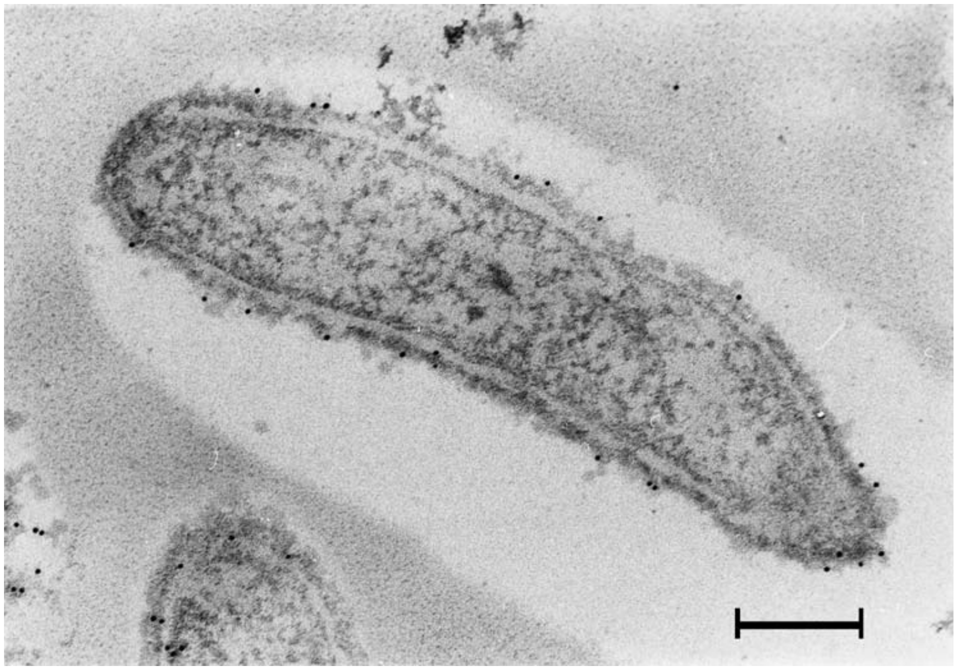

FIGURE BXII.δ.37. Ultrathin section of *Nitrospina gracilis*. The β-NOS was localized in the periplasmic space as shown by immunogold-labeling (MAbs 153-3). Bar = 250 nm.

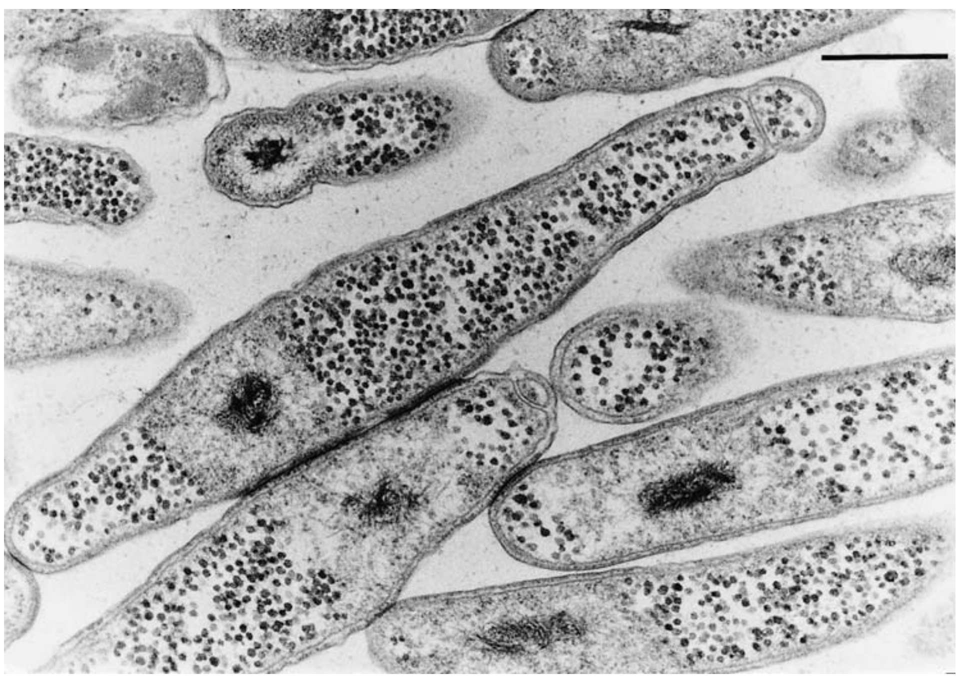

FIGURE BXII.δ.38. Ultrathin section of *Nitrospina* spec. 347. Regularly arranged particles are located in the periplasmic space. Bar = 500 nm.

BXII.δ.28. Freezing in liquid nitrogen is a suitable technique for maintenance of stock cultures suspended in a cryoprotective buffer containing sucrose and histidine.

Differentiation of the genus *Nitrospina* from other genera

The nitrite oxidizers are a diverse group of long or short rods, cocci, and spirilla. *Nitrospina* is nonmotile and has no carboxysomes or internal membranes, whereas the genera *Nitrobacter* and *Nitrococcus* possess a complex arrangement of intracytoplasmic membranes in the form of flattened vesicles or tubes. The taxonomic categorization is based on the work of Sergei and Helene Winogradsky (Winogradsky, 1892). Traditionally, the classification of genera is performed primarily on cell shape and arrangement of intracytoplasmic membranes. So far, four morphologically distinct genera (*Nitrobacter*, *Nitrococcus*, *Nitrospina*, and *Nitrospira*) have been described; the four genera contain a total of eight species (Watson et al., 1989; Bock and Koops, 1992; Ehrich

TABLE BXII.δ.28. Three different media for lithoautotrophic (medium A for terrestrial strains; medium B for marine strains), mixotrophic (medium C), and heterotrophic (medium C without $NaNO_2$) growth of nitrite oxidizers

[e]After sterilization pH should be 7.4–7.8.

et al., 1995; Sorokin et al., 1998). Differential traits of the four genera of nitrite-oxidizing bacteria are given in Table BXII.δ.29. Further properties are given in Table BXII.δ.30, and fatty acid profiles are listed in Table BXII.δ.31.

Nitrospina can be separated from *Nitrobacter* and *Nitrococcus* by means of monoclonal antibodies that recognize the key enzyme (Table BXII.δ.29). Aamand et al. (1996) developed three monoclonal antibodies (MAbs) that recognize the α- and the β-subunit of the NOR of *Nitrobacter*. The key enzyme NOR is ubiquitous in nitrite-oxidizing bacteria. MAb Hyb 153-2 was specific for the α-NOR of *Nitrobacter*, whereas MAb Hyb 153-1 recognized the β-NOSs of both *Nitrobacter* and *Nitrococcus*. The MAb Hyb 153-3 recognized the β-NOSs of *Nitrobacter*, *Nitrococcus*, *Nitrospina* and *Nitrospira* (Bartosch et al., 1999). Thus, the suite of MAbs permits detection of all known nitrite oxidizers and allows discrimination of *Nitrobacter* and *Nitrococcus* from *Nitrospina* and *Nitrospira*.

Taxonomic Comments

The classification of *Nitrospina* as a distinct genus is based on the unique morphology and ultrastructure of this organism. 16S rRNA sequence analysis confirmed the phylogenetic position of this organism. However, the phylogenetic affiliation of *Nitrospina* with the *Deltaproteobacteria* remains provisional due to the very limited data set (Ludwig, personal communication). Euclidian distances derived from fatty acid profiles indicated a higher similarity between *Nitrospina* and *Nitrospira* than between either genus and the nitrite-oxidizing bacteria of the *Proteobacteria* (*Nitrobacter* and *Nitrococcus*) (Lipski et al., 2001).

List of species of the genus Nitrospina

1. **Nitrospina gracilis** Watson and Waterbury 1971, 225[AL]
gra′ ci.lis. L. adj. *gracilis* slender.

The morphological, cultural and biochemical characteristics are as described for the genus. No growth occurs below 14°C or above 40°C. The minimum generation time is 24 h. High concentrations of nitrite are toxic. Growth is inhibited by many organic compounds but mixotrophic growth with low concentrations of pyruvate, yeast extract and peptone is possible. The type strain was isolated from a depth of 13 m in open Atlantic Ocean waters approximately 200 miles from the mouth of the Amazon River.

The mol% G + C of the DNA is: 57.7 (Bd).

Type strain: ATCC 25379.

JAN KUEVER, FRED A. RAINEY AND FRIEDRICH WIDDEL

De.sulf.ar′ cu.lus. L. pref. *de* from; L. n. *sulfur* sulfur; M.L. masc. n. *arculus* a small bow; M.L. masc. n. *Desulfarculus* a bow-shaped sulfate-reducer.

Vibrio-shaped cells, 0.5–0.7 × 1.5–4 μm. Occur singly or in pairs. Spore formation is not observed. Gram negative. The type species is motile. Strict anaerobe with respiratory type of metabolism. **Chemoorganotroph, using formate, butyrate, and higher fatty acids as electron donors and carbon sources**; these compounds are completely oxidized to CO_2. Growth on acetate and propionate is very slow. **Sulfate and other oxidized sulfur compounds serve as terminal electron acceptors and are reduced to H_2S. Sulfur, fumarate, and nitrate are not used as terminal electron acceptors**. **Growth does not usually occur in the absence of an external electron acceptor**. Optimal temperature for growth, 35–39°C. Anoxic media (with sulfide as a reductant) are necessary for growth. Vitamins are not required. Cells contain cytochromes of the *b*- and *c*-type. Carbon monoxide dehydrogenase activity is commonly observed, indicating the operation of the anaerobic C_1-pathway (carbon monoxide dehydrogenase pathway, Wood-pathway) for CO_2 fixation and complete oxidation of acetyl-CoA. *Desulfarculus* species are widespread in freshwater habitats, but might occur in brackish or marine sediments as well.

The mol% G + C of the DNA is: 66.

Type species: **Desulfarculus baarsii** *comb. nov.* (*Desulfovibrio baarsii* Widdel 1981, 382.)

FURTHER DESCRIPTIVE INFORMATION

The type strain of *D. baarsii* has vibrio-shaped cells under all growth conditions. Cells are motile and stain Gram negative. The temperature range for growth is 20–39°C. The type strain has an optimal growth temperature of 35–39°C. The pH range for growth is 6.5–8.2, with an optimal pH of 7.3.

D. baarsii reduces sulfate, sulfite, and thiosulfate to H_2S. Elemental sulfur, fumarate, and nitrate cannot serve as electron acceptors. The following compounds are utilized as electron donors and carbon sources: formate, acetate, propionate, butyrate, isobutyrate, 2-methylbutyrate, valerate, isovalerate, and higher fatty acids up to 18 carbon atoms. All organic substrates are completely oxidized to CO_2. Growth on formate does not require an additional organic carbon source. Growth does not usually occur in the absence of an external electron acceptor. However, very slow growth with presumably only a few cell divisions may occur after adaptation to sulfate-free medium with formate that is converted to acetate. Carbon monoxide dehydrogenase activity is commonly observed, indicating the operation of the anaerobic C_1-pathway (carbon monoxide dehydrogenase pathway, Wood-pathway) for formate and CO_2 fixation or complete oxidation of acetyl-CoA (Schauder et al., 1986).

Ammonium ions are used as a nitrogen source. Vitamins are not required. Desulfoviridin is not present.

Desulfarculus strains occur in anoxic zones of freshwater and brackish water habitats.

Strains of *Desulfarculus* may be cultured in a defined medium with sulfate as electron acceptor and fatty acids as the electron donor and carbon source. Even in the case of isolates from freshwater sediment, best growth is usually obtained with 7–20 g NaCl and 1.2–3 g $MgCl_2 \cdot 6H_2O$ per liter, but growth is nearly as rapid at lower concentrations.

ENRICHMENT AND ISOLATION PROCEDURES

The only known substrate for selective enrichment of *Desulfarculus* is stearate, which is added to defined medium with sulfate.[1] Bottles or tubes (100-, 50-, or 20-ml capacity) can serve as culture vessels and are kept anoxic by using tight screw caps (if completely filled), or by providing an anoxic head space of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated (2–5% of the total volume) with dark anoxic sediment or sludge from sewage digesters. Enrichment cultures are incubated at 37–39°C, because this temperature will favor growth of *Desulfarculus* spp. Cultures should be briefly mixed every day. After intense formation of H_2S has occurred, transfers to fresh medium are made. Enrichment cultures should be mixed well before subculturing. For isolation of *D. baarsii*, the agar dilution method (as described for *Desulfobacter* in this edition of the *Manual*) is recommended. The insoluble fatty acid stearate should be replaced by soluble fatty acids. Formate may also be used as the only organic substrate in agar. After inoculation, strains may be grown on any substrate including stearate.

MAINTENANCE PROCEDURES

Stock cultures are transferred every 2–3 months. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 2–5°C in the dark. *Desulfarculus* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen.

DIFFERENTIATION OF THE GENUS *DESULFARCULUS* FROM OTHER GENERA

Desulfarculus baarsii can be distinguished from other sulfate-reducing bacteria capable of growing on fatty acids (except *Desulfocella* and *Desulfobotulus*) by its vibrio-shaped morphology. *Desulfarculus baarsii* differs from *Desulfocella* and *Desulfobotulus* in its capacity for complete substrate oxidation to CO_2 and growth on formate without addition of other organic compounds. The mol% G + C content of DNA from *Desulfocella halophila* is much lower than that of *D. baarsii* (32 vs. 66). This property, together with the ability of *D. baarsii* to grow in freshwater media, allows a clear differentiation of these species. However, a definite differentiation requires comparative 16S rDNA sequence analysis and DNA–DNA hybridization.

TAXONOMIC COMMENTS

On the basis of 16S rRNA gene sequence analysis, *D. baarsii* falls into the *Deltaproteobacteria* and forms a distinct lineage. The closest relatives are *Desulfosarcina variabilis*, *Desulfonema magnum*, *De-*

1. For cultivation of *D. baarsii*, the mineral medium described in the *Desulfobacter* section (this *Manual*) is first prepared without NaCl and $MgCl_2$. The sodium salt of stearic acid is added from a stock solution (28 g of stearic acid plus 4 g/l NaOH, heated in a boiling water bath until the solution is clear; sterilized by autoclaving. The solution must be remelted by heating before use; prewarmed pipettes should be used to take aliquots). Volumes added per liter of medium: 10 ml stearate solution, followed by 3.0 ml of $MgCl_2$ solution (400 g/l $MgCl_2 \cdot 6H_2O$) and 25 ml of NaCl solution (300 g/l NaCl). Pure cultures can be grown alternatively on soluble monocarboxylic acids. For instance, 5–10 ml of sodium formate solution (100 g/l) or a butyrate–caproate–caprylate mixture (containing per liter: 6.0, 2.5, and 1.0 g, respectively, of acids neutralized with NaOH) may be added per liter of medium.

sulfonema limicola, and *Desulfococcus multivorans* (Family *Desulfobacteraceae*). A signature sequence for *Desulfarculus baarsii* (also for *Desulfomonile tiedjei* and *Syntrophus* species) is 5′-GCCGGTGCTTCCTTTGGCGG-3′ (oligonucleotide probe DSMA 488), which binds to the 16S rDNA at *E. coli* position 5′-488–507-3′ (Manz et al., 1998).

Order V. **Desulfuromonales** *ord. nov.*

Jan Kuever, Fred A. Rainey and Friedrich Widdel

De.sul.fu.ro.mo.na′les. M.L. fem. n. *Desulfuromonas* type genus of the type family of the order; suffix *ales* denotes order; M.L. fem. pl. n. *Desulfuromonales* the order that comprises *Desulfuromonaceae*.

The order *Desulfuromonales* has been established primarily based on 16S rRNA sequence analysis and combines three families of anaerobes, the *Desulfuromonaceae* and *Geobacteraceae* (see Fig. BXII.δ.40). Whereas the *Desulfuromonaceae* and *Geobacteraceae* also share several nutritional properties with each other, nutritional relationships to the family *Pelobacteraceae* are less obvious.

Cells are rod shaped and usually motile. **Strictly anaerobic chemolithoheterotrophs or chemoorganotrophs with respiratory or fermentative metabolism.** All members are moderate mesophiles with temperature optima for growth around 30°C. Menaquinones are present. Species have been isolated from anoxic freshwater and marine environments.

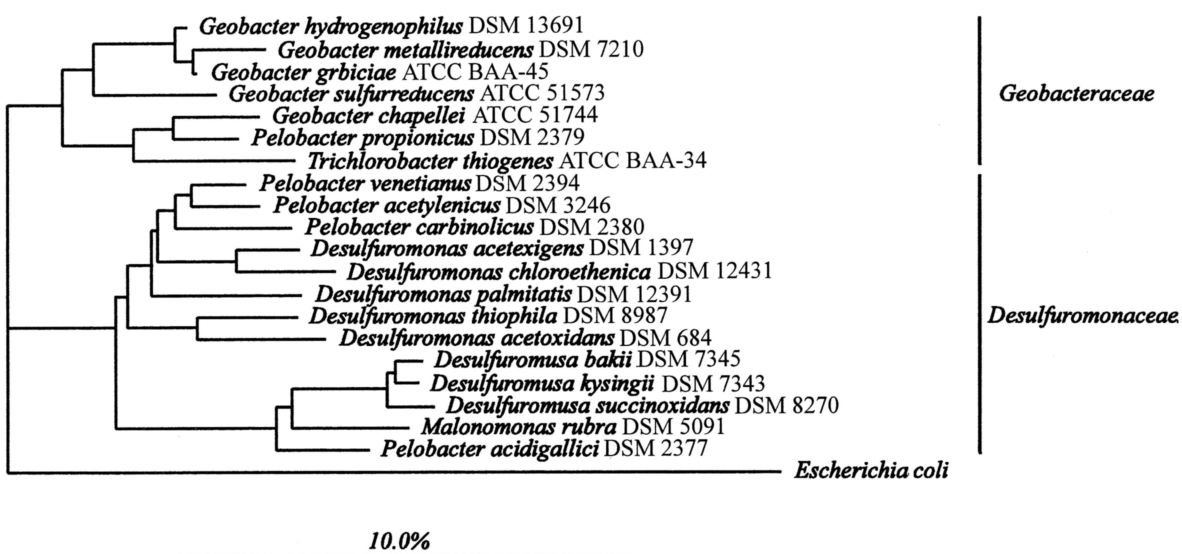

FIGURE BXII.δ.40. Phylogenetic relationships based on 16S rRNA gene sequence analyses of the taxa within the order *Desulfuromonales* for which 16S rRNA gene sequences are available. The scale bar represents 10 inferred nucleotide substitutions per 100 nucleotides. The dendrogram was reconstructed from distance matrices using the neighbor-joining method.

Most members of the *Desulfuromonaceae* and *Geobacteraceae* can use **ferric iron and elemental sulfur** (or polysulfide) as **electron acceptors** that are **reduced to ferrous iron and sulfide**; in addition, Mn(IV) and oxidized humic substances may be used by some species. Sulfate, thiosulfate, and sulfite do not serve as electron acceptors. Simple organic compounds such as acetate and other carboxylic acids serve as electron donors and carbon sources. Organic substrates are completely oxidized to CO_2; the mechanism of terminal oxidation is the citric acid cycle.

Members of the *Pelobacteraceae* show an exclusively fermentative metabolism; the main common fermentation product is acetate.

Type genus: **Desulfuromonas** Pfennig and Biebl 1977, 306.

Family I. **Desulfuromonaceae** *fam. nov.*

JAN KUEVER, FRED A. RAINEY AND FRIEDRICH WIDDEL

De.sul.fu.ro.mo.na.ce'ae. M.L. fem. n. *Desulfuromonas* type genus of the family; suffix *-ceae* denotes family; M.L. fem. pl. n. *Desulfuromonaceae* the family that comprises the genus *Desulfuromonas* and other genera.

The family comprises rod-shaped and curved cells. **Strictly anaerobic chemolithoheterotrophs or chemoorganotrophs with a respiratory or fermentative type of metabolism. Sulfur or ferric iron can act as electron acceptors for some members and are reduced to sulfide and ferrous iron**, respectively. Sulfate, sulfite, and thiosulfate are not used. Simple organic compounds such as long-chain fatty acids and alcohols serve as electron donors and carbon sources. Organic substrates are completely oxidized to CO_2. All members are mesophilic; thermophiles have not been isolated. Cells of most members contain various cytochromes and menaquinones. Mesophilic species have been isolated from various aquatic environments, including marine, brackish water, and freshwater habitats.

The family includes the genera *Desulfuromonas* and *Desulfuromusa*, *Malonomonas*, and *Pelobacter*. Differential characteristics for *Desulfuromonas* and *Desulfuromusa* are listed in Table BXII.δ.32.

Type genus: **Desulfuromonas** Pfennig and Biebl 1977, 306.

Genus I. **Desulfuromonas** *Pfennig and Biebl 1977, 306*[AL]

JAN KUEVER, FRED A. RAINEY AND FRIEDRICH WIDDEL

De.sul.fu.ro.mo′nas. L. pref. *de* from; L. n. *sulfur* sulfur; Gr. n. *monas* a unit, monad; M.L. fem. n. *Desulfuromonas* a monad that reduces sulfur.

Straight or slightly curved rods and elongated ovoid rods, 0.4–0.9 × 1.0–4.0 µm in length. Special resting forms such as spores are not known to occur. Gram negative. **Motile, generally by means of a single flagellum located at a lateral or subpolar position**; cells exhibit a characteristic propeller-like movement. Some strains have polar flagella. Strictly anaerobic. **Possess mainly a respiratory type of metabolism with elemental sulfur serving as the terminal electron acceptor, and being reduced to H_2S** (dissimilatory sulfur reduction). L-Malate or fumarate may be fermented, giving succinate as the main product in the presence or absence of acetate. Betaine may be fermented to acetate, CO_2, and trimethylamine. Optimal growth temperature, 30°C. Colonies on anaerobic agar media are translucent to opaque and either **peach-colored or pink**. Chemoorganotrophic, using acetate and other simple organic compounds as carbon sources (usually together with CO_2) and electron donors; **acetate and other substrates are completely oxidized to CO_2** via the citric acid cycle as indicated by 2-oxoglutarate dehydrogenase activity. Occur regularly in anoxic sediments of salt lakes and in marine or brackish habitats; have also been enriched from freshwater sediments.

The mol% G + C of the DNA is: 54–62.

Type species: **Desulfuromonas acetoxidans** Pfennig and Biebl 1977, 306.

FURTHER DESCRIPTIVE INFORMATION

Strains of *Desulfuromonas* isolated from anoxic sediments of saline lakes or marine habitats are generally straight or slightly curved slender rods, which are highly motile by a single lateral to subpolar flagellum. Most strains from anoxic freshwater sediments are elongated ovoid rods, which are motile by means of a subpolar or polar flagellum. Cells of freshwater strains have a tendency to form nonmotile clumps, which stick to the bottom of the culture vessel.

The ability to use the following electron donors and carbon sources also varies among *Desulfuromonas* strains: ethanol, 1-propanol, pyruvate, lactate, propionate, higher fatty acids, and glutamate. The oxidation of acetyl-CoA proceeds via the TCA cycle (Gebhardt et al., 1985). The following substrates generally cannot be used as electron donors and carbon sources: polysaccharides, sugars, sugar alcohols, most amino acids, and H_2/CO_2.

Besides elemental sulfur, poly- or disulfide bond-containing compounds such as polysulfide, cystine, or oxidized glutathione can serve as electron acceptors. Sulfate, sulfite, thiosulfate, nitrate, or oxygen cannot act as electron acceptors.

Strains differ in their ability to ferment malate or fumarate. Many strains grow well on a 4:1 mixture (molar ratio) of fumarate (or malate) and acetate, which is converted to succinate (Gottschalk and Andreesen, 1979). With the strains isolated in the initial study (Pfennig and Biebl, 1976), no growth was observed within three weeks on malate or fumarate when acetate was omitted; however, later studies showed that malate or fumarate can be fermented in bicarbonate-free medium supplemented with yeast extract in the absence of additional electron donors (Pfennig and Widdel, 1981; Widdel and Pfennig, 1992). The type strain can ferment betaine to acetate, CO_2, and trimethylamine (Heijthuijsen and Hansen, 1989).

Most marine and salt lake strains require 20 g/l NaCl and 3 g/l $MgCl_2 \cdot 6H_2O$ for growth; some strains can grow in both seawater and freshwater media. Biotin may be required as a growth factor.

The pH range for growth is 6.5–8.5, with the optimal being 7.2–7.5. The temperature optimal for growth is around 30°C. Some species have an optimal at 40°C.

Colonies of *Desulfuromonas* on agar media, as well as accumulations of cells in sediments or centrifuged pellets, are pink- to peach-colored, due to *c*-type cytochromes with absorption maxima at 419, 523, and 553 nm. In redox difference spectra, the β and α peaks are at 522 and 551.5 nm, respectively. A major component of the cytochromes of *D. acetoxidans* strain 5071 is the low potential, tri-heme cytochrome $c_{551.5}$ (c_7) (Probst et al., 1977). All members of the genus *Desulfuromonas* investigated so far contain MK-8 as the major menaquinone (Collins and Widdel, 1986). Major cellular fatty acids of the *Desulfomonas* strains are $C_{16:0}$ and $C_{16:1\ \omega7c}$ (Kohring et al., 1994).

A characteristic of all *Desulfuromonas* strains is that they grow well in syntrophic cultures containing phototrophic green sulfur bacteria and acetate (Biebl and Pfennig, 1978). Marine or salt lake isolates show particularly efficient growth in combined cultures containing the green bacterium *Prosthecochloris aestuarii* at moderate light intensities (e.g., 25W tungsten lamp, 50 cm distance). This is readily attributed to the fact that the illuminated *Prosthecochloris* oxidizes H_2S almost exclusively to extracellular elemental sulfur, which in turn is immediately reduced back to H_2S by *Desulfuromonas* as long as acetate is present.

Dissimilatory sulfur-reducing bacteria resembling *Desulfuromonas* occur regularly in the anoxic sulfide-containing sediments of marine and brackish water habitats and salt lakes. They have also been isolated, although much less successfully, from sulfide-containing, anoxic, freshwater sediments.

All strains of *Desulfuromonas* can be cultured in a defined anaerobic medium[1] containing sulfide as a reductant. The electron donor and carbon source (usually acetate) is added aseptically from a sterile stock solution (final concentration around 0.5 g/l). The electron acceptor, elemental sulfur, is added aseptically from a sterile slurry of sulfur flower in distilled water;[2] a pea-size amount is used for 50 ml of medium. Fermentative growth in the absence of sulfur is most commonly achieved with a fumarate–acetate mixture (2 g/l and 0.5 g/l, respectively), but several strains may not grow fermentatively.

ENRICHMENT AND ISOLATION PROCEDURES

For the selective enrichment of *Desulfuromonas* strains, mineral medium supplemented with 0.5 g anhydrous sodium acetate and

1. Defined basal medium has the following composition (per liter of distilled water): KH_2PO_4, 0.5 g; NH_4Cl, 0.3 g; $CaCl_2 \cdot 2H_2O$, 0.1 g; NaCl, 0.5 g (for salt water strains, 20.0 g); $MgCl_2 \cdot 6H_2O$, 0.4 g (for salt water strains, 3.0 g); trace element solution (see chapter on *Desulfobacter*), 1.0 ml. After the medium has been autoclaved and cooled under anoxic conditions, the following components are added aseptically from sterile stock solutions: 20 ml of a solution of 84 g/l $NaHCO_3$ (saturated with CO_2 and autoclaved under a CO_2 atmosphere), 2–3 ml of a solution of 120 g/l $Na_2S \cdot 9H_2O$ (autoclaved under an N_2 atmosphere), and 1 ml of a vitamin solution containing 4 mg of *p*-aminobenzoic acid and 1 mg of biotin per 100 ml. The pH of the medium is adjusted to 7.1–7.3 with sterile 1 M HCl or 0.5 M Na_2CO_3 solution (autoclaved in closed bottles with gas head phase). The medium is then distributed aseptically into sterile screw-capped bottles or test tubes and sealed against air.

2. Highly purified sulfur flower is ground thoroughly in a mortar together with distilled water. The slurry is autoclaved for 30 min at 112°C in a screw-capped bottle. The excess water is then decanted.

a spatula of ground, wetted sulfur flower is used. Bottles or tubes (100-, 50-, or 20-ml capacity) can serve as culture vessels and are kept anoxic with tight screw caps, or by using a headspace of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated with black anoxic mud from freshwater, brackish water, or marine habitats; 3–5% of the total culture volume should be added. *Desulfuromonas* species may be also enriched and isolated via direct serial dilution of anoxic environmental samples in liquid medium (according to most-probable-number method) or agar medium (see below) with acetate as organic substrate. Depending on the salinity of the anoxic mud sample that is used as the inoculum, salt- or freshwater medium is used. Sulfur flower may be kept in suspension by providing each bottle with a glass bead inside and incubation on a rotary shaker. Sulfur-reducing bacteria may become enriched under such conditions after 1 or 2 weeks of incubation at 28°C. Successful enrichment cultures are recognized by their strong odor of H_2S and by their lowered pH (6.5–6.8); microscopically, slender motile rods with a propeller-like movement are seen. Second and third transfers usually grow within a few days. Although the tolerance of *Desulfuromonas* to H_2S (some 10 mM) is considerable, growth is usually limited by the inhibitory effect of the H_2S.

The growth inhibition due to H_2S can be eliminated if the enrichment cultures for *Desulfuromonas* (in media with added sulfide as reductant) are inoculated with a phototrophic green sulfur bacterium and incubated in dim light from a tungsten lamp. In this case, no sulfur flower is added to the medium because the green sulfur bacterium continuously forms elemental sulfur and at the same time consumes the H_2S formed by the sulfur reducers being enriched. Repeated transfers may yield fast-growing syntrophic cultures, which can be used directly for isolation of a pure culture.

Pure cultures are obtained by repeated application of the agar dilution method. Repeatedly washed agar is used to prepare a sterile agar solution (33 g/l) in water, which is then dispensed in 3-ml amounts into test tubes. The molten agar is then combined with 6-ml amounts of prewarmed (42°C) complete culture medium, with 6–8 tubes being prepared for each dilution series. For use with agar, the complete culture medium is prepared with polysulfide solution instead of sulfur flower, in order to obtain a fine and homogeneous distribution of sulfur in the agar. A volume of 0.5 ml from an anoxically (under N_2) autoclaved polysulfide solution (10 g of $Na_2S \cdot 9H_2O$ and 3 g of sulfur flower dissolved in 45 ml of distilled water) are added per 50 ml of medium. The inoculated tubes are placed in a cold water bath and immediately sealed against air by overlaying an N_2/CO_2 mixture (9:1) and sealing with butyl rubber stoppers. The sealed tubes are incubated at 28–30°C. Clearing of the opaque yellowish sulfur and polysulfide and appearance of pink to peach-colored colonies indicate growth of *Desulfuromonas*.

In addition to microscopic examination, newly isolated strains are checked for purity by inoculating them into AC medium (Difco) and ethanol or lactate medium for sulfate-reducing bacteria. Absence of turbidity in both media supports absence of contamination.

Maintenance Procedures

Stock cultures are transferred every 3 months. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 2–5°C in the dark. Strains capable of using malate or fumarate are maintained on these substrates; strains lacking this ability are maintained with elemental sulfur as the electron acceptor. *Desulfuromonas* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen.

Differentiation of the genus *Desulfuromonas* from other genera

The genus *Desulfuromonas* is distinguished from other anaerobic, dissimilatory sulfur-reducing bacteria primarily by physiological characteristics. The special feature of the genus is the capacity to grow on acetate as the sole organic substrate by an anaerobic respiration in which the oxidation of acetate to CO_2 is stoichiometrically linked to the reduction of elemental sulfur to sulfide. Sulfate, sulfite, or thiosulfate cannot be utilized as electron acceptors. Lacking the ability to reduce oxidized sulfur compounds distinguishes *Desulfuromonas* from acetate-oxidizing sulfate-reducing bacteria. The ability to reduce elemental sulfur to H_2S in a dissimilatory metabolism also occurs in *Wolinella succinogenes*, *"Sulfospirillum"* species (formerly designated as *Campylobacter* strains; Laanbroek et al., 1978), and some sulfate-reducing bacteria of the genus *Desulfomicrobium* (Biebl and Pfennig, 1977; Schumacher et al., 1992; see chapter for *Desulfomicrobium*); however, these organisms are unable to oxidize acetate to CO_2 and require H_2 or formate (or lactate in the case of *Desulfovibrio*) as electron donors for reduction of sulfur. The use of other electron acceptors (ferric iron, dimethyl sulfoxide, etc.) allows no clear differentiation from other genera. In contrast to the closely related *Desulfuromusa* spp., the number of substrates used for dissimilatory sulfur reduction by members of the genus *Desulfuromonas* is limited (see Table BXII.δ.33). The only exception is *D. palmitatis*, which can also use long-chain fatty acids as substrates. A clear differentiation between these genera and other closely related genera (*Pelobacter* and *Geobacter*) is possible by determination of the 16S rRNA gene sequence. Differentiation of *Geobacter*, *Desulfuromusa*, and *Desulfuromonas* from *Pelobacter* is possible due to the presence of cytochromes, which are missing in *Pelobacter* strains.

In contrast to other rod-shaped anaerobic bacteria exhibiting dissimilatory reduction of sulfur compounds, most *Desulfuromonas* strains are motile by means of a single flagellum located at a lateral or subpolar position.

Taxonomic Comments

The closest relatives of the genus *Desulfuromonas* are *Geobacter*, *Pelobacter*, and *Desulfuromusa*.

are oxidized to CO_2 and elemental sulfur is reduced to H_2S. L-Malate or fumarate may be used as electron acceptors instead of sulfur, and are reduced to succinate; malate, fumarate, and betaine may also be fermented. Colonies or densely packed cells are peach-colored or pink due to the presence of *c*-type cytochromes. Occur regularly in anoxic sediments from marine or brackish water habitats or salt lakes.

The mol% G + C of the DNA is: 51 (T_m); 53.6 (HPLC).

Type strain: 11070, DSM 684.

GenBank accession number (16S rRNA): M26634.

2. **Desulfuromonas acetexigens** Finster, Bak and Pfennig 1997a, 601[VP] (Effective publication: Finster, Bak and Pfennig 1994, 331.)
a.cet.ex'i.gens. L. n. *acetum* vinegar; M.L. n. *acidum aceticum* acetic acid; L. v. *exigo* to demand; M.L. part. adj. *acetexigens* demanding acetate for growth.

Characteristics are summarized in Table BXII.δ.33. Occur in freshwater habitats. The type strain was isolated from digester sludge of the treatment plant, Göttingen, Germany.

The mol% G + C of the DNA is: 62 (T_m); 62.3 (HPLC).

Type strain: 2873, DSM1397.

GenBank accession number (16S rRNA): U23140.

3. **Desulfuromonas chloroethenica** Krumholz 1997, 1263[VP]
chlo.ro.e.the'ni.ca. M.L. adj. *chloroethenicus, -a, -um,* pertaining to chloroethene, as the organism utilizes such compounds as electron acceptors.

Characteristics are summarized in Table BXII.δ.33. Occur in freshwater sediment contaminated with chlorinated ethylenes.

The mol% G + C of the DNA is: not known.

Type strain: TT4B, ATCC 700295.

GenBank accession number (16S rRNA): U49748.

4. **Desulfuromonas palmitatis** Coates, Lonergan, Philips, Jenter and Lovley 2000, 1699[VP] (Effective publication: Coates, Lonergan, Philips, Jenter and Lovley 1995, 411.)
pal.mi.ta'tis. N.L. n. *palmitas* palmitate (chemical); N.L. gen. n. *palmitatis* of palmitate, because it oxidizes palmitate.

Characteristics are summarized in Table BXII.δ.33. The type strain was enriched from marine sediment of Palleta Creek in San Diego Bay, San Diego, California, USA.

The mol% G + C of the DNA is: 54.7 (HPLC).

Type strain: SDBY1, ATCC 51701.

GenBank accession number (16S rRNA): U28172.

5. **Desulfuromonas thiophila** Finster, Coates, Liesack and Pfennig 1997b, 757[VP]

thi.o.phi'la. Gr. n. *thios* sulfur; Gr. adj. *philos* loving; M.L. fem. adj. *thiophila* sulfur-loving.

Characteristics are summarized in Table BXII.δ.33. The type strain was enriched from anoxic freshwater mud from Ngawha Sulfur springs near Moerewa, New Zealand.

The mol% G + C of the DNA is: 62 (T_m); 62.3 (HPLC).

Type strain: NZ27, DSM 8987.

GenBank accession number (16S rRNA): Y11560.

Genus II. **Desulfuromusa** *Liesack and Finster 1994, 756*[VP]

Werner Liesack and Kai Finster

De.sul.fu.ro.mu'sa. L. pref. *de* from; L. n. *sulfur* sulfur; M.L. n. *musa* banana; M.L. fem. n. *Desulfuromusa* a banana-shaped bacterium that reduces sulfur.

Slightly curved or rod-shaped cells 0.4–0.8 × 1–6 μm. Motile by means of a single, subpolarly inserted flagellum. Gram negative. Spore formation not observed. **Strictly anaerobic**, having mainly a respiratory type of metabolism; however, fermentative growth may occur with fumarate or malate as the sole substrate. **Chemoorganotrophic**; all species utilize acetate, propionate, succinate, lactate, pyruvate, oxaloacetate, malate, maleate, glutamate, alanine, and aspartate as electron donors and as carbon sources; these **substrates are completely oxidized to CO_2**. Alcohols and sugars are not utilized. **S^0 is used as terminal electron acceptor and is reduced to H_2S** (dissimilatory sulfur reduction). Sulfate, sulfite, thiosulfate, tetrathionate, trimethylammonium oxide, cystine, oxidized glutathione, or N_2O are not utilized as electron acceptors. Strains can be cultivated in a defined medium without addition of complex nutrients such as yeast extract or peptone. Occur regularly in **anoxic marine or estuarine mud.**

The mol% G + C of the DNA is: 47.

Type species: **Desulfuromusa kysingii** Liesack and Finster 1994, 757.

Further descriptive information

When grown in anaerobic agar media with S^0 as electron acceptor, the cells of all strains tested form whitish filamentous colonies. Microscopic examination reveals the presence of highly light-dispersive globular bodies, probably droplets of S^0, in the center of these colonies. When grown with fumarate as the sole substrate, the cells form peach-colored colonies which are lens-shaped and have entire edges. Grown with fumarate as the sole substrate, the generation times are generally shorter than with S^0.

When growing on S^0 as terminal electron acceptor, direct contact between cells and sulfur particles is not necessary. However, when cells are not in contact with the sulfur, H_2S is required to initiate growth, most likely due to the formation of polysulfide. The addition of a reducing agent such as H_2S or dithionite to the medium is not necessary when the culture is inoculated in oxygen-free medium. However, the lag phase for sulfur reduction is reduced from 2 d without H_2S to 12 h in its presence.

Cultures of *D. kysingii* are relatively tolerant towards oxygen. Culturable cells were present after three weeks of continuous exposure to air. Cultures of *Desulfuromusa bakii* and *Desulfuromusa succinoxidans* do not survive this treatment.

Strains of *D. kysingii* and *D. succinoxidans* can grow by disproportionation of aspartate and maleate. Growth with one of these two substrates without an additional electron acceptor is considerably slower than growth in the presence of S^0.

Enrichment and Isolation Procedures

When samples of anoxic marine or estuarine muds were inoculated into media containing succinate, propionate, or lactate as the electron donor, a significant production of H_2S by sulfur reduction was observed after two weeks of anaerobic incubation. With valerate, sulfide production was noticeable after one month. Regardless of the electron donor used or the origin of the inoculum, after three transfers most enrichments were dominated by motile, rod-shaped, slightly curved cells (Fig. BXII.δ.41). Significantly larger cells developed only in an enrichment culture with lactate as electron donor. These cells were isolated and designated as strain Gylac, the type strain of the species *Desulfuromusa succinoxidans* (Table BXII.δ.34). In general, only a weak increase in medium turbidity was observed parallel to H_2S production. Most of the cells were attached to the sulfur precipitate. During growth, the pH of the medium decreased from 7.4 to 6.2–6.4. Pure cultures were obtained by repeated application of the deep-agar dilution method.

Maintenance Procedures

Pure cultures are maintained in liquid culture medium in screw-capped bottles or in anaerobically gassed bottles sealed with butyl rubber stoppers, with storage at 2–5°C. Stock cultures are transferred every three months.

Differentiation of the genus *Desulfuromusa* from other genera

Desulfuromusa species are obligately anaerobic, mesophilic sulfur reducers capable of complete oxidation of their substrates. Apart from one validly described species of the genus *Geobacter*, the dissimilatory Fe(III)-reducing *G. sulfurreducens* (Caccavo et al., 1994), these characteristics are shared only by members of the

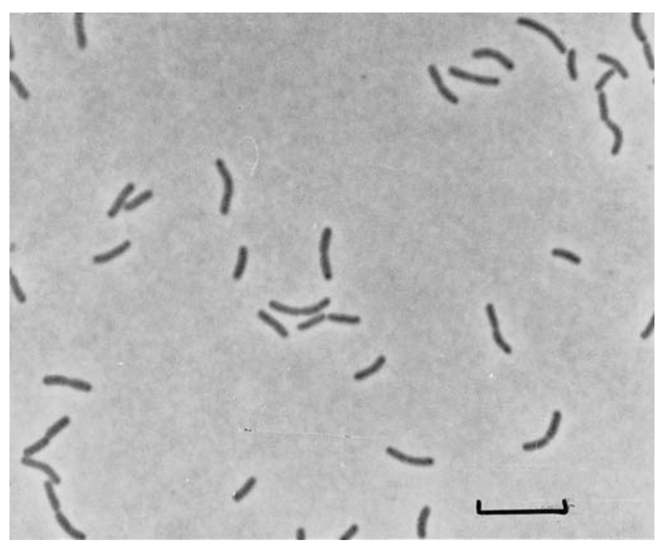

FIGURE BXII.δ.41. Phase-contrast photomicrograph showing cells of *Desulfuromusa kysingii* strain Kysw2 isolated from anoxic mud of the Kysing Fjord (Denmark). Bar = 10 μm.

[b]Data taken from Finster and Bak (1993).

[c]Cells grown on S^0 as electron acceptor.

[d]The alternative electron acceptors nitrate, dimethyl sulfoxide, and Fe(III)-citrate are reduced to ammonia, dimethyl sulfide, and dissolved Fe(II), respectively.

[e]Three weeks of continuous exposure to oxygen (2%) is tolerated, but no growth occurs in the presence of this compound.

[f]Brackish: Growth occurs equally well at concentrations between 114 and 340 mM for NaCl and between 3.3 and 14.7 mM for $MgCl_2$; no growth in the absence of NaCl or at a $MgCl_2$ concentration of 0.5 mM. Marine: Growth occurs equally well at concentrations between 230 and 340 mM for NaCl and between 9.8 and 14.7 mM for $MgCl_2$; no growth at a NaCl concentration of 114 mM and a $MgCl_2$ concentration of 3.3 mM.

genus *Desulfuromonas* (Widdel and Pfennig, 1992). Using S^0 as the sole electron acceptor, *G. sulfurreducens* is capable of growth with acetate but not with propionate, succinate, lactate, and several other substrates. In contrast, *Desulfuromusa* spp. are able to utilize these compounds as electron donors for growth (see generic description). Members of the genera *Desulfuromonas* and *Desulfuromusa* are phylogenetically related. (See Taxonomic Comments). The phylogenetically distinct *Desulfurella* species also grow by dissimilatory reduction of sulfur with complete oxidation of their substrates, but these microorganisms are moderate thermophiles with a temperature optimal around 55°C (Bonch-Osmolovskaya et al., 1990).

The *Desulfuromusa* species can be differentiated from the described members of the genus *Desulfuromonas* by their ability to utilize the amino acids alanine, aspartate, and glutamate as growth substrates. Apart from a very few exceptions listed in Table BXII.δ.34, the three described species of the genus *Desulfuromusa* share an identical set of electron donors which can be utilized for growth. With the exception of acetate, utilization patterns of electron donors are rather diverse between individual species of the genus *Desulfuromonas*. This heterogeneity might be a reflection of their phylogenetic diversity. The genus *Desulfuromonas* encompasses described species with up to 8% overall 16S rRNA gene sequence dissimilarity, while the three *Desulfuromusa* species form a phylogenetically tight cluster moderately related to, but clearly distinct from, members of the genus *Desulfuromonas* (see Taxonomic comments). The *Desulfuromonas* species tested so far, *D. acetoxidans* (Pfennig and Biebl, 1976), *D. acetexigens* (Finster et al., 1994), and *D. thiophila* (Finster et al., 1997b), require biotin as a growth factor, while members of the genus *Desulfuromusa* do not.

The mol% G + C values of the DNA are in a narrow range between 46 and 47 for members of the genus *Desulfuromusa*, while these values vary between 53.6 (*D. acetoxidans*) and 62.3 (*D. acetexigens*) for *Desulfuromonas* species.

Taxonomic Comments

The three described species of the genus *Desulfuromusa*, i.e., *D. kysingii*, *D. bakii*, and *D. succinoxidans*, share overall 16S rDNA sequence similarities above 98%. However, the levels of DNA relatedness in DNA–DNA hybridization between strains of the three described *Desulfuromusa* species were less than 30%. This was well below the DNA reassociation level of 70% generally accepted as a threshold for assigning strains as identical or different genomic species (Wayne et al., 1987). The genus *Desulfuromusa* belongs to a sublineage within the *Deltaproteobacteria*. This sublineage contains, in addition to *Desulfuromusa*, members of the genera *Geobacter*, *Desulfuromonas*, and *Pelobacter*. This group of microorganisms has recently been unified in the family *Geobacteraceae* by Lonergan et al., (1996), which is phylogenetically divided into two subgroups, the *Geobacter* and *Desulfuromonas* clusters. The three species of the genus *Desulfuromusa*, together with *Pelobacter acidigallici*, form a distinct line of descent within the *Desulfuromonas* cluster. More recently, the microaerotolerant, fermenting *Malonomonas rubra* has been shown to be closely related to *Pelobacter acidigallici* and the *Desulfuromusa* species (Kolb et al., 1998).

The analysis presented in Fig.BXII.δ.40 of the description of the order *Desulfuromonales* suggests that *Desulfuromonas*, *Desulfuromusa*, *Malonomonas*, and *Pelobacter acidigallici* are related, while *Geobacter*, *Pelobacter propionicus*, and *Trichlorobacter thiogenes* are related. The family *Desulfuromonaceae* would then include the organisms in the first group and the family *Geobacteraceae*, the organisms in the second group. The order would become *Desulfuromonales* because *Desulfuromonas* was described first and would have precedence over *Geobacter*.

The ability to carry out anaerobic respiration with Fe(III) and/or S^0 as terminal electron acceptors (dissimilatory iron and/or sulfur reduction) has been proposed as a common physiological characteristic of members of the family *Geobacteraceae* (Lonergan et al., 1996). Indeed, the ability to grow with ele-

mental sulfur has been demonstrated for *Geobacter sulfurreducens* (Caccavo et al., 1994), originally isolated and described as a Fe(III)-reducing microorganism, and *vice versa*, the ability to grow with Fe(III) as an electron acceptor has been shown for *Desulfuromonas acetoxidans* (Roden and Lovley, 1993) and *Desulfuromonas palmitatis* (Coates et al., 1995). Similarly, *D. kysingii* has been shown to utilize Fe(III) (added as Fe(III)-citrate) as an electron acceptor, while Fe(III)-citrate was not utilized by *D. bakii* and *D. succinoxidans* (Finster and Bak, 1993; Liesack and Finster, 1994; Lonergan et al., 1996). However, all three *Desulfuromusa* species were able to grow in medium with acetate as the electron donor and Fe(III)-NTA as the electron acceptor, with significant Fe(III) reduction over time (Lonergan et al., 1996). Finally, growth by dissimilatory reduction of Fe(III) and S^0 has also been demonstrated for *Pelobacter carbinolicus* (Lovley et al., 1995b), originally isolated and described as a strictly anaerobic, fermentative bacterium (Schink, 1984a, 1992). This mix-up of physiological traits originally considered as special characteristics of members of different genera is also reflected in the topology of the phylogenetic tree. The genus *Pelobacter* is phylogenetically intertwined with members of the genera *Geobacter* and *Desulfuromonas* (Evers et al., 1993; Lonergan et al., 1996). However, growth by dissimilatory reduction of Fe(III) or S^0 could not be demonstrated for *Malonomonas rubra* (Kolb et al., 1998). These data as a whole may indicate the need for a thorough study of the physiological features of members of the family *Geobacteraceae*, followed by a revision of the currently existing taxonomy within this family.

Differentiation of the species of the genus *Desulfuromusa*

Differential characteristics of the species *D. kysingii*, *D. bakii*, and *D. succinoxidans* are listed in Table BXII.δ.34.

List of species of the genus Desulfuromusa

1. **Desulfuromusa kysingii** Liesack and Finster 1994, 757[VP]
ky.sin' gi.i. M.L. gen. n. *kysingii* of kysing; named after the Fjord south of Århus (Jutland, Denmark) from which the organism was isolated.

Characteristics are as described for the genus and as shown in Table BXII.δ.34.

Isolated from anoxic mud of the Kysing Fjord south of Århus, Denmark.

The mol% G + C of the DNA is: 47 (HPLC).

Type strain: Kysw2, DSM 7343.

GenBank accession number (16S rRNA): X79414.

2. **Desulfuromusa bakii** Liesack and Finster 1994, 757[VP]
ba' ki.i. M.L. gen. n. *bakii* of Bak, named in memory of F. Bak, a German microbiologist who has made important contributions to our knowledge of sulfur- and sulfate-reducing bacteria.

Characteristics are as described for the genus and as shown in Table BXII.δ.34.

Isolated from an anoxic mud sample collected from the Guayamas basin (Gulf of California) at a depth of about 2000 m.

The mol% G + C of the DNA is: 46 (HPLC).

Type strain: Gyprop, DSM 7345.

GenBank accession number (16S rRNA): X79412.

3. **Desulfuromusa succinoxidans** Liesack and Finster 1994, 757[VP]
suc.cin.ox' i.dans. L. n. *succinum* amber; M.L. n. *acidum succinicum* succinic acid (derived from amber); M.L. v. *oxido* make acid, oxidize; M.L. part. adj. *succinoxidans* oxidizing succinate.

Characteristics are as described for the genus and as shown in Table BXII.δ.34.

Isolated from an anoxic mud sample collected from the Guayamas basin (Gulf of California) at a depth of about 2000 m.

The mol% G + C of the DNA is: 46 (HPLC).

Type strain: Gylac, DSM 8270.

GenBank accession number (16S rRNA): X79415.

Genus III. **Malonomonas** *Dehning and Schink 1990, 320[VP] (Effective publication: Dehning and Schink 1989a, 431)*

Jan Kuever and Bernhard Schink

Ma.lo.no.mo' nas. M.L. n. *acidum malonicum* malonic acid; Gr. n. *monas* a unit, monad; M.L. fem. n. *Malonomonas* malonic-acid-utilizing monad.

Straight or slightly curved rods, 0.4 × 3.1–4.0 µm. Resting forms such as spores are not known to occur. Gram negative. **Motile, generally by means of a single polar flagellum. Microaerotolerant anaerobe. Chemoorganotroph. Possesses a fermentative type of metabolism. Malonate is decarboxylated to acetate. L-Malate or fumarate is fermented to succinate and CO_2.** Optimal growth temperature, 28–30°C. Colonies on or in anoxic agar media are **red-colored, because of high amounts of periplasmic cytochrome *c* of unknown function**. Occur in anoxic sediments in marine habitats.

The mol% G + C of the DNA is: 48.3.

Type species: **Malonomonas rubra** Dehning and Schink 1990, 320 (Effective publication: Dehning and Schink 1989a, 431.)

Further descriptive information

Strains of *Malonomonas* isolated from anoxic sediments of marine habitats are generally straight or slightly curved rods with rounded ends, 0.4 µm in diameter and 3.1–4.0 µm in length, which are motile by a single subpolar flagellum. Motility may occur only during early growth phases. Spore formation is absent. At the end of exponential growth, cells tend to form large aggregates, which settle as clumps to the bottom of the culture vessel.

The only substrates utilized are malonate, fumarate, and malate. Malonate is decarboxylated to acetate, whereas malate and fumarate are fermented to succinate and CO_2. Methylmalonate is not used, not even in the presence of 2 mM acetate. Sulfur, sulfate, sulfite, thiosulfate, nitrate, and N_2O cannot act as electron acceptors.

The pH range for growth is 6.0–8.5, with the optimal being 7.1–7.3. The temperature range for growth is 22–45°C with an optimal at 28–30°C.

Colonies of *Malonomonas* on or in agar media, as well as accumulations of sedimented or centrifuged cell pellets, are red-colored, due to *c*-type cytochromes with absorption maxima at 418, 522, and 551 nm. This cytochrome comprises up to 12% of the total cell protein. It has been assumed that this cytochrome does not fulfill a physiological function, but may be a remnant from sulfur- or ferric iron-reducing ancestors.

Malonomonas occurs in anoxic sulfide-containing sediments of marine habitats. Freshwater strains have not been isolated so far.

Malonomonas strains require at least 8–9 g/l NaCl for growth. All strains of *Malonomonas* can be cultured in a defined anoxic medium with cysteine as reducing agent under exclusion of air (Dehning and Schink, 1989a).

Enrichment and Isolation Procedures

For selective enrichment of *Malonomonas* strains, basal mineral medium supplemented with 20 mM disodium malonate is used. Bottles or tubes (100-, 50-, or 20-ml capacity) can serve as culture vessels and are kept anoxic with tight screw caps, or by using a headspace of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated with anoxic mud from freshwater, brackish water, or marine habitats; 3–5% of the total culture volume should be added. *Malonomonas* species may also be enriched and isolated via direct serial dilution of anoxic environmental samples in liquid medium (according to most-probable-number method) or agar medium with malonate as the sole organic substrate. Depending on the salinity of the anaerobic mud sample that is used as the inoculum, salt- or freshwater medium is used. Gas production after 3–5 weeks incubation at 28–30°C indicates substrate degradation. Pure cultures are obtained by repeated application of the agar dilution method. Appearance of disk-shaped red-colored colonies indicates growth of *Malonomonas*.

Maintenance Procedures

Stock cultures are transferred every 3 months. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 2–5°C in the dark. *Malonomonas* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen.

Differentiation of the genus *Malonomonas* from other genera

The genus *Malonomonas* is phenotypically distinguished from other fermentative bacteria by using only malonate, fumarate, and malate as substrates for growth. Inorganic electron acceptors are not used. However, a clear differentiation of this genus from other closely related genera (*Pelobacter*, *Desulfuromusa*, *Desulfuromonas*, and *Geobacter*) can be achieved by determination of the 16S rRNA gene sequence. Differentiation of *Malonomonas* from *Pelobacter* is possible due to the presence of cytochromes absent in *Pelobacter* strains.

Taxonomic Comments

Malonomonas rubra is a member of the *Deltaproteobacteria*. The closest relatives are *Pelobacter acidigallici* and members of the genus *Desulfuromusa*.

Further Reading

Dehning, I. and B. Schink. 1989. *Malonomonas rubra* gen. nov. sp. nov., a microaerotolerant anaerobic bacterium growing by decarboxylation of malonate. Arch. Microbiol. *151*: 427–433.

List of species of the genus Malonomonas

1. **Malonomonas rubra** Dehning and Schink 1990, 320^{VP} (Effective publication: Dehning and Schink 1989a, 431.)
ru'bra. L. adj. *ruber* red, referring to the red color of the cells.

The description is as for the genus. Isolated using malonate as the sole substrate. Occur in anoxic sediments from marine or brackish water habitats.

The mol% G + C of the DNA is: 48.3 (T_m).

Type strain: GraMal1, DSM 5091.

GenBank accession number (16S rRNA): Y17712.

Genus IV. **Pelobacter** *Schink and Pfennig 1983, 896^{VP} (Effective publication: Schink and Pfennig 1982, 200)*

Bernhard Schink

Pe.lo.bac'ter. Gr. masc. n. *pelos* mud; M.L. masc. n. *bacter* the equivalent of Gr. neut. n. *bakterion* a small rod; M.L. masc. n. *Pelobacter* a mud-inhabiting rod.

Rod-shaped cells, 0.5–1.0 × 1.5–6.0 µm, with rounded ends, single, in pairs, or in chains. Motile forms may occur in some species; other species are nonmotile. Gram negative. Endospores not formed. Anaerobic. **Have a chemoorganotrophic, fermentative type of metabolism, using few simple organic compounds as substrates. Carbohydrates not utilized.** Media containing a reductant, e.g., sulfide, are necessary for growth. Catalase negative. Isolated from sediments of limnic or marine origin.

The mol% G + C of the DNA is: 50–58.

Type species: **Pelobacter acidigallici** Schink and Pfennig 1983, 896 (Effective publication: Schink and Pfennig 1982, 200.)

Further descriptive information

The restriction, in every instance, to only a few, structurally related substrates makes the pathways of substrate degradation simple. *P. acidigallici* and *P. massiliensis* are both restricted to the utilization of trihydroxybenzenes, which, after necessary modifications and reduction to dihydrofluoroglucinol, are degraded through β-thiolytic cleavage. The four other species described have been enriched with diols or acetylene, which all form acetaldehyde as a primary intermediate, which is subsequently fermented through various pathways to either acetate plus ethanol or acetate plus propionate. *P. venetianus*, *P. carbinolicus*, and *P. acetylenicus* can easily release electrons in the form of molecular hydrogen in syntrophic cooperation with, for example, methanogenic or acetogenic partner bacteria. They can also act as syntrophic ethanol oxidizers in the presence of such partners.

Enrichment and Isolation Procedures

All *Pelobacter* species known so far have been enriched and isolated from sediments of limnic or marine origin in simple mineral media with specific organic enrichment substrates. The mineral media for enrichment must be low in phosphate (1–2 mM KPO_4) and rich in CO_2/HCO_3^- (>20 mM). Sulfide is usually used as a reductant. Since all *Pelobacter* species grow with substrates that yield only C_2 degradation intermediates, they must form pyruvate and sugars via reductive carboxylation of acetyl CoA and therefore need carbon dioxide for this reaction. The enrichment medium used successfully for these organisms is derived from that used for the cultivation of sulfate-reducing bacteria (Widdel and Pfennig, 1981), but without sulfate, and is described in detail in the original publications (e.g., Schink and Pfennig, 1982). The respective substrates are applied in a concentration range of 10–20 mM, and inocula of at least 2–5 ml are used to secure sufficient attachment surfaces, structure-bound sulfides, and trace cosubstrates in the initial growth steps.

Maintenance Procedures

Cultures are maintained either by repeated transfer at intervals of 2–3 months or by freezing in liquid nitrogen using techniques common for strictly anaerobic bacteria. No information exists about survival upon lyophilization.

Differentiation of the genus *Pelobacter* from other genera

The genus *Pelobacter* differs from most other strictly anaerobic types of Gram-negative, rod-shaped bacteria by its lack of spore formation and lack of sugar utilization. All strains have been isolated in defined mineral media with single defined organic substrates and do not require complex, undefined medium additions. Differential characteristics of the genera *Pelobacter* and *Malonomonas* are listed in Table BXII.δ.35.

Taxonomic Comments

The genus *Pelobacter* has been proposed as a taxonomic entity consisting of strictly anaerobic, Gram-negative, non-sporeforming, rod-shaped bacteria that use only a very limited number of substrates. All members of this genus are unable to ferment sugars and therefore cannot be grouped with any other genus in the family *Bacteroidaceae* (Holdeman et al., 1984). The genus so far comprises six different species: *P. acidigallici* (Schink and Pfennig, 1982), *P. venetianus* (Schink and Stieb, 1983), *P. carbinolicus* (Schink, 1984a), *P. propionicus* (Schink, 1984a), *P. acetylenicus* (Schink, 1985), and *P. massiliensis* (Schnell et al., 1991a), each of which has been proposed on the basis of 3–5 described strains.

Comparison of the various *Pelobacter* species by DNA–DNA hybridization experiments has revealed that the genus is heterogeneous (J.P. Touzel and B. Schink, unpublished observations). The species *P. venetianus*, *P. carbinolicus*, and *P. acetylenicus* form a rather homogeneous cluster within the family *Geobacteraceae* that is closely related to various *Desulfuromonas* and *Geobacter* repre-

[d]Some species use Fe(III) and sulfur as electron acceptors.

[e]Use of external electron acceptors is coupled to fermentation shift and incomplete oxidation.

sentatives. In addition, *Pelobacter propionicus* is directly related to *Geobacter sulfurreducens* based on 16S rRNA sequence similarity data. The tight relationship to sulfur- and ferric iron-respiring organisms has led to speculations that the genus *Pelobacter* represents a group of fermenting bacteria that developed a fermentative metabolism as a secondary evolutionary event, meaning that they are separate from primarily fermentative bacteria (Stackebrandt et al., 1989).

Differentiation of the species of the genus *Pelobacter*

The key differences in substrate utilization among the various species are listed in Table BXII.δ.36.

List of species of the genus Pelobacter

1. **Pelobacter acidigallici** Schink and Pfennig 1983, 896[VP] (Effective publication: Schink and Pfennig 1982, 200.)
a.ci.di.gal′li.ci. M.L. neut. n. *acidum gallicum* gallic acid; M.L. gen. n. *acidigallici* of gallic acid.

Rod-shaped cells, 0.5–0.8 ×1.5–3.5 µm, with rounded ends, single, in pairs, or in chains. Motile in young cultures; however, motility may be lost early. No spore formation. Gram negative.

Gallic acid, pyrogallol, 2,4,6-trihydroxybenzoic acid, and fluoroglucinol are the only fermentable substrates, and acetate and CO_2 are the only fermentation products. No other phenolic compounds, fatty acids, dicarboxylic acids, or alcohols are metabolized. Sulfate, sulfur, and nitrate are not reduced. Growth requires mineral media with a reductant. The marine type strain requires at least 10 g/l NaCl and 1.5 g/l $MgCl_2$, whereas freshwater isolates do not need enhanced salt concentrations. No growth factors or vitamins are needed. Indole is not formed; gelatin and urea are not hydrolyzed.

pH range: 5.3–8.2; optimal, 6.5–7.0. Temperature

range, 10–37°C; optimal, 35°C. No cytochromes detectable. Habitats: anaerobic muds of freshwater or marine origin.

The mol% G + C of the DNA is: 51.8 (T_m).

Type strain: Ma Gal 2, DSM 2377.

GenBank accession number (16S rRNA): X77216.

2. **Pelobacter acetylenicus** Schink 1986, 354[VP] (Effective publication: Schink 1985, 300.)

a.ce.ty.le'ni.cus. M.L. adj. *acetylenicus* referring to acetylene utilization.

Rod-shaped cells, 0.6–0.8 × 1.5–4 μm, with slightly pointed ends, single, in pairs, or in chains. Motile in young cultures.

Acetylene, acetoin, ethanolamine, choline, 1,2-propanediol and glycerol are used as substrates, the latter two in the presence of acetate. Substrates are fermented to acetate and ethanol or the respective higher acids and alcohols. Ethanol is oxidized to acetate in the presence of H_2-scavenging anaerobes. Grows in freshwater medium, as well as in the presence of 2% (w/v) NaCl. Sulfate, sulfur, thiosulfate, sulfite, and nitrate are not reduced. Indole is not formed. Gelatin and urea are not hydrolyzed. Cytochromes are absent.

pH range, 6.5–7.5. Temperature range, 15–40°C; optimal, 28–34°C. Habitats: anoxic muds of freshwater or marine origin.

The mol% G + C of the DNA is: 57.1 ± 0.2 (T_m).

Type strain: WoAcy 1, DSM 3246.

GenBank accession number (16S rRNA): X70955.

3. **Pelobacter carbinolicus** Schink 1984b, 356[VP] (Effective publication: Schink 1984a, 39.)

car.bi.no'li.cus. M.L. adj. *carbinolicus* referring to carbinols.

Rod-shaped cells, 0.5–0.7 × 1.2–3.0 μm, with rounded ends, single, in pairs, or in chains. Nonmotile.

2,3-Butanediol, acetoin, and ethylene glycol are utilized for growth and fermented to acetate and ethanol. No other organic substrates are utilized. In coculture with H_2-consuming bacteria, ethanol, propanol, and butanol are oxidized to the respective fatty acids plus hydrogen. Grows in freshwater medium, as well as in the presence of 2% NaCl. Sulfate, sulfur, thiosulfate, sulfite, and nitrate are not reduced. Indole is not formed. Gelatin and urea are not hydrolyzed. Cytochromes are absent.

pH range, 6.0–8.0; optimal 6.5–7.2. Temperature range, 15–40°C; optimal 35°C. Habitats: anoxic muds of marine origin.

The mol% G + C of the DNA is: 52.3 ± 1.0 (T_m).

Type strain: Gra Bd1, DSM 2380.

GenBank accession number (16S rRNA): X79413.

4. **Pelobacter massiliensis** Schnell, Brune and Schink 1991b, 580[VP] (Effective publication: Schnell, Brune and Schink 1991a, 515.)

mas.si.li.en'sis. M.L. adj. *massiliensis* a citizen of Massilia (Latin), Marseille; referring to a strictly anaerobic fermenting bacterium enriched from sediments close to Marseille.

Rod-shaped cells, 0.4–0.5 × 0.7–1.5 μm. Motile in young cultures. Hydroxyhydroquinone, pyrogallol, fluoroglucinol, and gallic acid are the only fermentable substrates, and acetate, CO_2, and traces of resorcinol are the only fermentation products. Sulfate, sulfite, thiosulfate, sulfur, nitrate, and fumarate are not reduced. Growth requires mineral medium with at least 10 g/l NaCl and 1.5 g/l $MgCl_2 \cdot 6H_2O$ and sulfide as a reducing agent. Cytochromes not detectable.

pH optimal, 7.2. Temperature optimal, 30°C. *P. massiliensis* has been enriched and isolated so far only from marine sediments.

The mol% G + C of the DNA is: 59 (T_m).

Type strain: HHQ7, DSM 6233.

5. **Pelobacter propionicus** Schink 1984b, 356[VP] (Effective publication: Schink 1984a, 39.)

pro.pi.o'ni.cus. M.L. n. *acidum propionicum* propionic acid; M.L. adj. *propionicus* forming propionic acid.

Rod-shaped cells, 0.5–0.7 × 1.2–6.0 μm, with rounded ends, single, in pairs, or in chains. Nonmotile.

2,3-Butanediol, acetoin, ethanol, pyruvate, and lactate are utilized for growth; propanol and butanol are used in the presence of acetate. Propionate and acetate are the main fermentation products; butanol and propanol are oxidized to the respective fatty acids, with concomitant reduction of acetate and bicarbonate to propionate. No other substrates are utilized. Sulfate, sulfite, thiosulfate, sulfur, and nitrate are not reduced. Growth requires mineral media with bicarbonate and a reductant. Indole is not formed. Gelatin and urea are not hydrolyzed. Catalase negative. A *b*-type cytochrome is present.

pH range: 6.5–8.4; optimal: 7.0–8.0. Temperature range: 4–45°C; optimal: 33°C. Habitats: anoxic muds of freshwater origin; anaerobic sewage sludge digesters.

The mol% G + C of the DNA is: 57.4 ± 1.0% (T_m).

Type strain: Ott Bd 1, DSM 2379.

GenBank accession number (16S rRNA): X70954.

6. **Pelobacter venetianus** Schink and Stieb 1984, 91[VP] (Effective publication: Schink and Stieb 1983, 1912.)

ve.ne.ti.a'nus. L. n. *venetianus* from Venice, the origin of the type strain and the place where it was found in high numbers.

Cells rod-shaped, 0.5 × 1.0–2.5 μm, with rounded ends, occurring singly or in pairs. Motile in young cultures.

Polyethylene glycol, polyethylene glycol-containing compounds, and acetoin are the only substrates utilized. Substrates are fermented to nearly equal amounts of acetate and ethanol. 1,2-Propanediol, 1,2-butanediol, and glycerol are also fermented to the corresponding acids and alcohols, but for growth, acetate is necessary as a source of carbon. Sulfate, sulfur, thiosulfate, and nitrate are not reduced. Growth requires mineral media with a reductant. Growth yields and rates of the type strain are higher on media containing at least 10 g/l of NaCl and 1.5 g/l of $MgCl_2 \cdot 6H_2O$. No growth factors or vitamins are required. Indole is not formed. Gelatin and urea are not hydrolyzed. In coculture with H_2-consuming methanogenic or homoacetogenic bacteria, growth on ethanol is achieved by oxidation of ethanol to acetate. No cytochromes are detectable.

pH range: 5.5–8.0; optimal: 7.0–7.5. Temperature range: 10–40°C; optimal: 33°C. Habitats: anaerobic mud of freshwater or marine origin.

The mol% G + C of the DNA is: 52.2 ± 1.0 (T_m).

Type strain: Gra PEG 1, DSM 2394.

Family II. **Geobacteraceae** *fam. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Ge.o.bac.ter.a′ ce.ae. M.L. masc. n. *Geobacter* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Geobacteraceae* the *Geobacter* family.

The family *Geobacteraceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Geobacter* (type genus) and *Trichlorobacter*.

Nonmotile. Strict anaerobes. *Geobacter* utilizes Fe(III) as an electron acceptor; *Tricholorobacter* reduces trichloroacetic acid to dichloroacetic acid.

Type genus: **Geobacter** Lovley, Giovannoni, White, Champine, Phillips, Gorby and Goodwin 1995a, 619[VP] (Effective publication: Lovley, Giovannoni, White, Champine, Phillips, Gorby and Goodwin 1993a, 342.)

Genus I. **Geobacter** *Lovley, Giovannoni, White, Champine, Phillips, Gorby and Goodwin 1995a, 619[VP] (Effective publication: Lovley, Giovannoni, White, Champine, Phillips, Gorby and Goodwin 1993a, 342)*

JOHN D. COATES AND DEREK R. LOVLEY

Ge.o.bac′ter. Gr. n. *ge* the earth; masc. *bacter* equivalent of Gr. n. *bakterion* a small rod; M.L. masc. n. *Geobacter* a rod from the earth.

Cells are rod-shaped with rounded ends that grow as single cells, in pairs, or in chains. Cells are 1–4 μm × 0.6 μm, nonmotile, with no spore formation. They are Gram-negative **strict anaerobes** and belong to the *Deltaproteobacteria*. They are catalase and carotenoid negative. Cells contain menaquinone and *c*-type cytochromes, but lack ubiquinone. **Growth occurs chemoorganotrophically with Fe(III) serving as the sole electron acceptor. The organic electron donor is completely oxidized to carbon dioxide.** Vitamins are not required for growth, but growth is enhanced by their presence. Growth is also enhanced in media containing $FeCl_2$ as a reducing agent.

The mol% G + C of the DNA is: 50.2–60.6 (HPLC).

Type species: **Geobacter metallireducens** Lovley, Giovannoni, White, Champine, Phillips, Gorby and Goodwin 1995a, 619 (Effective publication: Lovley, Giovannoni, White, Champine, Phillips, Gorby and Goodwin 1993a, 342.)

FURTHER DESCRIPTIVE INFORMATION

Geobacter metallireducens was the first described dissimilatory Fe(III) reducer that is able to obtain energy to support growth from the complete oxidation of acetate and other multicarbon compounds coupled to the reduction of Fe(III) (Lovley et al., 1987; Lovley, and Phillips, 1988). Phylogenetic analysis of its 16S rRNA sequence placed it within the *Deltaproteobacteria* and closest to the acetate-oxidizing sulfur reducer *Desulfuromonas acetoxidans* (Lovley et al., 1993a). *D. acetoxidans* has subsequently been found to be able to grow with acetate as electron donor and Fe(III) as electron acceptor (Roden and Lovley, 1993). In addition to *G. metallireducens*, the genus *Geobacter* contains four other validly published species, *G. hydrogenophilus* (Coates et al., 2001), *G. grbiciae* (Coates et al., 2001), *G. chapellei* (Coates et al., 2001), and *G. sulfurreducens* (Caccavo et al., 1994), as well as *"G. humireducens"* (Coates et al., 1998, 2001).

The *Geobacter* species are the Fe(III)- and humics-reducing bacteria most readily isolated from a variety of freshwater, sedimentary, and soil environments (Coates et al., 1996, 1998). Analysis of 16S rDNA sequences in a broad diversity of environments including soils and sediments in which Fe(III) reduction was the terminal electron-accepting process indicated that *Geobacter* species were among the most numerous organisms present and orders of magnitude more numerous than other known Fe(III)-reducing microorganisms (Rooney-Varga et al., 1999; Snoeyenbos-West et al., 2000).

ENRICHMENT AND ISOLATION PROCEDURES

Geobacter species are mesophilic, complete-oxidizing, strict anaerobes. Amorphous Fe(III)-oxide (30 mM) (Lovley, 2000) is a suitable electron acceptor for *Geobacter* species with acetate (2 mM) as the sole electron donor. Enrichments are generally incubated at temperatures of 15–30°C. Positive enrichments can be visually identified by a color change in the amorphous Fe(III) from brown to black as the iron is reduced. If left for an extended period after complete reduction of the Fe(III) has taken place (1–2 weeks), the crystalline iron mineral magnetite (Fe_3O_4) will form, which can readily be identified by its magnetic properties. Initial enrichments usually take 1–2 weeks at 30°C. A suitable medium for *Geobacter* species is given below.[1] Initial positive enrichments should be transferred as soon as the iron precipitate in the medium has turned black. Inoculum transfers into fresh medium should be 10% of the culture volume. Sequential transfers should be done three times to remove residual particulates and biodegradable organics associated with the original sample. Enrichments should then be transferred into basal medium amended with a soluble form of Fe(III) such as Fe(III)-NTA (10 mM) (Roden and Lovley, 1993). Growth can be recognized by a color change in the medium from transparent orange to colorless and the formation of $FeCO_3$, which is seen as a white precipitate at the bottom of the culture vessel. Cell yields are generally poor, and an optical increase in cell density will not be apparent. Once growth has been achieved on Fe(III)-NTA, the enrichment should be transferred to solid medium with acetate (2 mM) and Fe(III)-NTA (10 mM) as the sole electron donor and acceptor, respectively, and amended with 2% by weight Noble agar. Colonies of Fe(III)-reducing bacteria can readily be recognized on the surface of agar medium as small white colonies

1. Freshwater Fe(III)-oxide basal medium contains (per liter): 30 ml amorphous Fe(III)-oxide, 0.25 g NH_4Cl, 0.60 g NaH_2PO_4, 1.36 g $CH_3COONa{\cdot}3H_2O$, 2.5 g $NaHCO_3$ (primary buffer with CO_2), 0.1 g KCl, 10 ml each of vitamin and mineral solutions (Lovley and Phillips, 1988). The medium is dispensed into tubes before sparging with 80% N_2 and 20% CO_2 (at least 6 min, the last minute with the stopper in place). The amorphous Fe(III)-oxide can be replaced with alternative Fe(III) forms as needed.

surrounded by a colorless halo in tan-brown colored agar. Colonies should be picked with sterile glass Pasteur-pipettes in an anaerobic glove box and restreaked onto fresh solid media. After incubation, several of the restreaked colonies should be picked and used to inoculate a single tube of fresh anaerobic Fe(III)-NTA medium. Growth in these nascent cultures is significantly improved with the addition of $FeCl_2$ (2.5 mM) as a reducing agent. A viable Fe(III)-reducing culture should be obtained after 7–10 days.

Maintenance Procedures

Geobacter cultures can be maintained as frozen stocks at −70°C. Cultures should be grown to mid-exponential phase in medium amended with a suitable soluble electron donor and acceptor. Aliquots (1 ml) should be anaerobically transferred into small serum vials (10 ml) that have previously been thoroughly sparged with an N_2:CO_2 mixture (80:20; v/v) and heat sterilized. The vials should be amended with an anaerobic aqueous glycerol solution (100 µl) (25% v/v) mixed and frozen at −70°C immediately. Frozen stocks should be checked regularly to ensure viability.

Differentiation of the genus *Geobacter* from other genera

The genus *Geobacter* differs from all other strictly anaerobic bacteria both phenotypically and genotypically. *Geobacter* species are the first complete-oxidizing dissimilatory Fe(III)-reducers described. Members of the genus *Geobacter* are also the only described organisms that can couple oxidation of monoaromatic compounds, including the hydrocarbon toluene, to Fe(III) reduction. All strains have been isolated in defined mineral medium and do not require complex undefined medium additions.

Differentiation of the species of the genus *Geobacter*

The key differences in electron donor and acceptor utilization among the various *Geobacter* species are listed in Table BXII.δ.37.

List of species of the genus Geobacter

1. **Geobacter metallireducens** Lovley, Giovannoni, White, Champine, Phillips, Gorby and Goodwin 1995a, 619[VP] (Effective publication: Lovley, Giovannoni, White, Champine, Phillips, Gorby and Goodwin 1993a, 342.)
me.tal.li.re.du′ cens. L. n. *metallum* metal; L. part. adj. *reducens* converting to a different state; N.L. adj. *metallireducens* reducing metal.

G. metallireducens is the type strain for the genus *Geobacter*. Its closest known relatives are *G. hydrogenophilus* (Lonergan et al., 1996) and *G. grbiciae* (Coates et al., 1996, 2001). It is

a strictly anaerobic, Gram-negative, nonmotile rod, 2–4 μm × 0.6 μm. *G. metallireducens* was first isolated from aquatic sediments that were enriched with acetate as the electron donor and amorphous Fe(III)-oxide as the electron acceptor. Cell walls display characteristics typical of a Gram-negative organism with an outer membrane separated from an inner membrane by a periplasmic region. Cellular inclusions or flagella are not detected. Cells divide by forming a central restriction between daughter cells. Colonies were also isolated on anaerobic agar slants with nitrate as the electron acceptor. Cells are catalase and ubiquinone negative but contain *c*-type cytochromes. In addition to Fe(III), *G. metallireducens* also utilizes nitrate, which is stoichiometrically reduced to ammonia. Although elemental sulfur is reduced by cell suspensions of *G. metallireducens*, energy for growth is not conserved during this metabolism.

The mol% G + C of the DNA is: 56.6 (T_m); 58.9 ± 0.3 (HPLC).

Type strain: GS-15, ATCC 53774, DSM 7210.

GenBank accession number (16S rRNA): L07834.

2. **Geobacter chapellei** Coates, Bhupathiraju, Achenbach, McInerney and Lovley 2001, 586[VP]
cha.pel′ le.i. N.L. gen. masc. n. *chapellei* of Chapelle, named after Frank Chapelle, who contributed to our knowledge of subsurface biogeochemistry.

G. chapellei is a strictly anaerobic, Gram-negative, nonmotile rod, 1–2 × 0.5 μm and contains *c*-type cytochrome(s). Its closest known relative is *Pelobacter propionicus*. *G. chapellei* was isolated from an acetate-oxidizing, amorphous Fe(III)-reducing enrichment of pristine aquifer sediments from the deep subsurface. In contrast to the other *Geobacter* species, it has an optimal growth temperature of 25°C. It was isolated on Fe(III)-NTA agar plates with acetate as the electron donor, which it completely oxidizes to CO_2. It is relatively restricted in the range of electron donors it can use; in addition to acetate it can only use formate, ethanol, and lactate. In addition to Fe(III)-NTA, it can use amorphous Fe(III)-oxide, Mn(IV), or fumarate as electron acceptors. In contrast to other *Geobacter* species, it cannot use Fe(III) chelated with citrate as an electron acceptor, probably due to toxicity of citrate at elevated concentrations.

The mol% G + C of the DNA is: 50.2 ± 0.3 (HPLC).

Type strain: 172, DSM 13688.

GenBank accession number (16S rRNA): U41561.

3. **Geobacter grbiciae** Coates, Bhupathiraju, Achenbach, McInerney and Lovley 2001, 587[VP]
grb.i′ ci.ae. N.L. gen. fem. n. *grbiciae* of Grbic, named in honor of Dunja Grbic-Galic, for her significant contributions to the field of anaerobic aromatic hydrocarbon oxidation.

G. grbiciae is a close relative (99% sequence identity based on 16S rRNA analysis) of *G. metallireducens* and was identified as a new species based on DNA–DNA hybridization (Coates et al., 2001). Morphologically *G. grbiciae* is a Gram-negative, strictly anaerobic, nonmotile, nonfermentative rod, 1–2 × 0.5 μm. It was isolated in agar shake tubes from a toluene-oxidizing, amorphous Fe(III)-oxide-reducing enrichment of aquatic sediments with benzoate as the electron donor and Fe(III)-NTA as the electron acceptor. Phenotypically, *G. grbiciae* is similar to *G. metallireducens*. It is a complete oxidizer and uses a diverse range of electron donors including toluene and H_2. With *G. metallireducens*, it is only the second Fe(III) reducer shown to utilize toluene as an electron donor; however, in contrast to *G. metallireducens*, it can also use H_2 as an electron donor. This ability to oxidize both aromatics and H_2 makes *G. grbiciae* unique among the known Fe(III)-reducers.

The mol% G + C of the DNA is: 57.4 ± 0.3 (HPLC).

Type strain: TACP-2, ATCC BAA-45, DSM 13689.

GenBank accession number (16S rRNA): AF335182.

4. **Geobacter hydrogenophilus** Coates, Bhupathiraju, Achenbach, McInerney and Lovley 2001, 586[VP]
hy.dro.ge.no′ phi.lus. N.L. n. *hydrogenium* hydrogen; Gr. adj. *philos* friendly to; N.L. adj. *hydrogenophilus* liking hydrogen, referring to the ability of the organism to grow by oxidation of hydrogen.

G. hydrogenophilus is a strictly anaerobic, Gram-negative, nonfermentative, nonmotile rod, 1–2 × 0.5 μm. Its 16S rRNA sequence is 99% identical to that of *G. metallireducens*; however, DNA–DNA hybridization homology indicates that *G. hydrogenophilus* is a separate species (Coates et al., 2001). It exhibits phenotypic traits characteristic of *G. metallireducens*. It was isolated from a petroleum-contaminated aquifer with acetate as the electron donor and Fe(III) chelated with nitrilotriacetic acid (Fe(III)-NTA) (Roden and Lovley, 1993) as the electron acceptor. In addition to simple organics, *G. hydrogenophilus* can also obtain energy for growth from the oxidation of H_2. It cannot grow autotrophically and requires citrate or acetate as a carbon source. Growth on H_2 is significantly enhanced in cultures amended with 0.1 g/l yeast extract. When growing on H_2 and Fe(III) chelated with citrate (Fe(III)-citrate), *G. hydrogenophilus* can oxidize H_2 to a threshold value of 0.092 Pa, which is between H_2 threshold values reported for pure cultures of sulfate-reducing bacteria growing with sulfate and H_2 threshold values obtained with *Shewanella algae* growing with Fe(III)-citrate. In addition to the various forms of Fe(III), *G. hydrogenophilus* can also reduce elemental sulfur with acetate as the electron donor; however, energy to support growth is not obtained from this metabolism. In contrast to *G. metallireducens*, *G. hydrogenophilus* could not use Mn(IV) as an alternative electron acceptor in the absence of Fe(III).

The mol% G + C of the DNA is: 58.4 ± 0.2 (HPLC).

Type strain: H-2, ATCC 51590, DSM 13691.

GenBank accession number (16S rRNA): U28173.

5. **Geobacter sulfurreducens** Caccavo, Lonergan, Lovley, Davis, Stolz and McInerney 1995, 619[VP] (Effective publication: Caccavo, Lonergan, Lovley, Davis, Stolz and McInerney 1994, 3757.)
sul′ fur.re.du′ cens. L. n. *sulfur* sulfur; L. part. adj. *reducens* converting to a different state; N.L. adj. *sulfurreducens* reducing sulfur.

G. sulfurreducens is a nonfermentative, strictly anaerobic, Gram-negative, nonmotile rod, 1–2 × 0.5 μm. It was isolated from a contaminated drainage ditch with acetate as the electron donor and Fe(III)-pyrophosphate as the electron acceptor. *G. sulfurreducens* is very limited in the number of electron donors it can use and, of those tested, only acetate and H_2 supported growth and Fe(III) reduction. This is

in contrast to *G. metallireducens*, which cannot oxidize H_2 but can use a broad range of organic compounds as electron donors. *G. sulfurreducens* was the first strictly anaerobic Fe(III)-reducer to be isolated that can obtain energy for growth by the oxidation of H_2. In addition to the various forms of Fe(III), *G. sulfurreducens* can also use sulfur, or cobalt chelated with EDTA (Co(III)-EDTA) as alternative electron acceptors. It is the first organism identified to be capable of sustaining growth with cobalt as an electron acceptor. Its ability to use elemental sulfur as well as its inability to use Mn(IV) or U(VI) as alternative electron acceptors is in contrast to *G. metallireducens*.

The mol% G + C of the DNA is: 60.6 ± 0.4 (HPLC).

Type strain: PCA, ATCC 51573, DSM 12127.

GenBank accession number (16S rRNA): U13928.

Other Organisms

1. *"Geobacter humireducens"*

hu.mi.re.du′ cens. N.L. n. *humi* humic acids, derived from humus; N.L. n. *humus* soil; L. part. adj. *reducens* converting to a different state; N.L. adj. *humireducens* reducing humic substances.

"G. humireducens" was isolated from hydrocarbon-contaminated wetland sediments with acetate as the electron donor and the humic substances analog, 2,6-anthraquinone disulfonate (AQDS), as the electron acceptor. It is the first organism to be isolated as a dissimilatory humics-reducer (Coates et al., 1998, 2001). *"G. humireducens"* can use the broadest range of electron acceptors of any of the *Geobacter* species.

The mol% G + C of the DNA is: unknown.

GenBank accession number (16S rRNA): AF019932.

Genus II. **Trichlorobacter** *De Wever, Cole, Fettig, Hogan and Tiedje 2001, 1VP (Effective publication: De Wever, Cole, Fettig, Hogan and Tiedje 2000, 2301)*

THE EDITORIAL BOARD

Tri.chlor.o.bac′ ter. L. pref. *tri* three; Gr. n. *chloros* chlorine; M.L. masc. n. *bacter* equivalent of Gr. neut. n. *bactrum* a rod; M.L. masc. n. *Trichlorobacter* a TCA-dechlorinating rod.

The description of the genus *Trichlorobacter* is the same as that of *Trichlorobacter thiogenes*.

The mol% G + C of the DNA is: unknown.

Type species: **Trichlorobacter thiogenes** De Wever, Cole, Fettig, Hogan and Tiedje 2001, 1 (Effective publication: De Wever, Cole, Fettig, Hogan and Tiedje 2000, 2301.)

FURTHER DESCRIPTIVE INFORMATION

Trichlorobacter thiogenes grows anaerobically on acetate or acetoin and reduces trichloroacetic acid (TCA) to dichloroacetic acid. In some media and in some physiological states the organism appears to be able to couple TCA reduction to the oxidation of sulfide to sulfur with precipitation of sulfur in the medium. The precipitated sulfur is then reduced to sulfide with electrons derived from acetate. However, the redox cycle involving sulfur and sulfide is not required for TCA reduction (De Wever et al., 2000).

Analysis of 16S rDNA sequences placed *Trichlorobacter thiogenes* in the *Deltaproteobacteria* (De Wever et al., 2000).

ENRICHMENT AND ISOLATION PROCEDURES

The organism was obtained from contaminated soil incubated in liquid anaerobic enrichment medium containing acetate and trichloroacetic acid as described by De Wever et al. (2000).

MAINTENANCE PROCEDURES

The organism was maintained on the enrichment medium (De Wever et al., 2000).

List of species of the genus Trichlorobacter

1. **Trichlorobacter thiogenes** De Wever, Cole, Fettig, Hogan and Tiedje 2001, 1VP (Effective publication: De Wever, Cole, Fettig, Hogan and Tiedje 2000, 2301.)

thi.o′ gen.es. Gr. n. *theion* sulfur; M.L. n. *genes* production; M.L. n. *thiogenes* because it produces sulfur.

Gram-negative nonmotile curved rods. Strict anaerobe. Oxidizes acetate with reduction of trichloroacetic acid to dichloroacetic acid. Sulfur and fumarate also used as electron acceptors.

The mol% G + C of the DNA is: unknown.

Type strain: K1, ATCC BAA-34.

GenBank accession number (16S rRNA): AF223382.

Order VI. **Syntrophobacterales** *ord. nov.*

Jan Kuever, Fred A. Rainey and Friedrich Widdel

Syn.troph.o.bac.te.ra' les. M.L. masc. n. *Syntrophobacter* type genus of the type family of the order; suffix *-ales* denotes an order; M.L. fem. pl. n. *Syntrophobacterales* the order that comprises the family *Syntrophobacteraceae* and others.

Cells are oval or rod shaped and often motile. **Strictly anaerobic chemoorganotrophic or chemolithoautotrophic growth by fermentative or respiratory metabolism. Several members use sulfate as an electron acceptor, which is reduced to sulfide; however, most described species of the genera *Syntrophobacter*, *Syntrophus*, and *Smithella* are unable to use sulfate as electron acceptor but rather reduce protons (or form formate) and thus require the presence of H_2-utilizing (or formate-utilizing) organisms** (methanogens or sulfate reducers) **as syntrophic partners**. In addition, sulfite or thiosulfate may be used; some members may also reduce elemental sulfur (or polysulfide) to sulfide. Simple organic compounds serve as electron donors and carbon sources that are oxidized incompletely to acetate or completely to CO_2. Most members are mesophilic; in addition, some moderate thermophiles with growth temperature optima at 60°C have been isolated. Cells contain various cytochromes and other redox proteins. Mesophilic species have been isolated from almost every type of anoxic aquatic environment, including marine and freshwater habitats, as well as sludge from sewage treatment plants. Thermophilic members have been isolated from geothermally heated marine environments. All members grow preferentially around neutral conditions.

The order comprises the families *Syntrophobacteraceae* and *Syntrophaceae.*

Type genus: **Syntrophobacter** Boone and Bryant 1984, 355 (Effective publication: Boone and Bryant 1980, 631).

Family I. **Syntrophobacteraceae** *fam. nov.*

Jan Kuever, Fred A. Rainey and Friedrich Widdel

Syn.troph.o.bac.te.ra.ce' ae. M.L. masc. n. *Syntrophobacter* type genus of the family; suffix *ceae* denotes family; M.L. fem. pl. n. *Syntrophobacteraceae* the family that comprises the genus *Syntrophobacter*.

The common electron acceptor for the genera *Desulfacinum*, *Thermodesulforhabdus*, *Desulforhabdus*, and *Desulfovirga* is sulfate, which is reduced to sulfide. In contrast, most members of the genus *Syntrophobacter* are unable to use sulfate as electron acceptor. Except for members of the genera *Thermodesulforhabdus* and *Desulfacinum*, all known members are mesophilic bacteria. Only members of the genus *Syntrophobacter* oxidize organic substrates incompletely to acetate. All other members show a complete substrate oxidation.

The family comprises the genera *Syntrophobacter*, *Desulfacinum*, *Thermodesulforhabdus*, *Desulforhabdus*, and *Desulfovirga*. Detailed properties of these genera are given in Table BXII.δ.38.

Type genus: **Syntrophobacter** Boone and Bryant 1984, 355 (Effective publication: Boone and Bryant 1980, 631).

Genus I. **Syntrophobacter** *Boone and Bryant 1984, 355^VP (Effective publication: Boone and Bryant 1980, 631)*

Michael J. McInerney, Alfons J.M. Stams and David R. Boone

Syn.tro.pho.bac' ter. Gr. adj. *syn* together with; Gr. n. *trophos* one who feeds; M.L. n. *bacter* masc. equivalent of Gr. neut. n. *bacterion* small staff, rod; M.L. masc. n. *Syntrophobacter* rod which feeds together with (another species).

Straight rods with rounded ends, 0.6–1.2 × 1.0–4.5 μm, sometimes oval to ellipsoid, occur singly and in pairs. May form short chains and filamentous cells (up to 35 μm). **Gram negative.** Endospores not formed. **Strictly anaerobic chemoorganotroph. Mesophilic.** Growth occurs at neutral pH (6.2–8.0) in low salinity media. **Growth occurs by syntrophic metabolism and sulfate reduction.** Propionate oxidation to acetate and CO_2 requires the presence of either a H_2/formate-using organism (methanogen or sulfate reducer) or sulfate as the electron acceptor. **Acetate and other fatty acids not oxidized.** Some species grow fermentatively with pyruvate, malate, or fumarate. Lactate and propanol may serve as electron donors for syntrophic metabolism or sulfate reduction. **Other common bacterial substrates such as sugars and aromatic compounds are not used** either in coculture with a H_2/formate-using organism or in pure culture with sulfate as the electron acceptor. Sulfite or thiosulfate, but not nitrate, may be used as the electron acceptor. Habitat is sludge from anaerobic waste treatment facilities.

The mol% G + C of the DNA is: 57–61.

Type species: **Syntrophobacter wolinii** Boone and Bryant 1984, 355 (Effective publication: Boone and Bryant 1980, 631.)

Further descriptive information

Cell morphology differs markedly between the species in the genus *Syntrophobacter. S. wolinii* is a short rod, with the ends tapering to a blunt point (Fig. BXII.δ.42) (Liu et al., 1999) and some cells forming long filaments (Boone and Bryant, 1980). Both *S. pfennigii* and *S. fumaroxidans* are oval- to egg-shaped rods, and individual cells do not form filaments (Wallrabenstein et al., 1995b; Harmsen et al., 1998).

Cells of *S. wolinii* have a typical Gram-negative ultrastructure, and the cytoplasm of fumarate-grown cells contains numerous membrane-delimited inclusions (Fig. BXII.δ.42) (Liu et al., 1999). Details of the ultrastructure of *S. pfennigii* and *S. fumaroxidans* have not been elucidated.

Surface colonies of *S. wolinii* in coculture with a *Desulfovibrio*

[d]Some species.

species are black-centered and convex, with circular, entire edges (Boone and Bryant, 1980). Colonies form in 3–5 weeks and may reach 2–3 mm in diameter. Subsurface colonies are lenticular. Colonies of a triculture of *S. wolinii*, *Methanospirillum hungatei*, and *Methanosarcina barkeri* are light yellow and take 6 months to develop in agar roll tubes (Liu et al., 1999). *S. pfennigii*, in association with *Methanospirillum hungatei*, forms large, yellow, lens-shaped, subsurface colonies after 10 weeks of incubation. Colony formation with *S. pfennigii* is observed only when agar medium is inoculated with a primary enrichment (Wallrabenstein et al., 1995b). *S. fumaroxidans* also forms brownish-yellow, lens-shaped colonies in agar medium with fumarate (Harmsen et al., 1998).

All three species of *Syntrophobacter* oxidize propionate to acetate, CO_2, and H_2 when grown in the presence of a hydrogen- and formate-using organism, such as a methanogen or a sulfate reducer. The presence of an organism that uses both hydrogen and formate is needed to maintain hydrogen and formate at low enough concentrations that the degradation of propionate is thermodynamically favorable (McInerney and Bryant, 1981; Schink, 1997). *S. fumaroxidans* is not able to degrade propionate in the presence of a methanogen that uses only hydrogen, suggesting that the use of both hydrogen and formate is required for syntrophic metabolism of propionate (Dong et al., 1994). In addition to propionate, *S. pfennigii* grows by the oxidation of propanol and lactate in the presence of a hydrogen/formate-using organism. All three species grow in pure culture by propionate oxidation coupled to sulfate reduction. *S. wolinii* and *S. fumaroxidans* also grow in pure culture by the fermentation of pyruvate, fumarate, or malate.

Pure cultures of *S. wolinii* (Wallrabenstein et al., 1994), *S. pfennigii* (Wallrabenstein et al., 1995b), and *S. fumaroxidans* (Harmsen et al., 1998) grow by sulfate reduction in a mineral medium with a B-vitamin solution and propionate as the only organic compounds added to the medium. Whether the vitamin solution is required for growth has not been determined.

Syntrophobacter species degrade propionate by the reversal of the methylmalonyl-CoA pathway used by fermentative bacteria to form propionate. A key characteristic of this pathway is that uniformly labeled acetate is produced from either 2-^{13}C-propionate or 3-^{13}C-propionate (Houwen et al., 1987). ATP is likely formed by substrate-level phosphorylation reactions involving acetate kinase or succinate thiokinase. Hydrogen production from propionate requires energy in the form of a proton motive force, with succinate and malate oxidation steps being the thermodynamically most difficult steps to couple to hydrogen production (Schink, 1997; van Kuijk et al., 1998).

Syntrophic propionate oxidizers can be enriched from anaerobic environments where organic matter is completely mineralized to methane and carbon dioxide. An excellent source for enrichment is the biomass from methanogenic reactors that are

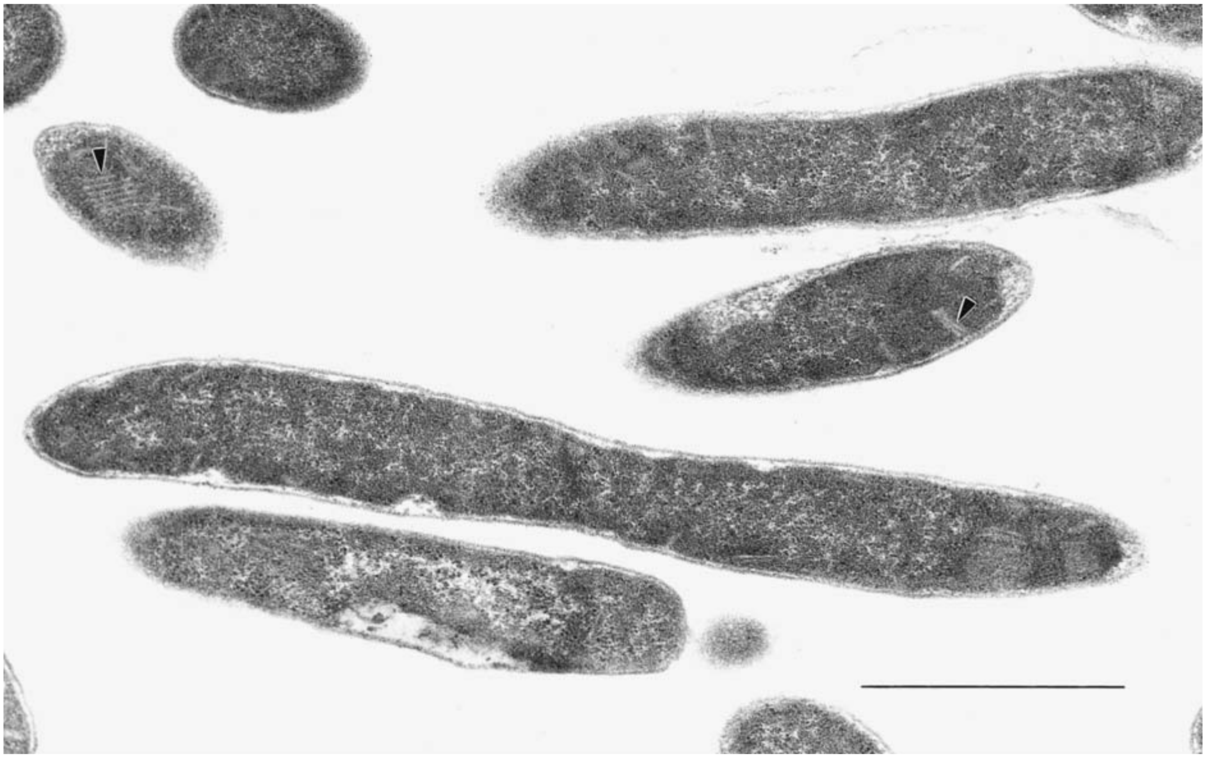

FIGURE BXII.δ.42. Transmission electron micrograph of *Syntrophobacter wolinii* strain DB. Cytoplasm contains flat parallel plates (*arrowheads*), which are invaginations of the plasma membrane. Bar = 1 μm. Micrograph by Henry C. Aldrich.

used for the stabilization of sewage sludge or the anaerobic treatment of industrial wastewater (Stams, 1994). Successful enrichment is also possible using other sources, such as freshwater sediments, rice paddy soils, and fermented manure. Syntrophic propionate oxidation is not restricted to only *Syntrophobacter* species; consequently, it is not yet clear in which methanogenic environments *Syntrophobacter* species are the main propionate oxidizers. In marine sediments, sulfate reduction is the main process for organic matter mineralization; therefore, syntrophic propionate oxidizers are not easily enriched from marine or brackish-water sediments. Although *Syntrophobacter* species are able to couple propionate to sulfate reduction, these bacteria are easily overgrown by *Desulfobulbus* species when sulfate is present. *Desulfobulbus* species grow much faster with propionate and sulfate than do *Syntrophobacter* species (Oude Elferink et al. 1994; Wallrabenstein et al., 1994; Van Kuijk and Stams 1995). Syntrophic propionate oxidation is a rather sensitive process and is easily inhibited by perturbations that lead to increases in the hydrogen, formate, or acetate concentrations (Boone and Xun, 1987; Schmidt and Ahring, 1993; Liu et al., 1999). Syntrophic propionate oxidizers live in close association with methanogens, allowing for efficient interspecies hydrogen and formate transfer. Growth conditions become less favorable upon disruption of the structure and subsequent cultivation in suspended culture.

Enrichment and Isolation Procedures

Selective enrichment of bacteria that syntrophically oxidize propionate is accomplished by using an anaerobic medium that lacks electron acceptors—such as oxyanions of nitrogen, sulfur, S^0, or ferric iron—and by incubating the cultures in the dark (McInerney et al., 1979; Boone and Bryant, 1980; Wallrabenstein et al., 1995b). Either a basal medium[1] with rumen fluid and B-vitamins or a mineral medium is used. The mineral medium has the same composition as the basal medium, except that it lacks organic components other than propionate and the B-vitamin solution. Anaerobic media and solutions are prepared using a modification of the Hungate technique (Bryant, 1972; Balch and Wolfe, 1976). Because of the slow growth rates of syntrophic associations, the medium must be prepared very carefully so that it remains reduced for a long period. The reducing solution is

1. The basal medium has the following composition (g/l distilled water): KH_2PO_4, 0.5 g; $MgCl_2 \cdot 6H_2O$, 0.3 g; NaCl, 0.4 g; NH_4Cl, 0.4 g; $CaCl_2 \cdot 2H_2O$, 0.5 g; resazurin, 0.001 g; clarified rumen fluid, 50 ml; B-vitamin solution, 5 ml; trace metal solution, 20 ml. The medium is boiled under a stream of N_2/CO_2 (80:20 v/v) gas mixture. Solid $NaHCO_3$ (3.5 g/l) is slowly added, and the medium is stoppered and brought inside an anaerobic chamber. The medium is dispensed into serum tubes, which are then stoppered and sealed. The gas phase is replaced by vacuuming and re-pressurizing each tube with an N_2/CO_2 (80:20 v/v) gas mixture using a gassing station (Balch and Wolfe, 1976). The medium is then autoclaved. Before use, the medium is reduced with a cysteine–sulfide reducing solution (0.2 ml/10 ml medium). Additions to the medium and inoculation are done using sterile needles and syringes that have been flushed with an anaerobic gas. The trace metal solution contains (g/l): nitrilotriacetic acid, 2.0; pH is then adjusted to 6 with KOH before addition of the other components (g/l): $MnSO_4 \cdot H_2O$, 1.0, $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$, 0.8; $CoCl_2 \cdot 6H_2O$, 0.2; $ZnSO_4 \cdot 7H_2O$, 0.2; $CuCl_2 \cdot 6H_2O$, 0.02; $NiCl_2 \cdot 6H_2O$, 0.02; $Na_2MoO_4 \cdot 2H_2O$, 0.02; Na_2SeO_4, 0.02; Na_2WO_4, 0.02. The B-vitamin solution contains (mg/l): pyridoxine-HCl, 10; thiamin-HCl, 5; riboflavin, 5; calcium pantothenate, 5; *p*-aminobenzoic acid, 5, thiotic acid, 5; nicotinic acid, 5; vitamin B_{12}, 5; biotin, 2; folic acid, 2. Cysteine–sulfide solution contains (g/l); cysteine, 12.5, neutralized with NaOH before the addition of sodium sulfide; and $NaS \cdot 9H_2O$, 12.5. The solution is boiled and dispensed under a 100% nitrogen gas phase and then autoclaved. The sodium sulfide solution contains 25 g/l of $NaS \cdot 9H_2O$ and is boiled and dispensed under a 100% nitrogen gas phase.

added to individual tubes several hours to a day before use. This ensures that each tube remains reduced for the long periods of time needed to grow syntrophic propionate-degrading cultures.

For primary enrichments, the basal medium (pH 7.2–7.4), with 20 mM sodium propionate and sodium sulfide as the reductant, is used. The inoculum is from a methanogenic environment, such as sewage sludge or a fresh water sediment. The enrichments are incubated at the temperature of the environment from which the sample was obtained. Propionate degradation is followed by gas chromatography or comparison of methane production in enrichments with propionate to that in controls without substrate. The enrichments are maintained by serially transferring 20–50% of the volume every 1–2 weeks.

When the numbers and types of cells in the enrichment are consistent after each transfer, as determined by microscopic analysis, the enrichment is serially 10-fold diluted in a mineral solution with the same composition as the medium used for the enrichment, but lacking the organic components. The highest dilutions are inoculated into tubes of molten agar medium having the same composition as the medium used for enrichment, plus cysteine–sulfide solution as the reductant and 2% agar as the solidifying agent (McInerney et al., 1979; Boone and Bryant, 1980). A hydrogen/formate-using bacterium (either a methanogen or a sulfate reducer) is added to each tube of agar or to the last few dilution tubes prior to their inoculation by the syntrophic enrichment. If a hydrogen/formate-using sulfate reducer is used, then 30 mM sodium sulfate is added to the agar medium. After inoculation, the agar tubes are spun quickly in ice water to solidify the agar along the side of the tube. The tubes are incubated in an upright position at the incubation temperature. The shake-tube method of Pfennig (1978), in which the agar medium is allowed to solidify in the base of the tube, can also be used. The agar concentration is about 0.5–1% for shake tubes.

Colonies of the propionate degrader will take weeks to months to appear. Colonies that appear within the first two weeks of incubation are probably not syntrophic associations and are marked so that late-forming colonies can be easily detected. Incubation of roll tubes inside anaerobic jars (or chambers) helps to maintain low redox conditions for the long periods of time needed for colonies to develop. Colonies with the sulfate reducer as the hydrogen/formate-using partner have black centers. Colonies with the methanogen as the hydrogen/formate-using partner are yellowish to greenish in color. Colonies are picked with bent Pasteur pipettes under a stream of anaerobic gas and are inoculated into agar slants containing the same medium as used for isolation. The addition of 0.1–0.5 ml of a mid-exponential phase culture of the hydrogen/formate-using partner to the medium in which the colony is transferred may increase the probability that the colonies will grow in new medium. Monoxenic cultures (cocultures) containing only the syntrophic bacterium and its partner may be obtained by repeating the above steps. Procedures for the growth of pure cultures of hydrogen/formate-using methanogens or sulfate reducers are described in Balch and Wolfe (1976) and McInerney et al. (1979).

Cocultures of a syntrophic propionate degrader with a hydrogen/formate-using methanogen have been obtained by serial dilution of the enrichment into propionate basal medium that has also been inoculated with a pure culture of the methanogen (Wallrabenstein et al., 1994, 1995b). After repeated attempts, a coculture containing the syntrophic propionate degrader and the methanogen may be obtained. Axenic cultures of *S. pfennigii* have been obtained by repeated transfer of the methanogenic coculture into mineral medium containing propionate sulfate and 5 mM bromoethanesulfonic acid (Wallrabenstein et al., 1995b). The latter compound is added to inhibit the growth of the methanogen. Similarly, pure cultures of *S. wolinii* and *S. fumaroxidans* have been obtained by repeated transfer of the methanogenic coculture into mineral medium with pyruvate or fumarate as the energy source (Wallrabenstein et al., 1994; Harmsen et al., 1998; Liu et al., 1999). One must be cautioned about the use of this approach, however, because it is difficult to demonstrate that a pure culture has been obtained. In addition, *Desulfovibrio* species often remain as contaminants in methanogenic propionate-degrading cultures. The fermentative growth of *Desulfovibrio* species with pyruvate and fumarate is much faster than that of *Syntrophobacter* species, making it difficult to eliminate the contaminant by dilution. The slow growth rates of *Syntrophobacter* species with propionate and sulfate make it unlikely that syntrophobacters can be enriched and isolated with a propionate–sulfate medium.

Maintenance Procedures

Methanogenic cocultures are grown in the basal medium with 20 mM propionate and transferred every 2–4 weeks. Sulfate-reducing cocultures require the addition of 30 mM sodium sulfate to this medium. Pure cultures of *S. wolinii* are grown in basal medium with 20 mM propionate and 30 mM sodium sulfate and are transferred as indicated above. Pure cultures of *S. pfennigii* can be maintained in a mineral medium with 20 mM propionate and 30 mM sulfate. *S. fumaroxidans* can be maintained in a mineral medium with 20 mM fumarate. Addition of 50–100 μM dithionite to the above media helps to initiate growth after transfer. The optimal growth temperature for the species is 35–37°C. *S. wolinii* can be stored in sealed glass vessels in liquid nitrogen vapor.

Procedures for Testing Special Characters

The ability to metabolize propionate syntrophically is tested by inoculating the organism into tubes of basal medium containing 20 mM propionate and reduced with cysteine–sulfide solution. To each tube, 0.1–0.5 ml of a pure culture of a hydrogen/formate-using methanogens or a sulfate reducer is added. When the latter is used, 30 mM sodium sulfate is added to the medium. Growth, propionate degradation, and methane or sulfide production are monitored over time and compared to controls lacking propionate. In addition, media with and without propionate are inoculated with only the hydrogen/formate-using organism to show that this organism is not responsible for metabolism of propionate.

To confirm that methanogenic cocultures require hydrogen and/or formate removal for propionate degradation, the effect of bromoethanesulfonic acid—an inhibitor of methanogenesis—on propionate degradation and growth of the coculture is determined. For sulfate-reducing cocultures, the effect of high partial pressures of hydrogen on propionate degradation is determined.

Differentiation of the genus *Syntrophobacter* from other genera

The most closely related genera to *Syntrophobacter*, as determined by 16S rDNA sequence analysis, are shown in Fig. BXII.δ.43. *Syntrophobacter wolinii* differs from *Desulforhabdus amnigena* by 6.9% and from *Thermodesulforhabdus norvegica*, *Desulfacinum infernum*, *Desulfomonile tiedjei*, *Smithella propionica*, *Desulfarculus baarsii*, and *Desulfobulbus propionicus* by at least 9%. The genus *Syntrophobacter* can be differentiated from the above genera by morphological and physiological characteristics. *Syntrophobacter* species and *Smithella propionica* (Liu et al., 1999) syntrophically ox-

idize propionate. However, *Smithella propionica* forms small amounts of butyrate from propionate and syntrophically metabolizes butyrate, which *Syntrophobacter* species cannot use. *Syntrophobacter* species, *Desulfobulbus* species, and *Desulforhabdus amnigena* grow by using propionate and sulfate, but neither *Desulfobulbus* species nor *Desulforhabdus amnigena* metabolize propionate syntrophically. The growth rate for *Desulfobulbus* species (0.9–1.6 h^{-1}) with propionate and sulfate is much faster than the growth rates of *Syntrophobacter* species (0.02–0.06 h^{-1}) (Wallrabenstein et al., 1994; Van Kuijk and Stams, 1995). In addition, *Desulforhabdus amnigena* completely oxidizes its substrates and grows with acetate, butyrate, and isobutyrate, substrates that *Syntrophobacter* species cannot use. *Thermodesulforhabdus norvegica* and *Desulfacinum infernum* are both thermophiles, while *Syntrophobacter* species are mesophilic. *Thermodesulforhabdus norvegica* and *Desulfacinum infernum* use acetate and other fatty acids that *Syntrophobacter* species cannot use. Morphological characteristics distinguish *Syntrophobacter* species from *Desulfomonile tiedjei*, which has a distinctive collar morphology, and *Desulfarculus baarsii*, which is a vibrio. In addition, *Desulfomonile tiedjei* uses benzoate and *Desulfarculus baarsii* uses butyrate and longer chain fatty acids; these are substrates that *Syntrophobacter* species cannot use.

Taxonomic Comments

Phylogenetic analysis of 16S rDNA sequences shows that the species of *Syntrophobacter* form a monophylogenetic group that is distinct from other genera in the *Deltaproteobacteria* (Harmsen et al., 1993, 1995). *Syntrophobacter* species are most closely related to group 7 of the sulfate-reducing bacteria as defined by Devereux et al. (1989). Distance-matrix-similarity coefficients between *Syntrophobacter* and other genera differ by at least 6.9% (Harmsen et al. 1993, 1995; Oude Elferink, et al., 1995). DNA–DNA hybridization studies show that there is little homology (<26%) between *Syntrophobacter wolinii*, *Syntrophobacter pfennigii*, *Syntrophobacter fumaroxidans*, and one phylogenetically related but as yet unnamed organism, strain HP1.1 (Harmsen et al., 1998). This supports the contention that all four organisms are distinct species. A signature sequence for *Syntrophobacter* species, *Desulforhabdus amnigena*, and other closely related sulfate-reducing bacteria is 5′-GCGGGUACUCAUUCCUG-3′, which hybridizes to the V5 region of the 16S RNA corresponding to positions 5′-835-850-3′ of the *Escherichia coli* 16S RNA sequence.

The three species of *Syntrophobacter* and one phylogenetically related but as yet unnamed organism, strain HP1.1, form a phylogenetically coherent group within the sulfate-reducing bacteria. All four organisms share the ability to metabolize propionate syntrophically, which suggests that this trait may be a suitable taxonomic marker for this group. However, there are several unnamed organisms that reduce sulfate or are thermophilic and that also have the ability to metabolize propionate syntrophically (Mucha et al., 1988; Heppner et al., 1992; Wu et al., 1992; Stams et al. 1993; Imachi et al., 2002; Plugge et al., 2002). Taxonomic characterization of these organisms may show that syntrophic propionate metabolism is not found exclusively in members of the genus *Syntrophobacter*.

Desulforhabdus amnigena is phylogenetically closely related to *S. wolinii* (93.1% sequence similarity) (Oude Elferink et al., 1995) and other *Syntrophobacter* species (Harmsen et al., 1998). However, the physiology of *D. amnigena* is significantly different from that of *Syntrophobacter* species in that *D. amnigena* can oxidize a wide range of organic compounds coupled to sulfate reduction and is unable to oxidize propionate syntrophically. Further work may show that some organisms that are unable to metabolize propionate syntrophically are also members of the genus *Syntrophobacter*.

Acknowledgments

We thank Henry C. Aldrich for the electron photomicrograph.

Differentiation of the species of the genus *Syntrophobacter*

Differential characteristics of the species of the genus *Syntrophobacter* are given in Table BXII.δ.39. Other characteristics are given in Table BXII.δ.40.

List of species of the genus Syntrophobacter

1. **Syntrophobacter wolinii** Boone and Bryant 1984, 355[VP] (Effective publication: Boone and Bryant 1980, 631.)
wo.lin′i.i. M.L. gen. n. *wolinii* of Wolin; named after Meyer J. Wolin, an American microbiologist who contributed substantially to the understanding of interspecies hydrogen transfer.

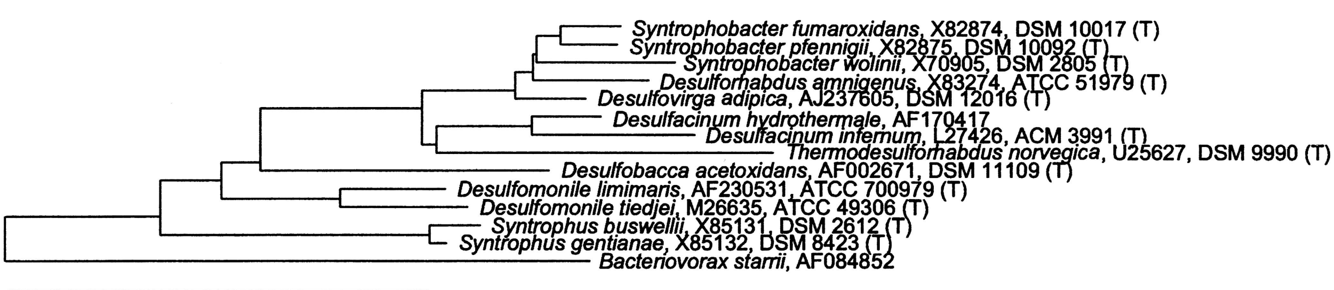

FIGURE BXII.δ.43. Phylogenetic tree showing the relationship of *Syntrophobacter* species to other members of the *Deltaproteobacteria*. The distances in the tree were calculated using 1101 positions (the least-squares method, Jukes-Cantor model). (Courtesy T. Lilburn of the Ribosomal Database Project.)

The characteristics are as described for the genus and as indicated in Tables BXII.δ.39 and BXII.δ.40. The width of the cells is sometimes irregular, especially in filaments. Cells are highly refractile.

No growth occurs in thioglycolate medium, suggesting that glucose and the materials present in yeast extract and a tryptic digest of casein do not support growth. Utilization of other carbohydrates or aromatic compounds has not been determined.

Habitat: Anaerobic sewage sludge

The mol% G + C of the DNA is: not determined.

Type strain: DB, DSM 2805.

GenBank accession number (16S rRNA): X70905.

Additional Remarks: S. wolinii was originally deposited as a coculture with *Desulfovibrio* sp. strain G11 under the designation DSM 2805 (Boone and Bryant, 1980). Subsequently, a pure culture of *S. wolinii* (Wallrabenstein et al., 1994) was obtained, which was deposited under the number given above.

2. **Syntrophobacter fumaroxidans** Harmsen, Van Kuijk, Plugge, Akkermans, De Vos and Stams 1998, 1386[VP]

fu.mar.ox' i.dans. M.L. neut. adj. *fumaricum* pertaining to fumaric acid (fumarate); L. adj. *oxidans* oxidizing; L. adj. *fumaroxidans* oxidizing fumarate. The ability to oxidize fumarate played an important role in the isolation and physiological characterization of this bacterium.

The characteristics are as described for the genus as indicated in Tables BXII.δ.39 and BXII.δ.40. Rod to eye-shaped cells with round ends; found singly or in pairs.

Succinate and formate also serve as electron donors for sulfate reduction, and aspartate also supports growth of the pure culture. Butyrate, isobutyrate, acetate, citrate, lactate, butanol, propanol, ethanol, methanol, glucose, fructose, xylose, and glutamate are not utilized. Thiosulfate and fumarate can serve as electron acceptors, but nitrate is not reduced. Growth is optimal in freshwater medium.

Habitat: granular sludge from an upflow anaerobic sludge bed (UASB) reactor treating sugar-beet processing wastewater.

The mol% G + C of the DNA is: 60.6 (HPLC).

Type strain: MPOB, DSM 10017.

GenBank accession number (16S rRNA): X82874.

3. **Syntrophobacter pfennigii** Wallrabenstein, Hauschild and Schink 1996, 836[VP] (Effective publication: Wallrabenstein, Hauschild and Schink 1995b, 351.)

pfen.ni' gi.i. M.L. gen. n. *pfennigii* of Pfennig; named after Norbert Pfennig, a German microbiologist who contributed

substantially to the understanding of syntrophic relationships and of the physiology of sulfate-reducing bacteria.

The characteristics are as described for the genus and as indicated in Tables BXII.δ.39 and BXII.δ.40. Oval to egg-shaped rods, found singly, in pairs, or in chains. Motility is observed only in the early exponential phase of growth. Gas vesicles formed in the late exponential phase of growth.

Other substrates that do not support the growth of the pure culture include fructose, xylose, arabinose, ethanol, methanol, succinate, fumarate, oxaloacetate, malate, acrylate, valerate, H_2/CO_2/acetate, and formate/acetate. Propionate and lactate are metabolized to acetate and CO_2 in the presence of a H_2/formate-using organism (methanogen or sulfate reducer). Sulfite and thiosulfate, but not nitrate or fumarate, serve as electron acceptors. Growth requires a mineral medium with a strong reductant (dithionite).

Habitat: Anaerobic sewage sludge.

The mol% G + C of the DNA is: 57.3 (HPLC).

Type strain: KoProp1, DSM 10092.

GenBank accession number (16S rRNA): X82875.

Other Organisms

Strain HP1.1 is a mesophilic, lemon- to peanut-shaped, Gram-negative rod that oxidizes propionate to acetate and CO_2 in the presence of methanogens. 16S rDNA sequence analysis shows that strain HP1.1 is closely related to *S. wolinii* strain DB, *S. pfennigii* strain KoProp1, and *S. fumaroxidans* with 93.4, 95.7, and 95.4% sequence similarity, respectively (Zellner et al., 1996). This suggests that strain HP1.1 represents a new species of *Syntrophobacter*. Like other *Syntrophobacter* species, strain HP1.1 is able to couple propionate oxidation to sulfate reduction.

Genus II. **Desulfacinum** *Rees, Grassia, Sheehy, Dwivedi and Patel 1995a, 88[VP]*

Gavin N. Rees and Bharat K.C. Patel

De.sul.fa.ci'num. L. pref. *de* from; L. n. *sulfur* sulfur; L. n. *acinum* a berry, especially a grape; L. n. *Desulfacinum* a berry-shaped, sulfate-reducing bacterium.

Oval cells, 1.5 × 2.5–3 µm, occurring singly or in pairs. **Gram negative. Nonmotile.** Endospores not formed. **Anaerobic, possessing a respiratory type of metabolism with sulfate, sulfite, and thiosulfate as terminal electron acceptors, which are reduced to sulfide.** Able to use a wide range of organic acids and alcohols as electron donors. **Autotrophic growth possible. Temperature range for growth, 40–65°C; optimum, 60°C.** Vitamins are required for growth and can be supplied as yeast extract. Isolated from the production fluids of high temperature petroleum reservoirs.

The mol% G + C of the DNA is: 64.

Type species: **Desulfacinum infernum** Rees, Grassia, Sheehy, Dwivedi and Patel 1995a, 88.

Further descriptive information

Thin sections examined by electron microscopy demonstrate a Gram-negative type of wall. Gram stain and lysis by KOH produce a Gram-negative reaction.

D. infernum can be grown in a phosphate-buffered, thioglycollate/ascorbic acid-reduced medium[1]. If a growth medium is required that does not have a high iron content, a bicarbonate-buffered, sulfide-reduced medium can be used[2]. Vitamins are required for growth and can be supplied either from a vitamin supplement or by the addition of 0.1 g/l yeast extract to the medium.

The pH range for growth is 6.6–8.4, with optimal growth occurring at 7.1–7.5.

The following compounds are used as electron donors and carbon sources: straight-chain monocarboxylic acids from C_1 to C_{18}, isobutyrate, isovalerate, lactate, pyruvate, fumarate, malate, succinate, glycerol, ethanol, propanol, butanol, hexanol, and alanine. Growth occurs with H_2 as an electron donor. Sulfate, thiosulfate, and sulfite are reduced to H_2S, with lactate, ethanol, or formate as the electron donor. Nitrate and sulfur are not used as terminal electron acceptors. Fermentative growth occurs on pyruvate in the absence of an exogenous electron acceptor. Fermentative growth does not occur on glycerol or fumarate.

Desulfoviridin is not present.

Current descriptions of *Desulfacinum* have been restricted to isolates obtained from the production fluids of high-temperature petroleum reservoirs. The type strain was obtained from the Beatrice Field, North Sea, United Kingdom, and a further isolate was obtained from an off-shore reservoir in Malaysia (Rees, unpublished data). Both reservoirs have approximately the same salinity as seawater. *Desulfacinum hydrothermale* was isolated from a submarine vent located in Palaeochori Bay, Milos, in the Aegean Sea.

Enrichment and Isolation Procedures

No selective medium exists for the isolation of *Desulfacinum*. The greatest likelihood of success will occur if production waters from off-shore petroleum reservoirs (field temperature approximately 60–80°C) are used for isolation. *Desulfotomaculum* spp. may be present in enrichments with acetate and *Thermodesulfobacterium* spp. and *Desulfotomaculum* spp. may occur when lactate is added as the carbon and energy source. All cultures should be incubated at 60°C. Pure cultures are obtained by dilution in agar shake tubes with bicarbonate-buffered, sulfide-reduced medium containing 2 g/l of agar. Once tubes are inoculated and the agar is set, the headspace of the tubes is flushed with a mixture of N_2/CO_2 (80:20), and tubes are sealed with the appropriate butyl rubber stoppers. Tubes are inverted during incubation to prevent contamination of the surface of the agar plug with liquid formed due to incubation at 60°C. Further details on the agar shake dilution procedure are described in the section on *Desulfobacter*.

1. Phosphate-buffered, thioglycollate/ascorbic acid-reduced medium is prepared as described in the footnote of the section on *Desulfovibrio*, with the following additions (g/l): NaCl, 10; $MgCl_2 \cdot 6H_2O$, 3.1. Sodium lactate (3.0–4.0 g/l) is added as the carbon and energy source.

2. The bicarbonate-buffered, sulfide-reduced medium is prepared as described in the footnote of the section on *Desulfobacter*, with the following addition (g/l): NaCl, 10; $MgCl_2 \cdot 6H_2O$, 3.1. Sodium lactate (3.0–4.0 g/l) is added as the carbon and energy source.

Maintenance Procedures

Short- to medium-term storage is achieved by inoculating phosphate-buffered, iron-rich medium. Bottles are incubated until growth occurs and significant amounts of iron sulfide form in the medium. The resulting cultures are stored at 20°C and should be transferred to fresh medium every 2–3 months. Long term storage is achieved by lyophilization.

Differentiation of the genus *Desulfacinum* from other genera

At present, species included in the genus are *Desulfacinum infernum* and *Desulfacinum hydrothermale*. The organisms most closely related to it are *Thermodesulforhabdus norvegica*, *Desulforhabdus amnigena*, and *Syntrophobacter wolinii* (with 16S rRNA similarities of 89.2, 90.3, and 90.6%, respectively). Characteristics differentiating *Desulfacinum* from these other species are presented in Table BXII.δ.41.

Taxonomic Comments

The 16S rRNA gene of *Desulfacinum infernum* possesses the signature sequences that define the *Proteobacteria* (Stackebrandt et al., 1988b). Phylogenetically, *D. infernum* and *D. hydrothermale* are placed in the *Deltaproteobacteria*. The most closely related organisms are *Thermodesulforhabdus norvegica* (Beeder et al., 1995), *Desulforhabdus amnigena* (Oude Elferink et al., 1995), and *Syntrophobacter wolinii* (Boone and Bryant, 1980; Harmsen et al., 1993). *Desulfacinum infernum*, *Thermodesulforhabdus norvegica*, and *Desulforhabdus amnigena* are almost equidistant from one another, with similarities of approximately 90%. Although they are currently recognized as three separate genera, analysis of the 16S rRNA sequences seems to suggest that the three organisms may represent a single genus; however, further study is required before the taxonomic status of these organisms is re-evaluated.

A phylogenetic tree showing *Desulfacinum*, its closest relatives, and representative members of the *Deltaproteobacteria* are shown in Fig. BXII.δ.44.

TABLE BXII.δ.41. Differential characteristics of *Desulfacinum* and related species[a]

List of species of the genus Desulfacinum

1. **Desulfacinum infernum** Rees, Grassia, Sheehy, Dwivedi and Patel 1995a, 88[VP]
in.fer′ num. L. adj. *infernum* that which is, or comes from below, especially the lower world.

The characteristics are as described for the genus and as listed in Table BXII.δ.41.

Isolated from production fluids of high petroleum reservoirs.

The mol% G + C of the DNA is: 64 (T_m).

Type strain: BaG1, ACM 3991, DSM 9756.

GenBank accession number (16S rRNA): L27426.

2. **Desulfacinum hydrothermale** Sievert and Kuever 2000, 1244[VP]
hy.dro.ther.ma′ le. Gr. n. *hydro* water; Gr. n. *thermos* heat; M.L. neut. adj. *hydrothermale* pertaining to hot water, i.e., to hydrothermal vents.

Cells oval to short rods, 0.8–1.0 × 1.5–2.5 μm. Requires at least 15g/l NaCl, optimal between 32 and 36 g/l. Growth occurs on 3 to 5, 8, 10, 12, 16, and 18 carbon straight-chain carboxylic acids, alcohols, lactate, and pyruvate. Does not use fumarate or succinate.

Isolated from a shallow submarine hydrothermal vent.

The mol% G + C of the DNA is: 59.5 (HPLC).

Type strain: MT-96, DSM 13166.

GenBank accession number (16S rRNA): AF170417.

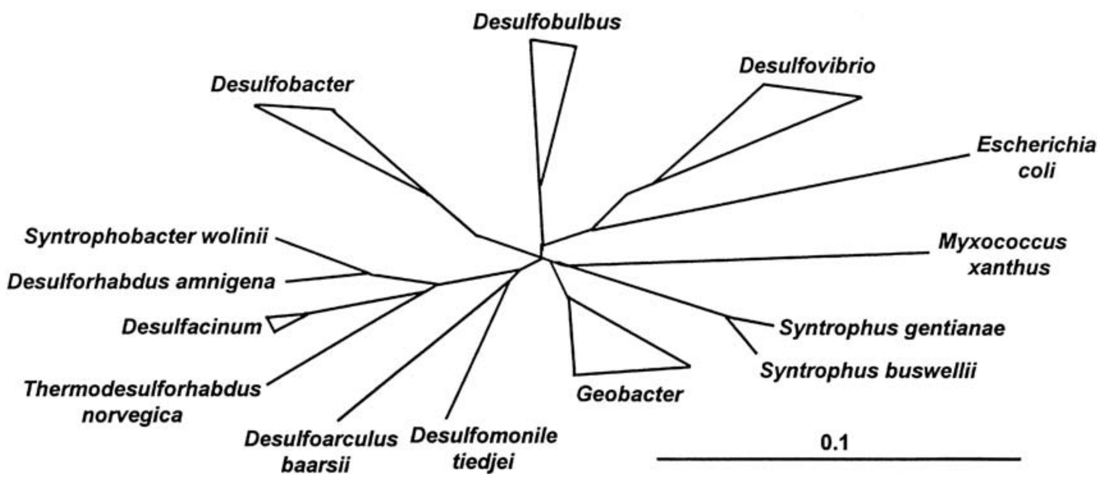

FIGURE BXII.δ.44. Phylogenetic tree of *Desulfacinum* spp. and related organisms. *Desulfovibrio*, *Desulfobulbus*, *Desulfobacter*, and *Geobacter* species are represented as clusters.

Genus III. Desulforhabdus *Oude Elferink, Maas, Harmsen and Stams 1997, 1274[VP]* *(Effective publication: Oude Elferink, Maas, Harmsen and Stams 1995, 123)*

JAN KUEVER, FRED A. RAINEY AND FRIEDRICH WIDDEL

De.sul.fo.rhab′ dus. L. pref. *de* from; L. neut. n. *sulfur* sulfur; Gr. fem. n. *rhabdus* rod; M.L. fem. n. *Desulforhabdus* a rod-shaped sulfate reducer.

Cells are rod-like to ellipsoid, 1.4–1.9 × 2.5–3.4 μm. Occur singly, in pairs, or in long chains. Spore formation is not observed. Gram negative and nonmotile. Strictly anaerobic, having a respiratory type of metabolism. **Chemoautotrophic or chemoorganotrophic**, using H_2 (+ CO_2), formate, acetate, propionate, butyrate, isobutyrate, lactate, pyruvate, ethanol, 1-propanol, and 1-butanol **as electron donors and carbon sources**. Organic substrates are completely oxidized to CO_2 via the anaerobic C_1-pathway (carbon monoxide dehydrogenase pathway, Wood-pathway) as indicated by carbon monoxide dehydrogenase activity, but transient excretion of acetate, isobutyrate, and propionate can occur. For chemoautotrophic growth, **H_2 serves as the electron donor and CO_2 as the carbon source**. **Sulfate, sulfite, and thiosulfate serve as terminal electron acceptors and are reduced to H_2S.** Sulfur is not reduced. **No growth by fermentation in the absence of an external electron acceptor.**

The only described species of the genus is able to grow in simple defined media containing a reductant (usually sulfide); vitamins are not required. The optimal pH for growth is 7.2–7.6. The optimal temperature is 37°C. Thermophilic species are not known. NaCl is not required. Desulfoviridin is absent. Type strain was isolated from anoxic granular sludge from a reactor treating sulfate-rich wastewater.

The mol% G + C of the DNA is: 52.5.

Type species: **Desulforhabdus amnigena** Oude Elferink, Maas, Harmsen and Stams 1997, 1274 (Effective publication: *Desulforhabdus amnigenus* (sic) Oude Elferink, Maas, Harmsen and Stams 1995, 123.)

Further descriptive information

The type strain of *D. amnigena* has rod-shaped to ellipsoid cells under all growth conditions. The cells are nonmotile and stain Gram negative.

The temperature range for growth is 25–45°C. The type strain has an optimal growth temperature of 37°C. The pH range for growth is 6.6–8.5, with an optimal pH of 7.2–7.6.

D. amnigena reduces sulfate, sulfite, or thiosulfate to H_2S. Elemental sulfur, fumarate, and nitrate cannot serve as electron acceptors. The following compounds are utilized as electron donors and organic carbon sources: formate, acetate, propionate, butyrate, isobutyrate, lactate, pyruvate, ethanol, 1-propanol, and 1-butanol. Despite the capacity for complete oxidation of organic substrates, transient excretion of organic products may occur; these products are acetate during growth on propionate or 1-butanol, acetate and isobutyrate (presumably by an isomerizing side-reaction) during growth on butyrate, and acetate and propionate during growth on lactate. For chemoautotrophic growth, H_2 serves as electron donor and CO_2 as carbon source. No growth in the absence of an external electron acceptor.

Strains of *Desulforhabdus* may be cultured in a defined freshwater medium (e.g., as used for *Desulfobulbus*) with sulfate as electron acceptor and lactate or various other substrates as the electron donor and carbon source. Ammonium ions are used as the nitrogen source. Vitamins are not required as growth factors. Cells contain cytochromes of the *c*-type. Desulfoviridin is not present.

Desulforhabdus strains occur in sewage sludge and probably other freshwater habitats.

Enrichment and Isolation Procedures

For the selective enrichment of *Desulforhabdus* strains, the acetate–sulfate medium for freshwater sulfate-reducing bacteria (e.g., as described for *Desulfobacter* without elevated salt concentration) should be used. The type strain was isolated from a serial dilution series with acetate as the only substrate. The inoculum was obtained from granular sludge of a reactor treating sulfate-rich wastewater. An enrichment culture with acetate, inoculated with 10% sewage sludge, may also be used. The cultures are incubated at 37°C. After intense formation of H_2S has occurred, transfers to fresh medium are made. Pure cultures of *Desulforhabdus* strains have been obtained by repeated application of the roll-tube-dilution method, but the agar dilution method (as described for *Desulfobacter* without elevated salt concentration) may also work.

Maintenance Procedures

Stock cultures are transferred every 3–5 months. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 2–5°C in the dark. *Desulforhabdus* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen.

Differentiation of the genus *Desulforhabdus* from other genera

In contrast to morphologically similar *Desulfococcus* strains, which are also found in freshwater habitats, *Desulforhabdus* strains are restricted to fatty acids with shorter chains as substrates. Clear differentiation requires a comparative analysis of the 16S rDNA sequence.

Taxonomic Comments

The closest relatives of *Desulforhabdus amnigena* are the syntrophic propionate oxidizer *Syntrophobacter wolinii* and the sulfate-reducing bacteria *Desulfomonile tiedjei* and *Desulfarculus baarsii.*

1. **Desulforhabdus amnigena** Oude Elferink, Maas, Harmsen and Stams 1997, 1274[VP] (Effective publication: *Desulforhabdus amnigenus* (sic) Oude Elferink, Maas, Harmsen and Stams 1995, 123.)
am.ni′ge.na. L masc. n. *amnis* water; L. fem. n. *genus* origin; L. adj. *amnigena* coming from water.

Characteristics are as described for the genus. Type strain isolated from sludge of a reactor (Netherlands) supplemented with acetate.

The mol% G + C of the DNA is: 52.5 (HPLC).

Type strain: ASRB1, ATCC 51979, DSM 10338.

GenBank accession number (16S rRNA): X83274.

Genus IV. Desulfovirga *Tanaka, Stackebrandt, Tohyama and Eguchi 2000a, 643*[VP]

Jan Kuever, Fred A. Rainey and Friedrich Widdel

De.sul.fo.vir′ga. L. pref. *de* from; L. n. *sulfur* sulfur; L. fem. n. *virga* twig, rod; M.L. fem. n. *Desulfovirga* a sulfate-reducing rod..

Rod-shaped cells, 0.8–2 × 2.2–4 μm. Occur singly or in pairs. Spore formation is not observed. Gram negative. Motile by a single polar flagellum. Strictly anaerobic, having a respiratory type of metabolism. **Chemoorganotrophic**, using C_1–C_{12} straight-chain fatty acids, other organic acids, and alcohols **as carbon sources and electron donors**. Electron donors are completely oxidized to CO_2. **Sulfate, sulfite, thiosulfate, and sulfur serve as terminal electron acceptors and are reduced to H_2S. Nitrate is not used as a terminal electron acceptor.** Optimal growth temperature, 35°C. Media containing a reductant and vitamins are necessary for growth. Cells contain cytochrome *c*, but no desulfoviridin. *Desulfovirga* species occur in freshwater habitats.

The mol% G + C of the DNA is: 60.

Type species: **Desulfovirga adipica** Tanaka, Stackebrandt, Tohyama and Eguchi 2000a, 643.

Further descriptive information

Cells are slightly curved short rods, 0.8–2 μm in diameter and 2.2–4.0 μm in length. Occur singly or in pairs. Spore formation is not observed. Gram negative. Cells are nonmotile or motile by subpolar flagella.

The temperature for growth is between 20 and 36°C with an optimal at 35°C. The pH range for growth is between 6.6 and 7.4 with an optimal at 7.0.

D. adipica uses sulfate, sulfite, thiosulfate, and sulfur as electron acceptors, whereas nitrate is not used. Adipate, (E)-2-hexendioate, (E)-hexenedioate, pyruvate, lactate, C_1–C_{12} straight-chain fatty acids, and C_2–C_{10} straight-chain primary alcohols serve as electron donors and also as carbon sources; these compounds are oxidized completely to CO_2. Adipate is degraded via (E)-2-hexenedioate by β-oxidation.

Media containing a reductant and vitamins are necessary for growth. Cells contain *c*-type cytochromes but no desulfoviridin. Ammonium ions are used as the nitrogen source. *Desulfovirga* strains occur in anoxic freshwater sediments rich in organic material.

Enrichment and Isolation Procedures

For the selective enrichment of *Desulfovirga* spp., the same defined sulfate medium as described for the isolation of the type species (Tanaka et al., 2000a) may be used. Other freshwater media (e.g., as described for *Desulfobulbus*) may be used in the same way. Adipate as sole electron donor and carbon source favors the development of *Desulfovirga* strains. Bottles or tubes (100-, 50-, or 20-ml capacity) can serve as culture vessels and are kept anoxic with tight screw caps, or by using a headspace of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated with black, anoxic, freshwater sediment slurry; 3–5% of the total culture volume should be added. *Desulfovirga* species may also be enriched and isolated via direct serial dilution of anoxic environmental samples in liquid medium (according to most-probable-number method) or agar medium (see next paragraph) with adipate as organic substrate. Enrichment cultures are incubated at 30°C. Cultures should be briefly shaken once a week. After intense formation of H_2S has occurred, transfers to fresh medium are made. The enrichment cultures should be mixed well before subculturing.

Pure cultures of *Desulfovirga* strains are obtained by repeated application of the agar dilution method. The method is similar to that described for the genus *Desulfobacter*, except that other substrates (see above) are used.

Maintenance Procedures

Stock cultures are transferred every 3–5 months. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 2–5°C in the dark. *Desulfovirga* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen.

Differentiation of the genus *Desulfovirga* from other genera

Desulfovirga adipica can be distinguished from other mesophilic sulfate-reducing bacteria by its ability to utilize adipate. So far, this is the only known sulfate-reducing bacterium able to use adipate as sole electron donor and carbon source. However, reliable differentiation of adipate-utilizing sulfate-reducing bacteria from other types requires comparative 16S rDNA sequence analysis.

Taxonomic Comments

The closest relatives of *Desulfovirga adipica* are members of the genera *Syntrophobacter* and *Desulforhabdus*.

List of species of the genus Desulfovirga

1. **Desulfovirga adipica** Tanaka, Stackebrandt, Tohyama and Eguchi 2000a, 643[VP]
a.di′pi.ca. M.L. n. *acidum adipinum* adipic acid (adipate); M.L. fem. adj. *adipica* pertaining to adipic acid and the organism's ability to degrade it.

Characteristics are as described for the genus. The type strain was isolated from an anaerobic digestor of a municipal wastewater treatment center, (Tsuchiura, Ibaraki, Japan) with adipate as substrate.

The mol% G + C of the DNA is: 60 (HPLC).

Type strain: TsuAS1, DSM 12016.

GenBank accession number (16S rRNA): AJ237605.

Genus V. **Thermodesulforhabdus** *Beeder, Torsvik and Lien 1996, 625[VP] (Effective publication: Beeder, Torsvik and Lien 1995, 335)*

Janiche Beeder

Ther.mo.de.sul.fo.rhab′dus. Gr. adj. *thermos* warm, hot; L. pref. *de* from; L. n. *sulfur* sulfur; Gr. fem. n. *rhabdos* rod; M.L. fem. n. *Thermodesulforhabdus* thermophilic, rod-shaped, sulfate reducer.

Rod-shaped cells 1 × 2.5 μm. Motile by means of a single polar flagellum. Gram-negative by staining and cell wall structure. **Anaerobic.** Chemoorganotrophic.

Nutritionally versatile, oxidizing various organic acids; these are oxidized completely to CO_2. Sulfate and sulfite are used as electron acceptors. Does not contain desulfoviridin, desulfofuscidin, desulforubidin, or P582.

Habitat: anaerobic warm oil field water.

The mol% G + C of the DNA is: 51.

Type species: **Thermodesulforhabdus norvegica** Beeder, Torsvik and Lien 1996, 625 (Effective publication: *Thermodesulforhabdus norvegicus* (sic) Beeder, Torsvik and Lien 1995, 335.)

Further descriptive information

Enrichment cultures were obtained from anoxic samples of hot oil field waters by the use of immunomagnetic beads (Christensen et al., 1992).

Differentiation of the genus *Thermodesulforhabdus* from other genera

Table BXII.δ.42 presents characteristics differentiating *Thermodesulforhabdus norvegica* from other phenotypically similar organisms.

Taxonomic Comments

Only a single species has been described, *Thermodesulforhabdus norvegica*, which belongs to the *Deltaproteobacteria*.

Fig. BXII.δ.45 indicates the relationship of this species to other bacteria in this class, based on analysis of 16S rRNA sequences.

Acknowledgments

The water samples from which *Thermodesulforhabdus* was isolated were contributed by the Norwegian oil company Statoil.

List of species of the genus Thermodesulforhabdus

1. **Thermodesulforhabdus norvegica** Beeder, Torsvik and Lien 1996, 625[VP] (Effective publication: *Thermodesulforhabdus norvegicus* (sic) Beeder, Torsvik and Lien 1995, 335.)
nor.ve′ gi.ca. M.L. fem. adj. *norvegica* Norwegian, describing the place of isolation.

The characteristics are as described for the genus and listed in Table BXII.δ.42. Temperature range for growth, 44–74°C, pH range for growth, 6.1–7.7. With SO_4^{2-} as the electron acceptor, electron donors are acetate, lactate, pyruvate, butyrate, succinate, malate, fumarate, valerate, caproate, heptanoate, octanoate, nonadecanoate, decanoate, tridecanoate, pentadecanoate, palmitate, heptadecanoate, stearate, and ethanol. Compounds not used as electron acceptors include formate, propionate, benzoate, H_2/CO_2, acetate (1 mM) + H_2, butanol, 1-propanol, yeast extract, undecanoate, dodecanoate, tetradecanoate, and crude oil. With acetate as the electron donor, electron acceptors are SO_4^{2-} and SO_3^{2-}. Acetate is metabolized via the oxidative carbon monoxide dehydrogenase pathway. Nitrate, fumarate, sulfur, and thiosulfate are not used as electron acceptors. Isolated from hot North Sea oil field water from a Norwegian oil platform.

The mol% G + C of the DNA is: 51 (HPLC).
Type strain: A8444, DSM 9990.
GenBank accession number (16S rRNA): U25627.

Pairwise evolutionary distances were computed using the correction of Jukes and Cantor (1969). The least-squares distance method of De Soete (1983) was used in the construction of the phylogenetic dendrogram from the distance matrix. Bar = 5 inferred nucleotide substitutions per 100 nucleotides. (Reproduced by permission from J. Beeder et al., Archives of Microbiology *164:* 331–336, 1995, ©Springer-Verlag.)

Family II. **Syntrophaceae** *fam. nov.*

JAN KUEVER, FRED A. RAINEY AND FRIEDRICH WIDDEL

Syn.troph.a.ce′ae. Gr. masc. n. *Syntrophus* type genus of the family; suffix *-aceae* denotes family; M.L. fem. pl. n. *Syntrophaceae* the family that comprises the genus *Syntrophus*.

For the genera *Desulfomonile* and *Desulfobacca*, the common electron acceptor is sulfate, which is reduced to sulfide. Sulfate reduction is coupled to complete oxidation of organic substrates. Members of the genera *Syntrophus* and *Smithella* are unable to use sulfate as an electron acceptor; rather they grow in syntrophic association with H_2-utilizing microorganisms, and oxidize substrates incompletely to acetate. All known members are mesophilic bacteria. The family comprises the genera *Syntrophus*, *Desulfomonile*, *Desulfobacca*, and *Smithella*. Detailed properties of these genera are given in Table BXII.δ.43.

Type genus: **Syntrophus** Mountfort, Brulla, Krumholz and Bryant 1984, 216.

[c]The type species *S. buswellii* and *S. gentianae* can use crotonate as electron acceptor.

Genus I. **Syntrophus** *Mountfort, Brulla, Krumholz and Bryant 1984, 216*[VP]

JAN KUEVER AND BERNHARD SCHINK

Syn′tro.phus. Gr. masc. n. *syntrophos* foster brother; N.L. masc. n. *Syntrophus* one living syntrophically with another so that each produces a nutrient required by the other.

Cells are rod shaped with rounded ends, 0.5–0.8 × 1.0–2.0 μm. Occur singly and in pairs. Gram negative. Endospores not formed. The type species is motile by means of monotrichous polar flagella in the early stage of growth, other species show no motility. **Strictly anaerobic and chemoorganotrophic. Possesses a fermentative type of metabolism. Crotonate is fermented by all species, whereas aromatic compounds such as gentisate, hydroquinone, and cinnamate are only fermented by some species. Some substrates, such as benzoate or fatty acids, are oxidized in the presence of H_2/formate-utilizing methanogenic or sulfate-reducing partner bacteria. Some species can grow on some substrates in the presence of crotonate as electron acceptor. Substrate oxidation is incomplete and leads to acetate. Sulfate, sulfite, thiosulfate, sulfur, and nitrate are not used as electron ac-**

ceptors. Cells contain cytochromes and menaquinones. Optimal growth temperature, 28–37°C. Occur in anoxic freshwater sediment or sludge from anaerobic wastewater treatment facilities.

The mol% G + C of the DNA is: 43–53.

Type species: **Syntrophus buswellii** Mountfort, Brulla, Krumholz and Bryant 1984, 216.

Further descriptive information

Strains of *Syntrophus* isolated from anoxic freshwater sediments or sewage sludge treatment plants may be motile only during early growth phases.

Crotonate is fermented by pure cultures of *Syntrophus* strains according to the following equation: 2 Crotonate$^-$ + $2H_2O \rightarrow$ 2 Acetate$^-$ + Butyrate$^-$ + H^+. Gentisate and hydroquinone are fermented to benzoate, acetate, and CO_2 by a pure culture of *S. gentianae*. One mol benzoate is degraded by syntrophic co-cultures to 3 mol acetate, 1 mol CO_2, and 3 mol H_2, which is consumed by sulfate-reducing or methanogenic partner organisms.

Benzoate is activated by a benzoyl-CoA ligase and not a benzoyl-CoA transferase (Auburger and Winter, 1996; Schöcke and Schink, 1999). In *S. gentianae* the pyrophosphate formed by this reaction is cleaved by a membrane-bound proton-translocating pyrophosphatase. Benzoyl-CoA reductase is not present. The further breakdown is catalyzed by glutaryl-CoA dehydrogenase and enzymes of the β-oxidation pathway (Wallrabenstein and Schink, 1994; Auburger and Winter, 1996). Reversed electron transport coupled to cytochromes and menaquinones is involved in hydrogen release during benzoate oxidation in co-cultures (Wallrabenstein and Schink, 1994; Auburger and Winter, 1996; Schöcke and Schink, 1999). Thus, these bacteria can synthesize no more than ⅓ to ⅔ mol ATP per mol benzoate oxidized (Warikoo et al., 1996; Schöcke and Schink, 1998, 1999).

The ability to use long-chain fatty acids and methyl esters of butyrate and hexanoate as electron donors and carbon sources is restricted to *S. aciditrophicus* (see Table BXII.δ.44).

The pH range for growth is 6.5–7.5, with the optimal being 7.1–7.4. The temperature range for growth is 10–42°C with an optimal at 28–37°C.

Cells of *Syntrophus* strains contain *b*- and *c*-type cytochromes and unidentified menaquinones. (Wallrabenstein and Schink, 1994; Auburger and Winter, 1996). Major cellular fatty acids of *Syntrophus aciditrophicus* are $C_{16:0}$, $C_{16:1\ \omega7c}$, and $C_{18:1\ \omega7c}$ (Jackson et al., 1999).

Syntrophus species occur in anoxic, sulfide-containing, freshwater sediments or sewage sludge treatment plants. Marine isolates have not been obtained so far.

Syntrophus strains can be cultured in a defined anaerobic medium with a reducing agent; *S. aciditrophicus* requires clarified rumen fluid as a supplement (Jackson et al., 1999).

Enrichment and Isolation Procedures

For the selective enrichment of *Syntrophus* strains, an anoxic mineral medium (e.g., as prepared for *Desulfobacter*) supplemented with 5–10 mM sodium benzoate is used. Bottles or tubes (100-, 50-, or 20-ml capacity) can serve as culture vessels and are kept anoxic with tight screw caps, or by using a headspace of N_2/CO_2 (90:10) and sealing with butyl rubber stoppers. The medium is inoculated with anoxic mud from a freshwater habitat; 3–5% of the total culture volume should be added. *Syntrophus* species may also be enriched and isolated via direct serial dilution of anoxic

[b]Might vary between strains.

environmental samples in liquid medium (according to most-probable-number method) or agar with benzoate as organic substrate. To prevent development of sulfate-reducing bacteria, the medium should contain either a low sulfate concentration (only for assimilatory purposes) or no sulfate (in which case the reductant, sulfide, serves as sulfur source). Depending on the salinity of the anaerobic mud sample that is used as the inoculum, salt- or freshwater medium is used. Gas (methane) production after 3–5 weeks incubation at 28–37°C indicates substrate degradation with the involvement of methanogens. Pure cultures are obtained by repeated application of the agar dilution method, using 20 mM crotonate as the sole electron donor and electron acceptor.

Maintenance Procedures

Stock cultures are transferred every 2–3 months. Towards the end of growth or at the beginning of the stationary phase, cultures are refrigerated and stored at 4–8°C in the dark. *Syntrophus* strains may be preserved indefinitely by suspension of cells in anoxic medium containing 5% dimethylsulfoxide and storage in liquid nitrogen.

Differentiation of the genus *Syntrophus* from other genera

The genus *Syntrophus* is distinguished from other fermentative bacteria by its limitation to benzoate and crotonate as the only substrates for growth, although some species can also use other aromatic compounds, and one species uses various fatty acids in syntrophic co-cultures. Inorganic electron acceptors are not used. However, a clear differentiation of this genus and other physiologically related genera is only possible via determination of the 16S rDNA sequence.

Taxonomic Comments

The closest relatives of the genus *Syntrophus* are *Smithella propionica*, *Desulfomonile tiedjei*, and *Desulfobacca acetoxidans*.

List of species of the genus Syntrophus

1. **Syntrophus buswellii** Mountfort, Brulla, Krumholz and Bryant 1984, 216[VP]
bus.wel′li.i. N.L. masc. gen. n. *buswellii* in honor of A.M. Buswell, who first demonstrated degradation of benzoate in enrichments from methanogenic ecosystems.

Characteristics are summarized in Table BXII.δ.44. The type strain was isolated with benzoate as the sole electron donor. Occurs in anoxic sediments from marine or brackish water habitats.

The mol% G + C of the DNA is: 54.6 (T_m) (Fardeau et al., 1993); strain GA, 54.4 (T_m) (isolated by Auburger and Winter, 1995).
Type strain: DM-2, DSM 2612.
GenBank accession number (16S rRNA): X85831.

2. **Syntrophus aciditrophicus** Jackson, Bjupathiraju, Tanner, Woese and McInerney 2001, 793[VP] (Effective publication: Jackson, Bjupathiraju, Tanner, Woese and McInerney 1999, 112.)
a.ci.di.tro′phi.cus. L. nom. n. *acidum* acid; Gr. v. *trephein* to feed; L. suff. *trophicus* relating to feeding; M.L. adj. *aciditrophicus* one that feed on acids, acid-feeding.

Characteristics are summarized in Table BXII.δ.44. *S. aciditrophicus* is more versatile than the other described species (see Table BXII.δ.44). The type strain was isolated with benzoate as the sole electron donor in association with H_2/formate-using partners. Pure cultures are obtained with crotonate as the sole substrate. Occurs in sewage sludge of municipal sewage treatment plants.

The mol% G + C of the DNA is: 53.2 (T_m).
Type strain: SB, ATCC 700169.
GenBank accession number (16S rRNA): U86447.

3. **Syntrophus gentianae** Wallrabenstein, Gorny, Springer, Ludwig and Schink 1996, 836[VP] (Effective publication: Wallrabenstein, Gorny, Springer, Ludwig and Schink 1995a, 65.)
gen.ti.a′nae. M.L. fem. n. *gentiana, gentianae,* of gentian, referring to the substrate gentisic acid, which has been isolated from gentian plants.

Characteristics are summarized in Table BXII.δ.44. The type strain was isolated with hydroquinone or gentisate as the sole electron donor. Occurs in anoxic freshwater sediments.

The mol% G + C of the DNA is: 53.2 (T_m).
Type strain: HQGö1, DSM 8423.
GenBank accession number (16S rRNA): X85832.

Genus II. **Desulfobacca** *Oude Elferink, Akkermans-van Vliet, Bogte and Stams 1999, 348*[VP]

Alfons J.M. Stams and Stefanie J.W.H. Oude Elferink

De.sul.fo.bac′ca. L. pref. *de* from; L. n. *sulfur* sulfur; M.L. pref. *Desulfo* desulfuricating, used to characterize a dissimilatory sulfate-reducing procaryote; L. fem. n. *baca, bacca* berry, especially olive; M.L. fem. n. *Desulfobacca* a sulfate-reducing olive-shaped bacterium.

Oval to rod-shaped cells, 1.3 × 1.9–2.2 µm, occurring singly or in pairs. Nonmotile. Gram negative. Endospores not formed. **Anaerobic, with respiratory type of metabolism. Sulfate and inorganic sulfur compounds including sulfite and thiosulfate, but**

not S^0, act as terminal electron acceptors and are reduced to H_2S. Acetate is used as the sole electron donor and carbon source and is oxidized to CO_2 via the carbon monoxide dehydrogenase pathway. Optimal pH, 7.5–7.7. Optimal temperature, 37°C. Belongs to the class *Deltaproteobacteria.* Isolated from sludge from an anaerobic sludge bed reactor fed with acetate and sulfate.

The mol% G + C of the DNA is: 51.

Type species: **Desulfobacca acetoxidans** Oude Elferink, Akkermans-van Vliet, Bogte and Stams 1999, 349.

Further descriptive information

Refractile gas vacuoles may occur in cells during the late log phase or stationary phase of growth. Cytochromes of the *c* type are present. Desulfoviridin is absent.

Optimal growth occurs in freshwater media. Growth is retarded in brackish water media, and no growth occurs in marine media.

Common bacterial substrates such as glucose, volatile fatty acids, lactate, H_2/CO_2, alcohols (ethanol, propanol, butanol), pyruvate, fumarate, amino acids (aspartate, glutamate), and aromatic compounds (phenol, benzoate) are not oxidized.

Enrichment and Isolation Procedures

Desulfobacca acetoxidans was isolated from granular sludge from a mesophilic upflow anaerobic sludge bed reactor fed with acetate and sulfate. In this reactor, it had outcompeted *Methanosaeta* species at low acetate concentrations. Granular sludge samples were crushed and diluted serially in liquid media containing 20 mM acetate and sulfate under a gas phase containing N_2 and CO_2 (Oude Elferink et al., 1995). After incubation at 30°C, the highest dilutions in which growth was detected were chosen for isolation of colonies using anaerobic roll-tubes. Purity of isolates may be verified microscopically and by failure to grow on media with substrates other than acetate.

Differentiation of the genus *Desulfobacca* from other genera

Desulfobacca differs from most other sulfate reducers in that it is restricted to acetate as its source of electrons and carbon. *Desulfobacca* is phenotypically similar to *Desulfobacter* in this respect, because both are restricted to acetate as an electron donor, although some *Desulfobacter* species can use H_2 or lactate. However, *Desulfobacter* species oxidize acetate by means of the citric acid cycle, whereas *Desulfobacca* uses the carbon monoxide dehydrogenase pathway. In addition, *Desulfobacter* is a typical marine sulfate reducer and does not grow in freshwater media, while *Desulfobacca* grows optimally in freshwater media. Moreover, some species of *Desulfobacter* are motile.

Desulfobacca differs from *Desulfotignum balticum* (originally described as *"Desulfarculus"*) in its inability to degrade aromatic compounds, its inability to use lactate, pyruvate, malate, fumarate, crotonate, and butyrate as electron donors, its inability to ferment pyruvate in the absence of an exogenous electron acceptor, and its lack of an NaCl requirement. Unlike the anaerobic, dehalogenating, sulfate-reducing genus *Desulfomonile*, *Desulfobacca* lacks a collar-like morphological feature, does not grow on pyruvate, and does not ferment pyruvate to acetate and lactate in the absence of other electron acceptors. Unlike *Nitrospina*, *Desulfobacca* is not an aerobic nitrifier.

Taxonomic Comments

In this edition of the *Manual*, the genus *Desulfobacca* has been placed in the class *Deltaproteobacteria*, the order *Syntrophobacterales*, and the family *Syntrophaceae*. Other genera in this family include *Desulfomonile*, *Syntrophus*, and *Smithella*.

In a study by Oude Elferink et al. (1999), *Desulfobacca* was only distantly related to the phenotypically similar genus *Desulfobacter*, and, in this edition of the *Manual*, *Desulfobacter* is placed in a different family, *Desulfobacteraceae*.

List of species of the genus Desulfobacca

The characteristics are as described for the genus.
The mol% G + C of the DNA is: 51 (HPLC).
Type strain: ASRB2, DSM 11109.
GenBank accession number (16S rRNA): AF002671.

Genus III. **Desulfomonile** *DeWeerd, Mandelco, Tanner, Woese and Suflita 1991, 178*[VP] *(Effective publication: DeWeerd, Mandelco, Tanner, Woese and Suflita 1990, 28)*

Kim A. DeWeerd, G. Todd Townsend and Joseph M. Suflita

De.sul.fo.mo.ni'le. L. pref. *de* from; L. n. *sulfur* sulfur; L. n. *monile* collar; M.L. neut. n. *Desulfomonile* a "collared" sulfate-reducer.

Single rod-shaped cells with rounded ends, 0.5–0.7 × 3–10 µm, each containing an invagination of the cell wall that resembles a collar. Cells may be slightly curved or bent at the collar region. Endospores not formed. Gram negative. Nonmotile. **Strict anaerobe.** A medium containing a reducing agent is required for growth. **Possess a respiratory type of metabolism with sulfur oxyanions reduced to H_2S or *meta*-halobenzoates reduced to dehalogenated products (reductive dehalogenation).** Pyruvate can be fermented to acetate and lactate. Optimal growth temperature 37°C. Cells grow poorly on solid agar medium, yielding small (0.5–1.0 mm diameter), white colonies after extended incubation (>3 weeks). **Growth in a mineral medium requires the vitamins thiamine, nicotinamide, and 1,4-naphthoquinone.** Isolated from a sewage sludge bacterial consortium enriched on 3-chlorobenzoate.

The mol% G + C of the DNA is: 49.0.

Type species: **Desulfomonile tiedjei** DeWeerd, Mandelco, Tanner, Woese and Suflita 1991, 178 (Effective publication: DeWeerd, Mandelco, Tanner, Woese and Suflita 1990, 28.)

Further descriptive information

Desulfomonile tiedjei, formerly known as strain DCB-1 ("dechlorinating bacterium"), was isolated from a sewage sludge bacterial consortium enriched on 3-chlorobenzoate as the sole carbon and

source (Shelton and Tiedje, 1984). Its long rod-shaped cells display a unique collar structure located anywhere along the length of the cell, depending on the growth stage (see Fig. BXII.δ.46). Unidirectional polar growth of the cell originates at the collar and proceeds until the total cell length is approximately twice the size of the original cell. Mother and daughter cells separate at the central collar, with each newly divided cell containing a terminal collar (Mohn et al., 1990). Cells stain Gram-negative, and transmission electron micrographs show that *D. tiedjei* cell walls have a bimembrane structure typical of Gram-negative procaryotes. Cells also have internal membranes in a stacked configuration and electron dense, spherical bodies that likely contain glycogen occurring preferentially near the poles (Mohn et al., 1990). Cells have a tendency to settle and form a film on the bottom of culture vessels.

The temperature range for growth is 30–39°C with an optimal of 37°C. The pH range for growth is 6.5–7.8 with an optimal of 6.8–7.0.

D. tiedjei reductively dehalogenates *meta*-chlorobenzoates, *ortho*- and *meta*-bromobenzoates, and all isomers of iodobenzoate to benzoate as a form of anaerobic respiration. *D. tiedjei* also dechlorinates *meta*-chlorine substituents from pentachlorophenol and tri- and di-chlorophenols and dechlorinates tetrachloroethene and trichloroethene, but it requires a *meta*-halobenzoate or a number of benzenoid analogs to induce these activities (Mohn and Tiedje, 1992). *D. tiedjei* reduces sulfate, sulfite, thiosulfate, and dithionite to sulfide, nitrate to nitrite, and fumarate to succinate. The presence of sulfur oxyanions in growth medium inhibits reductive dehalogenation activity (Townsend and Suflita, 1997). *D. tiedjei* cannot reduce S^0, Fe(III), or U(VI). Pyruvate, 3-anisate, 4-anisate, vanillate, or isovanillate can support growth in the mineral medium buffered with bicarbonate. With thiosulfate as the electron acceptor, additional carbon substrates that can support growth are benzoate, butyrate, lactate, acetate, L- and D-malate, L- and D-arabinose, and glycerol. With sulfate as the electron acceptor, *D. tiedjei* can grow with pyruvate, lactate, butyrate,

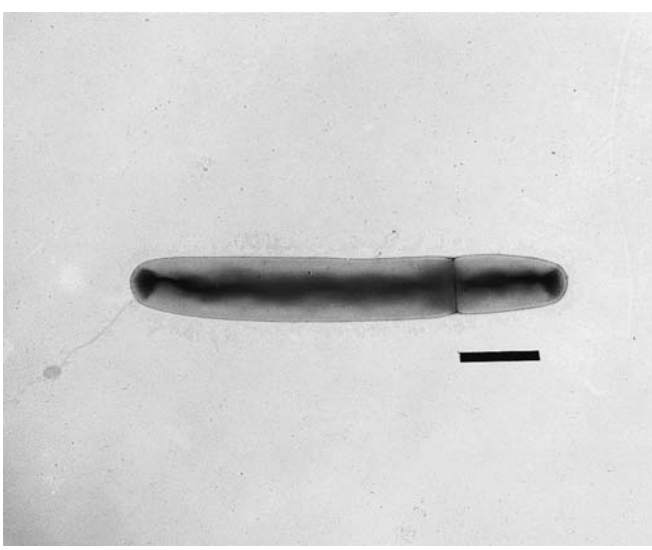

FIGURE BXII.δ.46. Electron micrograph of *Desulfomonile tiedjei*, displaying its distinctive collar-like morphology that serves as a site of cell elongation and probably cell division. Bar = 1 μm. (Reproduced with permission from K.A. DeWeerd et al., Archives of Microbiology, *154:* 23–30, 1990, ©Springer-Verlag, Berlin.) (Photograph courtesy of R.S. Tanner).

and 3-anisate as sources of carbon and energy. In mineral salts medium containing the essential vitamins, *D. tiedjei* grows poorly as a chemolithoautotroph with hydrogen or formate as the electron donor and sulfur oxyanions or *meta*-chlorobenzoates as electron acceptors. The addition of acetate to the medium stimulates growth under these conditions. Growth of *D. tiedjei* on acetate and thiosulfate occurs by utilizing the disproportionation of the latter as an energy source (Mohn and Tiedje, 1990). *D. tiedjei* requires nicotinamide, thiamine, and 1,4-naphthoquinone as growth factors in defined medium. Although NH_4Cl is supplied as the nitrogen source in the medium, *D. tiedjei* can fix N_2 for growth. Initiation of growth is favored by the addition of dithionite as a reductant.

The bacterium is inhibited by H_2S, $CuCl_2$, Na_2MoO_4, or Na_2SeO_4. *D. tiedjei* is sensitive to the electron transport inhibitors carbonyl-cyanide-*m*-chlorophenylhydrazine (CCCP), 8-hydroxyquinoline, diphenylamine, dimercaprol, metronidazole, 2,4-dinitrophenol (DNP), *N,N′*-dicyclohexylcarbodiimide (DCCD), pentachlorophenol (PCP), gramicidin, and monensin. Antibiotics that inhibit *D. tiedjei* are tetracycline, chloramphenicol, kanamycin, and streptomycin.

D. tiedjei cells contain desulfoviridin, cytochrome c_3, and a unique membrane-associated *c*-type cytochrome that is coinduced with the dehalogenase enzyme (Louie et al., 1997). Cells contain polyhydroxybutyrate and glycogen and are esculin negative.

D. tiedjei was isolated from a consortium enriched on 3-chlorobenzoate as the sole carbon and energy source over a 2-year period. Inoculum for the enrichment culture was originally obtained from the sludge digester of the municipality of Adrian, Michigan. The enrichment was maintained by a 10% (v/v) transfer into fresh media every two months; 3-chlorobenzoate (Na^+ salt) (2–3 mM) was added to the medium and replenished when depleted. Recently, closely related strains have been isolated from brackish and marine environments.

Enrichment and Isolation Procedures

For the selective enrichment of *Desulfomonile* strains, a defined anaerobic medium is used. Bottles or tubes sealed with gas-impermeable rubber stoppers can serve as culture vessels. The medium is inoculated with municipal digester sludge and amended with 3-chlorobenzoate as the sole carbon and energy source. Enrichments are incubated at 35–37°C in the dark without agitation. Continual replenishment of 3-chlorobenzoate to the medium and successive transfers (10%) into fresh media containing 3-chlorobenzoate should maximize the probability of obtaining higher numbers of *D. tiedjei*, despite the slow growth rate of *D. tiedjei*. The availability of benzoate as a product of the dehalogenation reaction precludes a numerically dominant enrichment. Pure cultures of *Desulfomonile* strains are obtained by serial dilution and repeated application of the agar roll tube method. Since *D. tiedjei* is a sulfate-reducing bacterium, several substrates, such as pyruvate, H_2 plus CO_2, formate plus CO_2, benzoate, or 4-anisate can be used. Using ferrous sulfate as the electron acceptor permits the detection of sulfide-producing bacteria through observation of black zones around colonies, which are due to an FeS precipitate. Alternately, H_2 plus acetate and CO_2 or formate plus acetate and CO_2 may be used as the carbon source with 3-chlorobenzoate as the electron acceptor. Regardless of substrate used, three weeks of incubation are typically required before the appearance of pinpoint colonies. Isolated colonies should be transferred to the defined medium containing pyru-

vate and 3-chlorobenzoate. Additions of yeast extract (0.1%) or clarified rumen fluid (10%) may be included in the liquid medium to stimulate growth. Once measurable growth occurs, identity can be presumptively verified by the unique collar structure and the dehalogenation of 3-chlorobenzoate.

Maintenance Procedures

Stock cultures may be maintained in the defined medium[1] in Balch tubes or serum bottles at 22–25°C with transfers every 1–3 months. *D. tiedjei* can be maintained on pyruvate alone or with 3-chlorobenzoate. Since H_2S is somewhat inhibitory to *D. tiedjei*, it is recommended that cultures not be maintained with sulfur oxyanions as electron acceptors.

For long-term preservation, an aliquot of culture can be mixed with an equal volume of sterile glycerol in a 5 ml serum bottle under a N_2 headspace and stored at −25°C. Cultures may also be lyophilized.

Differentiation of the genus *Desulfomonile* from other genera

The genus *Desulfomonile* is distinguished from other dissimilatory sulfate-reducing bacteria by its characteristic morphological and physiological attributes. Members of this genus contain an invagination of the cell wall, or "collar structure," which is visible under phase contrast microscopy. This feature is not present in other genera of sulfate-reducing bacteria. The ability of *Desulfomonile tiedjei* to reductively dehalogenate various halogenated benzoates distinguishes this bacterium from all of the other sulfate-reducing genera described. *Desulfitobacterium chlororespirans* can dechlorinate 3-chloro-4-hydroxybenzoate, but is unable to dechlorinate 3-chlorobenzoate (Sanford et al., 1996). *Desulfomonile tiedjei* possesses the ability to dechlorinate the *meta*-chlorines of pentachlorophenol and several tri- and dichlorophenols. However, this activity must be induced by a *meta*-halobenzoate or a specific analog (Mohn and Kennedy, 1992). Other isolated bacteria that can dechlorinate chlorophenols are *Desulfitobacterium* species, which dechlorinate chlorophenols at the *ortho* position—including *Desulfitobacterium hafniense*, which dechlorinates at the *ortho* and *meta* positions, and *Desulfitobacterium frappieri*, which dechlorinates at all positions. *Desulfitobacterium* species can reduce thiosulfate, but not sulfate, and are placed in the *Desulfotomaculum–Clostridium* group. *Desulfomonile tiedjei* can also reductively dechlorinate tetra- and trichloroethylene, but this activity must be induced with 3-chlorobenzoate or a suitable analog. A large and diverse group of isolated anaerobic bacteria can also dechlorinate PCE and TCE. The anaerobic dechlorination activity of isolated bacteria has recently been summarized (El Fantroussi et al., 1998). The induction of the dehalogenase by *Desulfomonile tiedjei* is repressed by the presence of sulfur oxyanions, and sulfate and thiosulfate also directly inhibit the dehalogenation activity of the enzyme. The ability of *Desulfomonile tiedjei* to grow via the disproportionation of thiosulfate is a trait that is also found in *Desulfovibrio sulfodismutans*, *Desulfovibrio desulfuricans* CSN, *Desulfovibrio oxyclinae*, *Desulfocapsa thiozymogenes*, and several other strains of sulfate-reducing bacteria. The ability to fix nitrogen is found among members of the genera *Desulfovibrio*, *Desulfotomaculum*, and *Desulfobacter*. Two characteristic lipopolysaccharide hydroxy fatty acids ($C_{Br\text{-}19:0\ 3OH}$ and $C_{Br\text{-}21:0\ 3OH}$) have been used as signature molecules to detect *Desulfomonile tiedjei* inoculated in sediments (Ringelberg et al., 1994). *Desulfomonile tiedjei* was also detected in soil slurry microcosms using five specific oligonucleotide primers for PCR amplification of 16S rDNA genes of *D. tiedjei*. The five oligonucleotide primers used in a nested PCR analysis were located at 16S rRNA gene positions 59–79, 205–227, 476–495, 608–628, and 1032–1054 (El Fantroussi et al., 1997). Cell-specific polyclonal antibodies were also used to detect *D. tiedjei* in an upflow anaerobic granular-sludge blanket reactor (Ahring et al., 1992).

Taxonomic Comments

The 16S rRNA of *Desulfomonile* shows two higher order structural features that link it strongly to the *Deltaproteobacteria*: (1) a lengthening of the stalk of the helix covering positions 184–193 from three pairs (characteristic of the *Alphaproteobacteria*, *Betaproteobacteria*, and *Gammaproteobacteria*) to about ten pairs and (2) a form of the helix covering positions 198–219 unique to the *Deltaproteobacteria* (Woese, 1987). 16S rRNA sequence analysis indicates that the genus belongs to the family *Syntrophaceae* family in the order *Syntrophobacterales* of the *Deltaproteobacteria*. The family *Syntrophaceae* contains two syntrophic genera (*Syntrophus* and *Smithella*) and one other sulfate-reducing genus (*Desulfobacca*).

1. Defined basal medium consists of (per liter of distilled water): PIPES (piperazine-*N,N'*-bis-[2-ethanesulfonic acid]) dipotassium salt, 1.5 g; NaCl, 0.8 g; NH_4Cl, 1.0 g; KCl, 0.1 g; KH_2PO_4, 0.1 g; $MgCl_2\cdot6H_2O$, 0.2 g; $CaCl_2\cdot2H_2O$, 0.02 g; $NaHCO_3$, 3.0 g; trace element solution, 10 ml; and resazurin solution (0.1%), 1.0 ml. The pH of the solution is adjusted to 7.8. Medium is prepared and dispensed using strict anaerobic technique and the gas phase is N_2/CO_2 (4:1) at 138 kPa positive pressure. After the medium has been autoclaved and cooled, the following components are added aseptically from filter sterilized, anoxic stock solutions: vitamin solution, 10 ml; sodium pyruvate (1 M), 40 ml; 3-chlorobenzoate (0.2 M in 0.2 M NaOH), 10 ml; and dithionite (10 mM), 10 ml. The pH of the autoclaved medium is 6.9–7.1. Trace element solution (per liter): nitrilotriacetic acid, 2.0 g; $MnSO_4\cdot H_2O$, 1.0 g; $Fe(NH_4)_2(SO_4)_2\cdot6H_2O$, 0.8 g; $CoC1_2\cdot6H_2O$, 0.2 g; $ZnSO_4\cdot7H_2O$, 0.2 g; $CuCl_2\cdot2H_2O$, 0.02 g; $NiCI_2\cdot6H_2O$, 0.02 g; $Na_2MoO_4\cdot2H_2O$, 0.02 g; Na_2SeO_4, 0.02 g; Na_2WO_4, 0.02 g; pH adjusted to 6.0 with KOH. Vitamin solution (per liter): nicotinamide, 50.0 mg; 1,4-napthoquinone, 20.0 mg; thiamine, 5.0 mg; hemin, 5.0 mg; d-biotin, 5.0 mg; folic acid, 5.0 mg; pyridine-HCI, 5.0 mg; riboflavin, 5.0 mg, d-pantothenic acid, 5.0 mg; cyanocobalamin, 5.0 mg; *p*-aminobenzoate, 5.0 mg; lipoic acid (DL-6,8-thioctic acid), 5.0 mg. The 1,4-naphthoquinone and hemin are dissolved in 0.1 M NaOH to solubilize prior to addition to vitamin solution. The vitamin solution must be sterilized by filtration and not by autoclaving. Both the pyruvate stock solution and the dithionate stock solution should be freshly prepared and filter sterilized prior to use.

List of species of the genus Desulfomonile

1. **Desulfomonile tiedjei** DeWeerd, Mandelco, Tanner, Woese and Suflita 1991, 178 (Effective publication: DeWeerd, Mandelco, Tanner, Woese and Suflita 1990, 28.)
tied'je.i. M.L. gen. n. *tiedjei* of Tiedje, named to recognize the contributions of James M. Tiedje and his laboratory to the field of microbial ecology.

The description is as given for the genus, with the following additional information. Esculin negative. Can grow with H_2 or formate with CO_2 using sulfur oxyanions or *meta*-chlorobenzoates as electron acceptors, which are reduced to H_2S and benzoates, respectively. 3-Anisate, 4-anisate, vanillate, and isovanillate can serve as carbon sources, and benzoate is used as a growth substrate in the presence of sulfate or thiosulfate.

Occurs in municipal digester sludge enriched under anaerobic conditions to use 3-chlorobenzoate as sole carbon and energy source.

The mol% G + C of the DNA is: 49.0 (T_m).

Type strain: DCB-I, ATCC 49306, DSM 6799.

GenBank accession number (16S rRNA): M26635.

2. **Desulfomonile limimaris** Sun, Cole and Tiedje 2001, 370^VP^
li.mi.ma'ris. M.L. gen. n. *limimaris* of mud from the sea, referring to its isolation from marine sediments.

Displays morphology and dehalogenation activities similar to those of *D. tiedjei*. 16S rRNA sequences show 93% similarity. Unlike *D. tiedjei*, growth and dehalogenation require 0.32 to 2.5% NaCl with an optimal of 1.25%. Other physiological traits that distinguish *D. limimaris* from *D. tiedjei* are its ability to use propionate and its inability to use acetate as electron donors and its inability to ferment pyruvate.

The mol% G + C of the DNA is: unknown.

Type strain: DCB-M, ATCC 700979.

GenBank accession number (16S rRNA): AF230531.

Genus IV. Smithella *Liu, Balkwill, Aldrich, Drake and Boone 1999, 553*[VP]

Martin Sobieraj and David R. Boone

Smi.thel'la. N.L. fem. n. *Smithella* named for Paul H. Smith in honor of his many contributions to the understanding of methanogenic propionate degradation.

Elongated, slightly sinuous rods, 0.5 µm in diameter, with round ends. **Weakly motile. Gram negative.** Endospores have not been observed. **Strictly anaerobic.** Mesophilic. **Grows on crotonate as energy source; also capable of using butyrate, propionate, malate, and fumarate in syntrophic association with H_2- or formate-utilizing microorganisms.** Catabolism of propionate involves its reductive carboxylation to butyrate (or butyryl-CoA).

Habitat: methanogenic environments in which propionate is degraded, such as anaerobic digestors.

Type species: **Smithella propionica** Liu, Balkwill, Aldrich, Drake and Boone 1999, 554.

Further descriptive information

Cells of *Smithella* are usually 3–5 µm long, with some longer cells up to 10 µm. They may contain granules of poly-β-hydroxyalkanoate that can be observed by staining with Sudan black. The cell wall has a typical Gram-negative structure.

The organism grows most rapidly at pH values near neutrality and at salt concentrations lower than 100 mM. *Smithella* grows on crotonate in pure culture. In coculture with *Methanospirillum hungatei*, it grows on a variety of substrates including crotonate, butyrate, propionate, malate, and fumarate, but not lactate, succinate, oxalate, valerate, caproate, or pyruvate. Yeast extract and peptones are required for growth.

Smithella (in coculture with *Methanospirillum hungatei*) degrades propionate to acetate, CO_2, and H_2 by an unknown catabolic pathway. The only other known syntrophic propionate-degrading bacterium, *Syntrophobacter wolinii*, uses the randomizing pathway, yielding 1 mol of acetate, 1 mol of CO_2, and 3 mol of H_2 per mol of propionate degraded (Houwen et al., 1990). In contrast, *Smithella* produced more acetate and less H_2. A ^{13}C-NMR study of *Smithella propionica* (de Bok et al., 2001) indicates a novel pathway of propionate oxidation that includes the condensation of two propionates into a 6-carbon intermediate (possibly bound to coenzyme A), with the 6-carbon intermediate subsequently cleaved to form acetate and butyrate.

Enrichment and Isolation Procedures

Cultivation of *Smithella* requires stringent anaerobic techniques as described by Hungate (1969) or modifications of those techniques (Sowers and Noll, 1995). Cells can be enriched from methanogenic environments such as anaerobic digestors or methanogenic sediments. MS enrichment medium (Boone et al., 1989) at pH 7.2 with 20 mM propionate has been used to enrich *Smithella*, but any bicarbonate-buffered medium containing small amounts of yeast extract and peptones, plus propionate as catabolic substrate, would probably be satisfactory.

Although *Smithella* grows on crotonate in pure culture, it has not been directly isolated from natural environments or from enrichment cultures. Methanogenic cocultures are the first cultures obtained after enrichment. Such cocultures of *Smithella* with methanogens can be obtained by using a propionate-containing enrichment medium solidified in roll tubes. Dilutions of the enrichment culture are inoculated into the roll-tube media and coinoculated with H_2-utilizing and acetate-utilizing methanogens. Colonies may take several months to develop, and they result in methanogenic cocultures. Axenic cultures are obtained from these cocultures by culturing in MS medium with 20 mM crotonate and then inoculating dilutions into medium with 20 mM crotonate as the catabolic substrate. The highest dilution that shows growth may contain only *Smithella*, but if methanogens are present, repetition of the extinction dilution technique will remove them. The complete removal of methanogens can be confirmed by inoculating the purified *Smithella* culture into media containing H_2 or acetate.

Differentiation of the genus *Smithella* from other genera

The ability to grow on propionate in syntrophic association with methanogens is the most distinctive and perhaps the most important phenotypic feature of *Smithella*. The only other genus to contain such syntrophs is *Syntrophobacter*, and *Smithella* can be differentiated from *Syntrophobacter* by the pathway for propionate degradation. *Syntrophobacter* uses the randomizing pathway, resulting in 1 mol of acetate and 1 mol of CO_2 per mol of propionate degraded, whereas *Smithella* uses a different pathway that results in more than 1 mol of acetate, plus traces of butyrate, per mol of propionate degraded (Liu et al., 1999).

Taxonomic Comments

Phylogenetic analysis of the 16S rDNA sequence of *Smithella propionica* LYP[T] indicates a relationship (88% sequence similarity) to the genus *Syntrophus*. However, this relationship is sufficiently distant to support the placement of *Smithella* as a separate genus.

The 16S rDNA sequence of *Smithella propionica* is very similar (99.4% sequence similarity) to the sequence obtained from a

propionate enrichment culture named Syn7 (Harmsen et al., 1995). This culture was obtained from roll tubes by a colony pick, but a rod-shaped bacterium contaminates the culture in small numbers. To date, only the type strain of *Smithella* has been isolated in pure culture and characterized.

Phylogenetically, *Smithella* is most closely associated with *Syntrophus*. Table BXII.δ.45 compares some important phenotypic characteristics of *Smithella* with some of its phylogenetic relatives in the order *Syntrophobacterales*.

List of species of the genus Smithella

1. **Smithella propionica** Liu, Balkwill, Aldrich, Drake and Boone 1999, 554[VP]
pro.pi.o′ni.ca. M.L. n. *acidum propionicum* propionic acid; M.L. adj. *propionica* pertaining to propionic acid, on which the bacterium grows.

The characteristics are those given for the genus, with the following additional features. Cells are Gram-negative rods, elongated and slightly sinuous, 0.5 × 3–5 μm, with some cells as long as 10 μm. Contain granules of poly-β-hydroxybutyrate. Weakly motile. Strictly anaerobic. Fastest growth at mesophilic temperatures, at near neutral pH, and in media with Na^+ and Cl^- concentrations less than 100 mM. Grows syntrophically on propionate with H_2/formate-utilizing methanogens. Grows slowly in pure culture by fermenting crotonate to butyrate and acetate. Habitat: methanogenic digestors.

The mol% G + C of the DNA is: unknown.

Type strain: LYP, OCM 661.

GenBank accession number (16S rRNA): AF126282.

TABLE BXII.δ.45. Phenotypic characteristics of the genus *Smithella* and some of its phylogenetic relatives in the order *Syntrophobacterales*[a]

Characteristic	*Smithella propionica*	*Syntrophobacter wolinii*	*Syntrophospora bryantii*	*Syntrophus buswellii*	*Syntrophus aciditrophicus*	*Syntrophus gentianae*
Gram reaction	−	−	+[b]	−	−	−
Motility	W	nd	−	+	−	−
Mol% G + C of DNA	nd	nd	37.6	54.1	43.1	53.2
Optimal pH	6.5–7.5	~7	6.5–7.5	nd	nd	7.1–7.4
Optimal temperature, °C	33-35	34–37	28–34	nd	35	28

$C_{5:0}$–$C_{8:0}$ (aliphatic) acids	nd	−	+	−	+	−
Acetate	−	−	nd	−	nd	−
Benzoate	nd	−	nd	+	+	+

[a]For symbols see standard definitions; W, weakly positive; nd, not determined.

[b]Ultrastructure is typical Gram positive, but Gram stain results are variable.

Order VII. **Bdellovibrionales** *ord. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Bdel.lo.vib.ri.on.a′les. M.L. masc. n. *Bdellovibrio* type genus of the order; *-ales* ending to denote order; M.L. fem. n. *Bdellovibrionales* the *Bdellovibrio* order.

The order *Bdellovibrionales* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the order contains the family *Bdellovibrionaceae*.

Description is the same as for the family *Bdellovibrionaceae*.

Type genus: **Bdellovibrio** Stolp and Starr 1963, 243.

Family I. **Bdellovibrionaceae** *fam. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Bdel.lo.vib.ri.on.a′ce.ae. M.L. masc. n. *Bdellovibrio* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Bdellovibrionaceae* the *Bdellovibrio* family.

The family *Bdellovibrionaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Bdellovibrio* (type genus), *Bacteriovorax*, *Micavibrio*, and *Vampirovibrio*.

Predatory bacteria with differing prey specificities and modes of attack. *Bdellovibrio*, *Bacteriovorax* and *Micavibrio* prey on other bacteria, while *Vampirovibrio* preys on the alga *Chlorella*. *Bdellovibrio* and *Bacteriovorax* invade the periplasmic space of the prey cell, while *Micavibrio* and *Vampirovibrio* do not.

Type genus: **Bdellovibrio** Stolp and Starr 1963, 243.

Genus I. Bdellovibrio *Stolp and Starr 1963, 243*[AL]*

Henry N. Williams, Marcie L. Baer and John J. Tudor

Bdel.lo.vib'ri.o. Gr. n. *bdella* leech, sucker; M.L. masc. n. *Vibrio* a generic name; M.L. n. *Bdellovibrio* a leechlike vibrio.

Vibrios, 0.20–0.4 × 0.5–1.4 μm. Motile by a single, polar, sheathed flagellum. Gram negative. **Prey upon Gram-negative bacteria. Have a predatory lifestyle characterized by two distinct phases, a free-living attack phase and an intraperiplasmic growth phase** (Fig. BXII.δ.47). Prey-independent mutants that have lost their requirement for prey cells occur spontaneously and can be isolated in the laboratory. Some of these prey-independent mutants retain the ability to grow predaciously and are considered to be facultative with respect to their requirement for prey cells. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Contain cytochromes *a*, *c*, and *b*. **Mesophilic**. **Oxidase positive.** Catalase variable. Occur in fresh and salt water, soil, and sewage.

The mol% G + C of the DNA is: 49.5–51 (Torrella et al., 1978).

Type species: **Bdellovibrio bacteriovorus** Stolp and Starr 1963, 243.

Further descriptive information

Morphology and structure Cells exhibit a typical Gram-negative morphology of an outer membrane surrounding a thin peptidoglycan layer. The highly motile, attack-phase bdellovibrios are propelled with a single, polar, sheathed flagellum (Fig. BXII.δ.48); the sheath is continuous with and similar in structure to the outer membrane of the cell envelope (Burnham et al., 1968; Seidler and Starr, 1968). Bdellovibrios represent some of the swiftest known bacteria, capable of exceeding 100 cell lengths/second.

Except for the presence of phosphonosphingolipids (Steiner et al., 1973) in their cell envelope, both the outer membrane and peptidoglycan have been shown to be chemically similar to most Gram-negative bacteria (Thomashow and Rittenberg, 1978a; Tudor et al., 1990). The function of these lipids is not known.

Cultivation Culture requirements for predacious *Bdellovibrio* strains include a dilute nutrient medium containing a prey bacterium; the medium is inoculated with bdellovibrios and incubated at 30°C, with shaking at 200 rpm overnight. Among the more cited media used to grow the organisms are NB/500[1] (Staples, 1973) and DNB[2] (Stolp, 1973). As the bdellovibrios grow, they lyse the prey bacteria in the culture fluid, producing a "lysate" that has a lower optical density than did the starting culture.

Bdellovibrios can also be cultured on agar plates as plaques in a lawn of prey cells. Molten agar medium (0.7% agar, cooled to 45°C) is inoculated with a suspension of prey bacteria and

**Editorial Note:* The previous edition of *Bergey's Manual of Systematic Bacteriology* described three species of *Bdellovibrio: B. bacteriovorus, B. starrii,* and *B. stolpii* (Burnham and Conti, 1984). However, the authors acknowledged that variability in physiological, biochemical, and genetic properties stressed the single-genus concept for these organisms. As a result of these and other differences revealed more recently by molecular studies, two of the species, *B. starrii* and *B. stolpii,* have been reclassified into a new genus, *Bacteriovorax*, to be described in the following chapter.

1. NB/500 is nutrient broth (Difco) at 1/500 normal strength (equals 0.016 g of dehydrated broth/liter).

2. DNB is a dilute nutrient broth, consisting of (per liter): nutrient broth (Difco), 0.8 g; yeast extract (Difco), 0.1 g; vitamin-free Casamino acids, 0.5 g; 2 mM $CaCl_2$; and 1 mM $MgCl_2$. The pH is adjusted to 7.2 with 1 M NaOH.

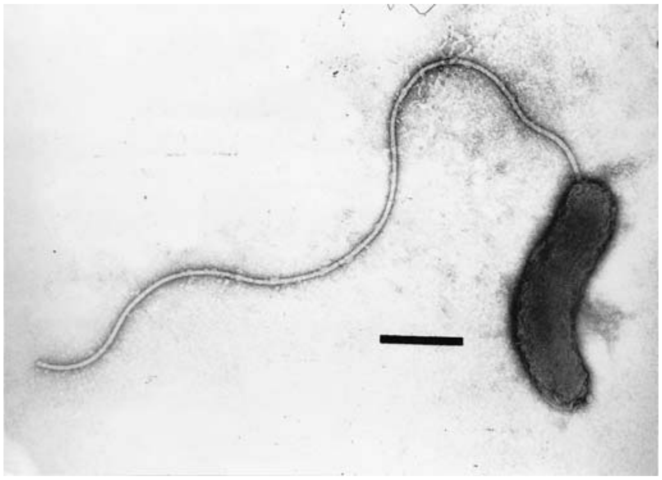

FIGURE BXII.δ.48. Negatively stained preparation of *Bdellovibrio bacteriovorus* ATCC 15143 showing the comma-shaped cell with its ensheathed polar flagellum. Bar = 0.2 μm.

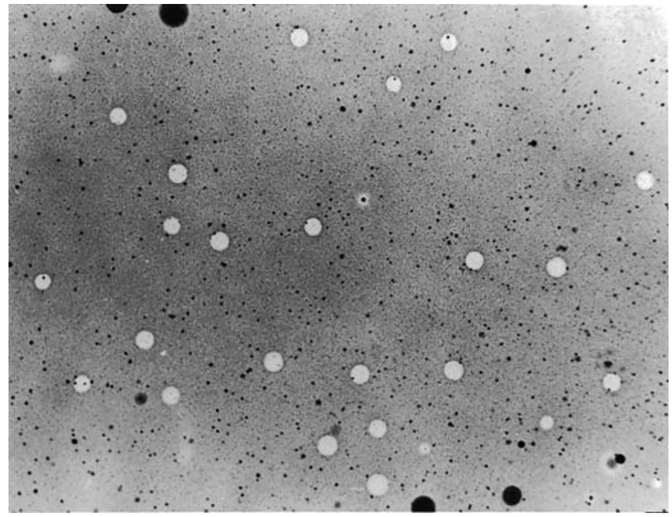

FIGURE BXII.δ.49. *Bdellovibrio* plaques demonstrating the typical clearing observed in a lawn of bacterial growth when bdellovibrios lyse their prey cells.

bdellovibrios. It is then poured over a layer of solidified agar (1.2% agar), allowed to cool and solidify, and incubated at the appropriate temperature. Plaques or clearings (Fig. BXII.δ.49) in the turbid lawn of prey cells will develop within 2–6 d. Plaques begin as small pinpoints and increase in size with continued incubation.

Prey-independent and facultative mutants of *Bdellovibrio* can be cultured in PYE[3] broth at the appropriate temperature with shaking, or on agar plates. Colonies will appear on plates after 3–4 d, and typically exhibit a yellow pigmentation.

Salt requirements Isolates from fresh water and from soil were observed to be inhibited by low concentrations (<0.85%) of salt (Varon and Shilo, 1968) and have been given the unofficial designation of fresh water or "terrestrial" bdellovibrios.

Life cycle These unusual bacteria were discovered by Stolp and Petzold (1962) while attempting to recover bacteriophage lytic against phytopathogenic pseudomonads (Stolp and Starr, 1963). In the initial description, bdellovibrios were reported to attach and lyse their prey from outside the cell wall. Subsequent studies by Starr and Baigent (1966) revealed that the predators breach the cell wall and penetrate into the periplasmic space.

Every *Bdellovibrio* strain that has been isolated from nature has been obligately predacious, requiring prey bacteria within the culture medium to initiate growth (Burnham and Conti, 1984; Ruby, 1992). The life cycle alternates between the motile, nongrowing attack phase, spent in a variety of macroenvironments, and the growth phase, spent within the periplasm of a susceptible bacterium. The mobility of the bdellovibrio enables it to collide with prey bacteria; however, collisions appear to be random and are not enhanced by chemotactic attraction toward prey (Straley and Conti, 1977). However, it has been shown that at least some strains of *Bdellovibrio* exhibit a chemoattraction to soluble nutrients such as amino acids and other organic compounds (Straley and Conti, 1974; Straley et al., 1979). This attraction may increase the chances of a collision with prey since most of their prey would be attracted to the area by the same chemicals.

The attachment of the *Bdellovibrio* cell to its prey following the initial collision proceeds in two stages. Initial attachment is reversible and nonspecific. The second stage of attachment is specific and irreversible, and is followed immediately by penetration of the prey's outer envelope (Fig. BXII.δ.50) and the transformation of the prey cell into an osmotically stable growth chamber, termed a bdelloplast (Starr and Baigent, 1966; Abram et al., 1974) (Fig. BXII.δ.51). This irreversible attachment involves the interaction between the *Bdellovibrio* cell pole opposite the flagellum and the prey cell's outer membrane. The precise nature of this interaction is not understood, but there is evidence that it involves the core polysaccharide of the prey cell lipopolysaccharide (LPS) (Chemeris et al., 1984; Schelling and Conti, 1986). The specificity of this interaction is presumably responsible for the specific prey ranges of individual *Bdellovibrio* strains, although their prey ranges may be quite broad (Stolp, 1973). Most *Bdellovibrio* strains are capable of preying upon Gram-negative enteric bacteria and others with similar LPS structure. With the exception of a single report (Varon and Seijffers, 1975), attempts to isolate *Bdellovibrio* prey cells that have developed resistance to the predators have been unsuccessful. Gram-positive bacteria cannot serve as prey for the bdellovibrios, presumably due to the lack of outer membrane receptors.

Once irreversibly attached, the bdellovibrio flagellum continues to rotate, setting the entire invading cell spinning about the attachment axis. A few minutes following irreversible attachment, the bdellovibrio moves through the outer membrane and peptidoglycan of its prey, leaving its detached flagellum behind. It has been shown that a variety of enzymatic activities that are directed against the prey cell envelope are released at this time (Thomashow and Rittenberg, 1978a, b, c). Enzymes that have been detected include a glycanase, a peptidase, an *N*-deacetylase, an acylase directed against the prey peptidoglycan, a LPSase, and an enzyme that removes the Braun's lipoprotein. Presumably, the enzymatic activities permit the bdellovibrio to enter the prey cell periplasm through an entry pore and then to modify the penetrated cell envelope, producing a stabilized bdelloplast. Pep-

3. PYE is peptone-yeast extract medium (Seidler and Starr, 1969) and consists of (per liter): peptone (Bacto), 10.0 g; and yeast extract (Difco), 3.0 g. The pH is adjusted to 7.2 with 1 M NaOH.

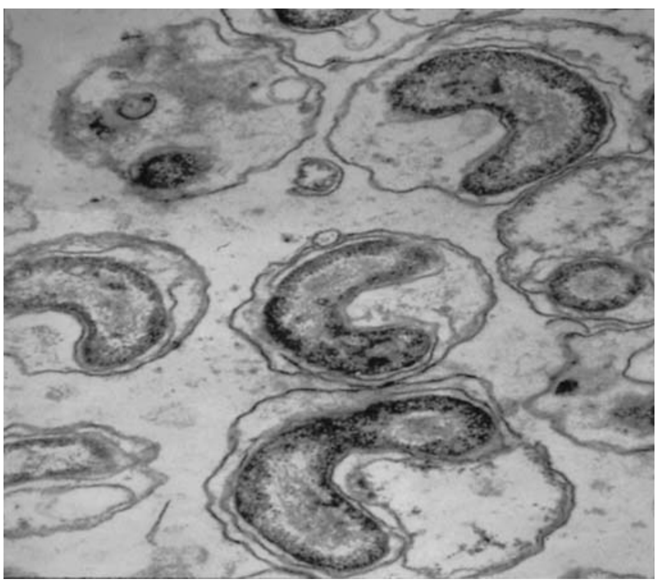

FIGURE BXII.δ.51. An electron micrograph of a thin section demonstrating spheroplasts and developing bdellovibrios. (Reprinted with permission from M.P. Starr and N.L. Baigent, Journal of Bacteriology *91:* 2006–2017, 1966 ©American Society for Microbiology.)

tidase activity is apparently required for penetration (Tudor et al., 1990), probably allowing the glycan chains of the peptidoglycan to spread enough to allow entry of the bdellovibrio. Penetration appears to be achieved by a combination of both mechanical and enzymatic means, and results in the almost immediate death of the invaded cell (Rittenberg and Shilo, 1970). The bdelloplast generally becomes spherical, providing the maximum area for growth of the bdellovibrio (Fig. BXII.δ.51). This rounding, the result of glycanase activity directed against the glycan chains of the peptidoglycan (Tudor et al., 1990), is abruptly stopped by the modification of the substrate by the coordinate action of the *N*-deacetylase and acylase (Thomashow and Rittenberg, 1978a, b). Following penetration, the bdelloplast is typically immune to invasion by additional bdellovibrios, probably due to the extensive alterations of the outer membrane of the prey. The invading bdellovibrio is capable of modifying the prey cell envelope in other ways as well (Ruby, 1989). *Bdellovibrio* macromolecular synthesis and cellular growth appear to begin between 45 and 60 min following the initial attack.

The bdelloplast serves as a unique chamber specifically modified by the *Bdellovibrio* for its growth, which proceeds in a highly efficient manner (Rittenberg and Hespell, 1975). DNA replication is confined to the intraperiplasmic growth phase. It has been shown that access to the nutrients within the prey's protoplast is acquired through the translocation of outer membrane porins into the cytoplasmic membrane of the bdelloplast (Tudor and Karp, 1994). These porins either may be derived from the prey outer membrane during penetration, or may be *Bdellovibrio*-specific outer membrane proteins. It has been shown that the major *E. coli* outer membrane protein, OmpF, is translocated to the *Bdellovibrio* outer membrane during penetration (Diedrich et al., 1983, 1984). Degradative activity within the invaded prey's cytoplasm results from the methodical breakdown of the prey cell's macromolecules. This degradation of macromolecules produces potential biosynthetic building blocks for the growing bdellovibrios. These building blocks are typically small enough to move through the translocated porins or by other means of entry into the periplasmic space, but too large to escape the bdelloplast envelope. Macromolecular synthesis within the growing *Bdellovibrio* cell then results from the uptake of monomeric units derived from the degrading prey cell cytoplasm that have leaked into the periplasmic space (Matin and Rittenberg, 1972; Hespell et al., 1975; Kuenen and Rittenberg, 1975). The bdellovibrios are capable of taking up nucleotide and phospholipid precursors from their prey as the respective monophosphates (Rittenberg and Langley, 1975; Ruby et al., 1985; Ruby and McCabe, 1986). These unusual abilities provide the bdellovibrios with an energy efficiency that is almost twice that exhibited by most procaryotes.

Growth of the intraperiplasmic bdellovibrio proceeds with the elongation of the cell into a long aseptate spiral-shaped filament. The length of the filament is limited by the size of the invaded prey cell (Kessel and Shilo, 1976). A prey cell such as *E. coli* will give rise to an average of four to five progeny bdellovibrios (Thomashow and Rittenberg, 1979). When the bdelloplast is exhausted of nutrients, the elongated spiral receives a signal to fragment into individual attack-phase bdellovibrios, each with a newly synthesized polar sheathed flagellum. This signal may be a small peptide that accumulates and causes division to begin (Eksztejn and Varon, 1977). A lytic enzyme is then induced that breaks down the modified bdelloplast peptidoglycan from the inside, resulting in lysis of the bdelloplast and release of the progeny bdellovibrios (Thomashow and Rittenberg, 1978b). The length of the intraperiplasmic growth phase is approximately 3.5 h at 30°C for *B. bacteriovorus* using *E. coli* as prey. When grown axenically, prey-independent and facultative strains of *Bdellovibrio* follow the same pattern of growth elongation into nonmotile spiral-shaped filaments and fragmentation into individual motile progeny. These axenic mutants also appear to shed their flagella prior to growth (Burnham et al., 1970).

It has been proposed that at least two distinct signals are required for bdellovibrios to complete growth intraperiplasmically: one necessary to convert attack-phase cells into growth-phase cells, and the other needed for the initiation of DNA synthesis (Gray and Ruby, 1990, 1991). These potential signals could conceivably correspond to two major waves of protein synthesis that have been demonstrated to occur in the early stages of bdellovibrio development (Thomashow and Cotter, 1992). It is clear that the growth of intraperiplasmic bdellovibrios involves multiple cascades of protein synthesis indicative of tightly controlled differential gene expression (McCann et al., 1998).

Bdellovibrio strain W exhibits an additional variation in the life cycle in that the cells can produce encysted, resting stages, termed bdellocysts, within the bdelloplast (Fig. BXII.δ.52) (Burger et al., 1968; Tudor and Conti, 1978). Bdellocysts are characterized by a thick layer (25–30 nm) of peptidoglycan formed outside the original *Bdellovibrio* cell wall (Tudor and Conti, 1977b; Tudor, 1980). This outer layer of cyst wall appears to be intimately associated with the bdelloplast wall and is synthesized *de novo*, not from preformed precursors from the prey wall (Tudor and Bende, 1986). Bdellocysts are much more resistant to physical stresses such as heat, starvation, desiccation, and disruption by nonionic detergents. Bdellocysts are produced at the expense of cellular reproduction since only one cyst is produced per prey cell, thus liberating only one attack-phase bdellovibrio upon germination. Bdellocysts contain more DNA, RNA, protein, and carbohydrate per cell than vegetative bdellovibrios (Tudor and Conti, 1977a). The increased carbohydrate represents large stores of glycogen within the bdellocyst that appear to be mobilized during germination (Tudor and Conti, 1978). *Bdellovibrio* strain W is a part of a unique group of procaryotic organisms that exhibits three different developmental stages: motile attack phase, intraperiplasmic growth phase, and dormant encystment phase.

Genetics Genome sizes of *Bdellovibrio* strains have been determined chemically, and range from 1.32×10^9–1.7×10^9 Da (Torrella et al., 1978). These molecular weights correspond to genome sizes ranging from 2 to 2.6 Mb in length (Torrella et al., 1978; Baer, 1998), about half the size of the *E. coli* genome. The genome size for *B. bacteriovorus* (2.07×10^6 base pairs, estimated by pulsed-field gel electrophoresis of digested whole cell genomes) has been reported by Scognamiglio and Tudor (1996).

Prey-independent, or axenic, mutants have been reported to arise spontaneously at a frequency of about 1 in 10^6–10^7 cells, a rate that suggests that they result from a single mutation (Seidler and Starr, 1969). These mutants are either obligately prey-independent (i.e., have lost the ability to grow predaciously) or facultatively prey-independent, retaining the ability to grow on prey cells. It has been proposed that two independent mutational events may be involved: one (type I) relieves the negative regulation necessary to initiate the growth phase, and a second (type II) to initiate DNA synthesis (Thomashow and Cotter, 1992). Methods by which the basis of the obligately predacious and prey-independent phenotypes can be understood at the molecular

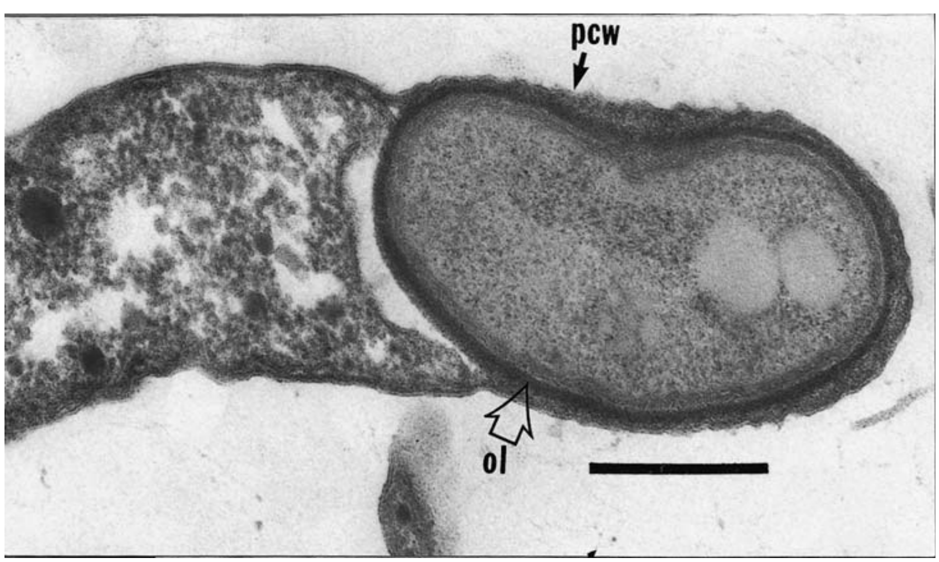

FIGURE BXII.δ.52. Electron micrograph of *Bdellovibrio* sp. strain W during encystment in *Rhodospirillum rubrum*. The outer layer of the bdellovibrio has *(ol)* increased in thickness and is intimately associated with the prey cell wall *(pcw)*. Bar = 0.2 μm.

level have been devised. This was done through the development of a genetic system by which DNA can be transported via conjugation from *E. coli* to *B. bacteriovorus* (Cotter and Thomashow, 1992a; Jennings et al., 1998). To date, only a single locus has been identified that affects the ability of the prey-independent mutants to form plaques on susceptible prey cells. This locus codes for the production of a 10.5-kDa protein, termed the hit polypeptide, which relieves an apparent negative control on the ability of prey-independent mutants to produce large clear plaques (Cotter and Thomashow, 1992b). Recombination with the *Bdellovibrio* wild-type locus does not, however, abolish the ability of mutants to grow prey-independently. The *hit* locus appears to be present just in *B. bacteriovorus* and could not be detected in *B. stolpii* or *B. starrii* (Schwudke et al., 2001).

Phages and phage typing From 1970 to 1972, several laboratories reported the recovery of bacteriophage lytic for some strains of *Bdellovibrio*. Phage typing thus became an additional tool for assessing the diversity among the predators. Six phage-susceptibility groups have been reported thus far among the *Bdellovibrio* and *Bacteriovorax* groups (Hashimoto et al., 1970; Althauser et al., 1972; Varon and Levisohn, 1972). Groups I to IV contain the *B. bacteriovorus* strains. Brentlinger et al. (2002) described a novel single-stranded DNA, phi MH2K, of *B. bacteriovorus*. This phage is a member of the *Microviridae* family.

Antigenic structure Diversity among bdellovibrios has also been observed by the application of antigenic analysis. Serologic studies of terrestrial strains of *Bdellovibrio* have suggested the presence of serogroups as well as a common group antigen (Kramer and Westergaard, 1977; Schelling et al., 1977; Schelling and Conti, 1983). Serological studies of 21 strains of *B. bacteriovorus* revealed nine serovars (Burnham and Conti, 1984).

Antibiogram Patterns of sensitivity and resistance to a panel of antibiotics (antibiogram) may be a useful method for differentiating *Bdellovibrio* isolates. In one study (Guether and Williams, 1993), all *Bdellovibrio* strains tested were susceptible to antibiotic disks of ampicillin (20 µg), ampicillin (2 µg), carbenicillin (100 µg), gentamicin (10 µg), kanamycin (30 µg), and penicillin (10 U, BBL), and all were resistant to colistin (10 µg) (Table BXII.δ.46), metronidazole (80 µg), nalidixic acid (5 µg), and vancomycin (30 µg).

Pathogenicity As far as is known, the pathogenicity of the *Bdellovibrio* appears to be limited to the susceptible bacteria on which they prey. However, the ability to colonize animal tissue, an essential prerequisite for pathogenicity to animals, has been only superficially investigated and more extensive studies are warranted. Attempts to establish the organisms in the intestines of frogs, mice, and rabbits (Westergaard and Kramer, 1977) were unsuccessful. A report of bdellovibrio-like organisms from human fecal samples in China has been confirmed (Hu et al., 1990; Schwudke et al., 2001).

Habitat and distribution in nature Bdellovibrios are recovered from a wide variety of ecosystems. However, a common feature among the diverse habitats from which large numbers of the predators are recovered is an abundance of bacteria. Bdellovibrios have been recovered in relatively large numbers from sewage and other areas that are densely populated with bacteria. Presumably, many of the bacteria are prey to the bdellovibrios and account for the large numbers of the predators. However, bdellovibrios are not recovered from all habitats with an abundance of bacteria. This includes the intestinal tract of some animals (frogs, crabs) examined (Westergaard and Kramer, 1977; Kelley and Williams, 1992). *B. bacteriovorus* has been recovered from the gut of humans, horses, and chickens (Schwudke et al., 2001). Habitats with low abundance of bacteria such as pristine waters contain few, if any, culture-detectable bdellovibrios. Other specific habitats are described below.

Many studies have revealed that the distribution of bdellovibrios in nature is both ubiquitous and diverse. The organisms have been recovered from soil, sewage, and fresh waters (Klein and Casida, 1967; Taylor et al., 1974; Fry and Staples, 1976), including water distribution systems (Richardson, 1990).

The occurrence and distribution of bdellovibrios in nature is influenced by several known environmental factors and undoubtedly by factors that remain unknown. Among the known factors are salinity, temperature, habitat, prey population density, and pollution.

In regard to salinity, the presence of NaCl in as low a concentration as 0.5% can determine the distribution of bdellovibrios in the environment (Varon and Shilo, 1968). The halophilic bdellovibrio-like organisms (HBLO), for which the salt selects, occur in saltwater environments but not in fresh waters or soils where only the terrestrial strains are present. Shifts in the occurrence of HBLO and terrestrial bdellovibrio populations at the same site were observed by one of the authors (H. Williams) to correlate to salinity fluctuations between 0 and 1%.

Various types of pollutants may influence, positively or negatively, the density of *Bdellovibrio* populations in natural habitats. Fry and Staples (1976) reported the influence of sewage pollution on the occurrence of bdellovibrios. Numbers of the predators were greater in sewage-polluted rivers than in pristine waters. Moreover, *Bdellovibrio* numbers were greater at the point of entry of sewage effluent than either upstream or several hundred or more meters downstream. In this case, the source of the greater numbers of bdellovibrios appeared to be the sewage itself, rather than increased growth of autochthonous bdellovibrios promoted by prey bacteria or other organic pollutants in the sewage. Klein and Casida (1967) reported similar increased numbers of bdellovibrios in sewage-polluted soils versus normal soils.

The population of bdellovibrios also may be adversely affected by certain environmental chemical pollutants. Laboratory studies reported by Varon and Shilo (1981) have shown that the predatory activity of a *Bdellovibrio* isolate was inhibited by detergents, heavy metals, and pesticides. Undoubtedly, other factors such as acidity, cations (Bell and Latham, 1975), light (Friedberg, 1977), etc. influence the presence of bdellovibrios, but these effects have not been sufficiently investigated in nature.

The few attempts to establish that certain animals harbor *B. bacteriovorus* or other bdellovibrios have not met with much success, because the predators were either not recovered or were recovered in low, insignificant numbers. In one study, animals were forced-fed suspensions of *Bdellovibrio*, but the organisms failed to become established in the intestinal tract (Westergaard and Kramer, 1977). However, the isolation of *B. bacteriovorus* from the gut of humans and animals was recently reported (Schwudke et al., 2001).

Role in nature The early observations that bdellovibrio infection of a susceptible bacterium is a lethal event, and that in laboratory cultures the prey population is substantially reduced by the predators, provoked speculation on the potential role of bdellovibrios as biological control agents in the environment. Perhaps the expectation of total prey population eradication by bdellovibrios was unrealistically high, especially since the pred-

TABLE BXII.δ.46. Characteristics of *Bdellovibrio bacteriovorus* and of halophilic bdellovibrios[a]

Characteristic	*B. bacteriovorus*	Halophilic bdellovibrios (representative halophilic strain AQ)

[b]Cultures may be initially positive but become variable with subsequent transfer (Seidler and Starr, 1969).

[c]Low indicates <6% hydrolytic activity.

[d]Test results are the same for prey-dependent and prey-independent mutants tested.

ators do not completely eradicate the prey even in laboratory cultures under optimal conditions. Prey cultures initiated with 10^9 CFU/ml will be typically reduced by bdellovibrio predation to 10^2–10^3 CFU/ml. This is a logical strategy since complete elimination of the prey population would exhaust the food source of the predators, a condition that would bring about their own starvation and demise. Unfortunately, properly designed studies to determine the impact of bdellovibrios on the mortality of the bacterial population in nature have not been conducted. The few studies that have addressed this issue have yielded circumstantial evidence that is often conflicting with other reports. Several investigations have concluded that bdellovibrios were not a factor in reducing bacterial populations in water and sewage (Fry and Staples, 1974, 1976). If, in fact, bdellovibrio multiplication occurs exclusively by the predatory cycle described previously, then to some extent the organisms must contribute to the mortality of susceptible bacteria in nature. Perhaps the greatest role of bdellovibrios in nature is one of modulation of its prey population. In this scenario when the population becomes high, 10^6 or greater, predation becomes more efficient, subject to suitable temperature and other environmental parameters, and the rate of prey killing increases—resulting in lower numbers of prey. However, at numbers of 10^3 and below, the predators may have little, if any, effect on the prey population. This hypothesis, of course, remains speculative until properly designed studies to confirm it have been conducted.

Enrichment and Isolation Procedures

Several procedures have been used for the enrichment and isolation of bdellovibrios. The procedure selected is dependent upon the nature of the source of the sample. Samples that potentially harbor large numbers of bacteria, protozoa, or fungi that may overgrow and mask the presence and growth of small numbers of bdellovibrios may require special isolation procedures. In these cases, filtration, centrifugation, or other methods to reduce the number of the large heterotrophic bacterial population or other undesirable organisms may be necessary. These procedures respectively trap or sediment the larger, denser cells. In filtration, the filter size selected may vary; however, a sound rule is to use the largest pore size filter possible to reduce the cultivable bacteria, protozoa, and fungi to a level that does not mask bdellovibrio plaques on plates, and that minimally decreases the numbers of the bdellovibrios. A pore size of 1.2 μm has been used for some samples (Varon and Shilo, 1970). Centrifugation is done at low speed to sediment the larger bacteria while leaving the smaller bdellovibrios suspended in the supernatant fluid. Differential or gradient centrifugation may be used to achieve better separation of bdellovibrios from other microbial cells (Varon and Shilo, 1970).

Samples from environmental sources with relatively small numbers of cultivable bacteria such as pristine rivers or other bodies of water typically contain small numbers of bdellovibrios. In these samples, filtration or centrifugation to reduce the number of bacteria may reduce as well the bdellovibrio population, exacerbating the difficulty of their recovery. For such samples, and those with moderate numbers of cultivable bacteria, direct plating may be the most promising approach. Filtration and centrifugation procedures may also be used for samples with extremely small numbers of bdellovibrios to concentrate the organisms so as to yield numbers sufficient for recovery. In this case, the objective of filtration is to trap the bdellovibrios and other bacteria on the filter surface. For this, a small pore size filter (≤0.2 μm) is required. Concentration of bdellovibrios may also be accomplished by high speed centrifugation of samples to

pellet all bacteria present. Alternatively, an initial low speed centrifugation (3–5 × g) may be done to pellet large cells, followed by high speed centrifugation to capture the smaller cells including the bdellovibrios. Gradient centrifugation may improve both the yield and separation of the bdellovibrios.

Plating environmental samples for the recovery, isolation, or direct quantitation of bdellovibrios is done using the double agar overlay procedure as described by Staples and Fry (1973). The volume of sample inoculum used by investigators has varied over a wide range from 0.1 to 10 ml (Taylor et al., 1974; Williams, 1988). Typically, samples are plated undiluted, although in some situations 10-fold dilutions are plated. Both the volume and dilution of inoculum plated is dependent upon the relative numbers of bdellovibrios and other cultivable bacteria expected to be in the sample. For ocean water samples where the total cultivable bacteria and bdellovibrio counts are typically low, Taylor et al. (1974) used 10 ml of sample as the inoculum. In several studies conducted in the Chesapeake Bay, the sample inoculum typically consisted of volumes of 0.1, 1.0, and 5.0 ml. In the colder months when bdellovibrio numbers decreased (Williams, 1988; Williams et al., 1995b) the 0.1-ml sample plating was eliminated. To accommodate the larger inoculum size for plating, Petri dishes of 150 × 25 mm or 150 × 15 mm are used. For plating of suspensions of sediment or surface biofilms from oyster shell, typically 0.1 and 1.0 ml of the undiluted sample and 1.0 ml of 10-fold serial dilutions up to 10^{-4} were plated. The sample is added to a tube of molten top (soft overlay) agar just previously inoculated with an appropriate prey suspension and held between 45 and 47°C. The agar concentration of the top agar is determined by the size of the sample inoculum to be added. The final agar concentration, following addition of sample and prey suspension, should range from 0.6 to 0.7%. The top agar suspension is mixed and overlaid onto prewarmed bottom agar (agar concentration 1.2 to 1.5%) plates. The plates are immediately swirled in a circular, figure-eight pattern to spread the molten agar evenly, before hardening, over the bottom agar surface.

The top agar is allowed to harden (~10 min) and the plates are inverted and incubated at 30°C. Plaques of bdellovibrios typically appear in 2–6 d and increase in size with prolonged incubation. *Bdellovibrio* plaques are usually round with a sharp, distinct boundary and clear in the center (Fig. BXII.δ.49). *Bdellovibrio* plaques must be differentiated from those caused by viruses, protozoa, myxobacteria, or other organisms. Plaques produced by bacteriophage will typically appear by 24 h incubation and do not increase in size. Plaque-like clearings with a central bacteria colony are not typical of those produced by bdellovibrios. *Bdellovibrio* plaques should be confirmed by microscopic examination. Phase contrast or dark-field microscopy is the most practical, but light microscopy of Gram-stained preparations is possible.

To obtain pure cultures from agar plates, plaque material may be removed with an inoculating loop or needle or the point of a scalpel blade and streaked for isolation directly on hardened top agar. Alternatively, the plaque material may be emulsified in a small volume (1–3 ml) of sterile medium that is subsequently serially diluted and plated to obtain a few well-isolated plaques on a plate. If desired, the plaque suspension may be filtered to remove extraneous organisms prior to plating. Material from a well-isolated plaque is again emulsified, serially diluted, and plated or transferred into broth and incubated. Several such passages of plaque material should be performed before the isolate is considered to be a pure culture.

Recovery of bdellovibrios is favored by use of a low-nutrient, minimal medium. Such a medium, when inoculated with a bacterial suspension to yield a final concentration of 10^7–10^9 prey per ml, retard the normal growth of the large numbers of heterotrophic cultivable bacteria typically found in environmental samples, and simultaneously promote rapid multiplication by the bdellovibrios. The medium most widely used for the recovery of *Bdellovibrio bacteriovorus* is NB/500 (Staples, 1973). The recommended prey is *Achromobacter* sp. (NCIB 8250) (Staples, 1973), although other genera and species have been used. The prey can be grown in an appropriate broth or agar medium and harvested to produce a concentrated suspension. Nutrient agar or other suitable medium can be used for this purpose. When grown in broth, the cells can be harvested by centrifugation, and if desired, washed by re-centrifugation in sterile medium. The pellet is then resuspended in the appropriate medium to yield a dense suspension. As an alternative to broth culture, prey cells can be grown on agar plates for 24–48 h. The colonies are harvested by flooding the plate with approximately 5 ml of sterile DNB. Following a period of about 5 min, the colonies are suspended in the overlying liquid by using a glass "hockey stick" in a spreading motion over the agar surface. The cell suspension is removed from the plate by pipetting and placed in a sterile tube and mixed. As a rinse, the agar plate may be flooded once again with 2–3 ml of sterile medium to harvest any residual bacteria from the plate and the rinse fluid added to the original tube. These procedures typically yield a suspension containing 10^8–10^{10} cells per ml. Just prior to inoculation into the top agar, the tube is mixed to prevent the settling of the cells.

Enrichment in broth may be preferred in situations where the primary objective is the recovery of bdellovibrios from environmental samples rather than quantitation. This procedure is also indicated in samples where the numbers of bdellovibrios are expected to be low, making their recovery by plaque assay difficult. Whereas the size of the sample inoculum in the double agar overlay plating procedure is limited to 10 ml, enrichment in broth has the advantage of accommodating a larger sample inoculum. For example, 100 or 1000 ml of an environmental sample could be collected in a flask and directly enriched with a concentrated prey suspension to yield a final prey cell density of 10^8–10^9 cells/ml. The larger sample size enhances recovery where bdellovibrios occur in very small numbers.

The typical enrichment procedure for recovery of the bdellovibrios is to add directly into the collected sample sufficient prey cells to yield a final concentration of approximately 10^9 cells/ml. At the discretion of the investigator, the sample may be prefiltered through a 0.3–1.2 µm pore size filter prior to adding to the enrichment vessel to reduce the number of heterotrophic bacteria. When working with soil or solid sample material, the sample may be added to a minimal broth medium. Natural water or a prepared salts solution is suggested. The lack of added chemical nutrients to the medium retards the growth of the large population of extraneous bacteria in the sample. The addition of a high concentration of prey cells to the minimal medium provides the nutrient source to promote the growth of bdellovibrios capable of predation on the prey selected. The enrichment culture should be incubated at 30°C. Enrichment cultures should be examined macroscopically for some degree of clearing in the broth, and microscopically, by phase contrast or dark-field microscopy, for the presence of small, highly motile, vibrio-like bacteria. Fluorescence microscopy using acridine orange or DAPI or the Gram stain may be used as alternatives but are not suitable

for visualization of live cell preparations. With either clearing of broth cultures or microscopic observation of bdellovibrio-like organisms at 72 h incubation, samples of the enrichment culture should be serially diluted and plated for the recovery of bdellovibrio-type plaques. The enrichment sample may be pre-filtered prior to plating to reduce the number of persisting heterotrophic bacteria. If bdellovibrio-type plaques are not recovered, incubation should continue for at least 14 d with daily examination and periodic culturing for plaques. Plaques that are recovered may be subcultured to obtain pure cultures as described above.

Maintenance Procedures

Cultures of bdellovibrios can be maintained by either serial transfers of plaque material from isolated plaques or broth cultures as described in the first edition of *Bergey's Manual of Systematic Bacteriology* (Burnham and Conti, 1984). The use of a minimal medium and appropriate prey bacterium species is recommended. In addition to the use of NB/500, some investigators prefer to use dilute nutrient broth (DNB) or agar for the maintenance of isolates. The bacterial species selected for prey is typically the species on which the bdellovibrio isolate was initially recovered or other bacterium on which the predator grows well. Prey organisms reported to yield good recovery of bdellovibrios include *Achromobacter* sp. (NCIB 8250) (Staples, 1973) and *E. coli* (Klein and Casida, 1967).

When maintaining bdellovibrio cultures in broth, serial transfers should be done at least weekly. A small inoculum of 0.1 ml or less from a week-old bdellovibrio lysate into a dense prey suspension (approximately 10^9 per ml) will yield clearing of the suspension in several days typically and sustain the growing bdellovibrios for a week or more. A larger inoculum of the predators will exhaust the prey more rapidly and may require more frequent transfers. When maintaining bdellovibrio cultures in broth, it is recommended that periodically, and before using the culture for investigative purposes, a sample of the culture be plated to recover well-isolated plaques, which should be used to initiate a new broth culture. This procedure provides a safeguard for maintaining a single bdellovibrio culture and avoiding mixed cultures. This is important since bdellovibrios cannot be differentiated on the basis of cultural features and practical biochemical methods of distinguishing between isolates have not found wide use.

The preservation of bdellovibrio cultures remains as described in the first edition of *Bergey's Manual of Systematic Bacteriology* (Burnham and Conti, 1984). Cultures for preservation should be centrifuged at 10,000 × g for 10 min. The pellet should be suspended to the original volume in either skim milk or 12% sucrose (Burnham and Conti, 1984). This suspension can be distributed in ampoules for freeze-drying. Freeze-dried specimens can be revived by suspending in NB/500 broth or other medium in which they may be grown. The suspension may be inoculated either into broth or onto plates using the appropriate prey species.

Procedures for Testing Special Characters

Biochemical characterization The metabolic and biochemical characterization of bdellovibrios is handicapped, since the wild-type, predatory organisms have not been grown in pure culture and do not metabolize commonly used substrates. Special strategies must be employed to characterize and differentiate the bdellovibrios.

One such strategy employed is the use of tests that do not require growth of the organisms. The API-Zym identification system (BioMerieux) is a battery of miniaturized tests that characterize and differentiate among bacteria by the presence or absence of certain enzymes and does not require growth of the organism. Wild-type bdellovibrios have been characterized with this system (Guether and Williams, 1992; Deidrich, personal communication), and it proved useful in revealing some distinguishing traits among them. The important step prior to performing this test is to ensure that the bdellovibrio suspension used as inoculum is free from prey cells and is pure.

Another strategy for differentiation and characterization of bdellovibrios is to use prey-independent mutant strains from wild-type isolates. Mutants have been reported to arise at a relatively high rate among the bdellovibrios and are not too difficult to recover. However, this may not be true for all wild-type strains isolated. A protocol for recovering mutant strains has been described (Seidler and Starr, 1969). Evidence suggests that the mutant isolates result from a single mutation that relieves a negative repressor for multiplication. Preliminary reports suggest that in most cases, many properties of the mutant strains are very similar to, if not identical with, the wild type. Mutant strains may therefore be a useful research tool for studying the differential properties of the bdellovibrios for not only metabolic functions but also fatty acid analysis, genetic analysis by molecular "fingerprinting" techniques, and comparisons of 16S rRNA sequences. However, specific mutant strains used for such purposes should be given a specific designation and characterized since mutants having different properties may derive from a single wild-type clone (Barel and Jurkevitch, 2001).

Differentiation by molecular fingerprinting techniques Characterization of bdellovibrios using molecular techniques is a recent development (Scognamiglio and Tudor, 1996) and are useful for differentiating wild-type bdellovibrios, although some are beyond the means of most small laboratories. However, commercial companies offer as a service molecular bacterial identification and differential analysis. Molecular methods that have proven useful include pulsed field gel electrophoresis (PFGE), arbitrarily primed PCR (AP-PCR), and ribotyping.

Pulsed field gel electrophoresis (PFGE) PFGE was performed on five prey-independent strains of *Bdellovibrio bacteriovorus*, the two *Bacteriovorax* species, one environmental terrestrial isolate, and two halophilic *Bdellovibrio*-like organisms (Baer et al., 1998). It was observed that only the *Bdellovibrio bacteriovorus* strains (100, 109J, Ox9-2, E, and 2484Se2) were restricted by enzymes having an "8 base" recognition site (*Asc*I, *Fse*I, *Sfi*I, and *Not*I). Restriction patterns produced for the *B. bacteriovorus* strains were similar but strain differences (± 2–3 bands) were observed (Baer, 1998; Baer et al., 1998).

Arbitrarily primed PCR (AP-PCR) When amplification patterns produced by arbitrary primers were compared for 10 prey-independent isolates consisting of *B. bacteriovorus*, *Bacteriovorax*, and HBLO, each strain was observed to produce its own unique amplification banding pattern. However, the patterns produced by the *B. bacteriovorus* strains were the most similar (only 1–3 bands different) (Baer, 1998; Baer et al., 1998). Dendrograms based on the degree of similarity of the band patterns revealed that the *B. bacteriovorus* strains clustered as a group distinct from the HBLO and *Bacteriovorax* spp., which formed a second group.

Ribotyping *Bdellovibrio* and other predatory strains including 13 HBLO and the *Bacteriovorax* species were analyzed by ribotyp-

ing using two restriction enzymes, *Eco*RI and *Pvu*II. Similar results were observed as for PFGE and AP-PCR. *B. bacteriovorus* strains were found to be the most similar to each other, whereas the other strains tested produced their own distinct ribotyping profiles.

Differentiation of the genus *Bdellovibrio* from other genera

Plaque-forming bacterial strains that are tentatively identified as members of the family *Bdellovibrionaceae* must be confirmed to grow in the periplasmic space of their respective prey bacteria. This characteristic serves as the primary factor that differentiates members of this family from other comma-shaped bacteria. Confirmation of the location of the bdellovibrios within the prey cell may be accomplished by examining plaque material, or dual predator-prey cultures, by phase-contrast or transmission electron microscopy.

Differentiation of the genus *Bdellovibrio* from the new genus *Bacteriovorax* may be accomplished through the combination of phenotypic and molecular analyses (see Table BXII.δ.48 in the *Bacteriovorax* chapter).

Taxonomic Comments

In the previous edition of the *Manual*, all predatory, intraperiplasmic bacteria were placed into a single genus, *Bdellovibrio* (Burnham and Conti, 1984). However, the substantial diversity among the organisms was noted including a broad range of mol% G + C values (17%) and wide differences in DNA hybridization values. High levels of diversity among *Bdellovibrio* species have been observed in studies examining cultural, physiological, and biochemical characteristics such as fatty acid composition (Guether et al., 1993), antibiotic resistance patterns (Guether and Williams, 1993), enzymatic activities (Guether and Williams, 1992), serological properties (Schelling et al., 1977; Schoeffield et al., 1991), and phage typing (Hashimoto et al., 1970; Althauser et al., 1972; Varon and Levisohn, 1972). The level of diversity observed among these strains places considerable stress upon the concept of including these organisms within the same genus (Burnham and Conti, 1984). Recent analysis of complete 16S rDNA sequences and DNA–DNA hybridization (Baer et al., 2000) from *B. bacteriovorus* 100^{T}, *B. stolpii* Uki2^{T}, and *B. starrii* A3.12^{T} confirms the diversity among the predatory bacteria. The collective results from these studies demonstrate that it is no longer appropriate to use the presence of predatory behavior as the sole defining property for placing organisms within the *Bdellovibrio* genus. The bacteria formerly classified as *Bdellovibrio stolpii* and *Bdellovibrio starrii* have now been assigned to a new genus, *Bacteriovorax*, as described in the following chapter. The type species of the *Bdellovibrio* remains *Bdellovibrio bacteriovorus* strain 100 (ATCC 25622).

The genus *Bdellovibrio* is now better defined except for the halophilic strains, which are being further analyzed. The taxonomy of these strains remains in a primitive state with isolates being loosely designated as *Bdellovibrio* sp. since none of the organisms has been sufficiently characterized and defined to warrant designation as a taxonomic species. This lack of information has made it impossible to investigate the diversity of the organisms and the abundance and distribution of various species in nature. To avoid confusion in terminology and designations, the genus *Bacteriovorax* and the HBLO and other undefined isolates are referred to in this edition as bdellovibrio-like organisms (BLO). The halophilic bdellovibrios are referred to as the HBLO as described above. All the intraperiplasmic predatory bacteria with the morphological and life cycle features as described for the bdellovibrios including *B. bacteriovorus*, *Bacteriovorax* sp., and the HBLO are referred to as the *Bdellovibrio* and like organisms.

From an evolutionary standpoint, it has been suggested that bacteria that are described as *Bdellovibrio* strains have originated from diverse organisms, which through converging patterns of evolution, have developed their predacious way of life (Varon and Shilo, 1980). The first phylogenetic tree for the *Bdellovibrio* was constructed by Donze et al. (1991). Results from this study revealed that the bdellovibrios clustered within the *Deltaproteobacteria*, clustering most closely with *Desulfovibrio desulfuricans* and *Myxococcus xanthus*. All *Bdellovibrio* strains were shown to be more closely related to each other than to other members of the *Deltaproteobacteria* or to organisms within the *Alphaproteobacteria*, *Betaproteobacteria*, and *Gammaproteobacteria*. The most interesting revelation was that the bdellovibrios formed two distinct branches. The first branch consisted of *B. bacteriovorus* and *Bdellovibrio* strains W, 6-5-S, 109, 109D, 114, Ox9-2, and Ox9–3. The second branch included *B. starrii*, *B. stolpii*, and their halophilic isolate BM4. The results reported by Donze et al. (1991) support the findings of several earlier independent studies by other investigators (Hespell et al., 1983; Stackebrandt and Woese, 1984; Oyaizu and Woese, 1985; Woese, 1987; Stackebrandt, 1988). The recent development of phylogenetic trees based on analysis of complete sequences of 16S rRNA genes has confirmed these findings (Fig. BXII.δ.53) (Baer et al., 1998). These data suggest a reevaluation of the assignment of the halophilic strains to the genus *Bdellovibrio*, as they are more closely related to members of the genus *Bacteriovorax* and may warrant a separate genus designation.

DNA–DNA hybridization A high degree of DNA–DNA hybridization values (ranging from 70 to 100%) has been observed among four of the different strains of *B. bacteriovorus* (100^{T}, 109J, Ox9-2, and E) (Baer et al., 2000). A lower degree of hybridization (ranging from 32 to 55%) has been noted between 2484Se2 and each of the other four *B. bacteriovorus* strains tested (Baer et al., 2000). A previous report (Seidler et al., 1972) demonstrated very little hybridization between *B. bacteriovorus* 100^{T} and related organisms (1% hybridization with *B. starrii* A3.12^{T} and no hybridization with *B. stolpii* Uki2^{T}, both of which are now classified as *Bacteriovorax*). Low hybridization values were observed between *B. bacteriovorus* and the halophilic isolates tested in this study (<5%).

List of species of the genus Bdellovibrio

1. **Bdellovibrio bacteriovorus** Stolp and Starr 1963, 243[AL]
bac.te.ri.o'vo.rus. Gr. dim. n. *bacterium* a small rod; L. v. *voro* to devour; M.L. adj. *bacteriovorus* bacteria devouring.

The characteristics are as described for the genus and as listed in Tables BXII.δ.46 and BXII.δ.47. Isolated from soil, sewage, and freshwater sources.

The mol% G + C of the DNA is: 50.4 ± 0.9 (Bd).

Type strain: HD 100, DSM 50701, ICPB 3268, NCIB 9529.

GenBank accession number (16S rRNA): AJ292759.

Other Organisms

Isolates of the intraperiplasmic predatory bacteria (IPPB) from seas and oceans were observed to require NaCl for growth and were referred to as the "marine" bdellovibrios (Shilo, 1966). In the first edition of the *Manual*, these organisms were placed in the group *Bdellovibrio* species. It is now recognized that these salt-dependent organisms also occur in estuarine environments and hypersaline lakes. This makes the designation "halophilic" more appropriate. Conversely, isolates from fresh water and from soil were observed to be inhibited even by low concentrations (<0.85%) of salt (Varon and Shilo, 1968) and were given the common designation of fresh water or "terrestrial" bdellovibrios. Although initially named bdellovibrios, the halophilic isolates have long been recognized as being distinct from *Bdellovibrio bacteriovorus*. Results from recent studies have revealed even greater differences and suggest that the variations between the organisms warrant consideration for a separate genus for the halophilic predators. Based on this, and to avoid confusion of the salt-tolerant IPPB with *Bdellovibrio*, they will be referred to in this volume as the halophilic bdellovibrio-like organisms (HBLO).

The HBLOs are like *Bdellovibrio bacteriovorus* and the *Bacteriovorax* sp. in major physical features and lifestyle. Many halophilic strains appear to be just slightly smaller in diameter and pass more readily through 0.3-μm pore size filters than the terrestrial *Bdellovibrio* and *Bacteriovorax*. Besides tolerance to sodium chloride, the most prominent distinctions between the halophilic

[c]Both PD wild-type and PI mutant strains were used. Test results are from PD isolates unless otherwise noted.

[d]Test results from wild-type PD isolates.

[e]Defined to mean that some strains have been observed to complete their life cycle either prey-dependently or prey-independently.

[f]0/129, 24-diamino-6,7-diisopropylpteridine phosphate.

[g]Test result is from PI mutant.

[h]Data from Althauser et al. (1972) and Varon and Levisohn (1972).

[i]Most halophilic strains have a mol% G + C between 33.4–38.6 (Marbach et al., 1976); only one has been found to have a mol% G + C as high as 43.5 (Taylor et al.,1974).

[j]Test result is the same for both PD and PI mutants.

[k]Using API-Zym (BioMerieux) test system and prey-independent mutants of *Bdellovibrio*.

and terrestrial predators are G + C ratios, growth temperature, and nucleic acid molecular "fingerprint" as revealed by various techniques.

The properties of the DNA vary substantially between the HBLO and *Bdellovibrio bacteriovorus*. The mol% G + C content of the DNA of the HBLO ranges typically from 33.4 to 38.6, much lower than strains of *B. bacteriovorus*. The banding patterns produced by PFGE, ribotyping, and other molecular fingerprint techniques also revealed major differences between the two groups. Analysis of 16S rDNA sequence data from isolates of *Bdellovibrio*, *Bacteriovorax*, and HBLO revealed major differences (Baer, 1998). The level of similarity among *Bdellovibrio bacteriovorus* strains was >97%. However, when *B. bacteriovorus* 100 was compared to isolates of HBLO, lower similarity values, 80–82%, were observed. All HBLO isolates fell into three different groups within this same clade. The Chesapeake Bay isolates formed two groups; one contained isolates JS2, JS4, JS6, JS7, and JS10 and the other, JS5 and JS3. Ocean isolate SJ and aquarium salt-water isolate AQ were in the last group. These were more similar to each other than either was to the terrestrial strains (Fig. BXII.δ.53). Phylogenetic data suggest a reevaluation of the assignment of the HBLO to the genus *Bdellovibrio*.

The HBLOs, like *Bdellovibrio bacteriovorus* and the *Bacteriovorax* species, give rise spontaneously to mutants capable of growing without prey. The same procedure described to enrich the mutants of *Bdellovibrio* may be used to recover prey-independent HBLOs, using a medium with at least 1% salt. These mutants may be useful tools for studying the genetics and metabolism of the HBLOs and how they differ from the other members of the *Bdellovibrionaceae*.

Other differences that have been described between the HBLOs and the terrestrial predators include immunological properties, resistance to certain antibiotics, and metabolic properties (Table BXII.δ.47). Immunodiffusion analysis performed with antisera against eight isolates of HBLO and a single terrestrial isolate and antigen preparations from 45 HBLO environmental isolates yielded seven serogroups that were distinct from the terrestrial isolate (Falkler et al., 1979). Immunoelectrophoresis revealed a shared antigen between the halophilic and terrestrial isolates. Further study may reveal that this shared antigen is universal among the *Bdellovibrionaceae* (*Bdellovibrio bacteriovorus*, *Bacteriovorax* species, and HBLO). These results suggested the presence of various serotypes among the HBLO and inferred that these serologic differences would allow definition of subgroups of these organisms as well.

Differences in antibiotic susceptibilities among the *Bdellovibrionaceae* have been observed. These differences may be useful in differentiating the organisms within the family. The terrestrial

and halophilic predators were differentiated based on their susceptibility to polymyxin B 300, being resistant and sensitive respectively (Guether and Williams, 1993).

The distribution of the *Bdellovibrionaceae* has been the subject of several reports. The HBLOs occur in oceans, seas, estuaries, man-made aquatic systems including a marine aquarium (Williams et al., 1987), and salt lakes, but not in fresh waters or soils. Strains of HBLO reportedly require ≥0.5% NaCl for growth. Although the HBLOs are not known to occur in fresh water, shifts in the occurrence of halophilic and fresh water bdellovibrio populations at the same site have been observed to correlate to salinity fluctuations between 0 (fresh water) and 1% (Kelley et al., 1997). Most distribution studies have focused on the occurrence of HBLO in the water column where the numbers recovered were typically low, i.e., less than 100 plaque-forming units (PFU) per ml of water (Marbach et al., 1976; Williams, 1988; Williams et al., 1995a, b). Earlier, Shilo (1969) had suggested the possibility that investigators had been examining the wrong habitats for greatest bdellovibrio abundance and activity. Subsequent studies in an estuary revealed that HBLOs were more abundant at the air–water interface, in sediments, and in microbial biofilms on surfaces (Williams et al., 1995a, b), all of which are densely populated with bacteria. These data confirm Shilo's hypothesis. The HBLOs, and perhaps the other *Bdellovibrionaceae*, are similar to many other aquatic bacteria in that they tend to associate with available surfaces (Bernheimer et al., 1993; Baer et al., 1994; Williams et al., 1995a, b). When sterile glass slides were submerged in the Patuxent River, bacteria, including HBLOs, associated rapidly with the surfaces (Williams et al., 1995b). Samples of biofilms from the surfaces of oyster and crab shells yielded the highest numbers of HBLO recorded from the aquatic ecosystem (Kelley and Williams, 1992; Williams et al., 1995a, b). Microbial biofilms appear to host the most enriched and stable population of the HBLO. The most obvious example of this is the stable occurrence of the predatory bacteria over an annual cycle in surface biofilms as opposed to the seasonal fluctuations observed in water and sediments (Kelley et al., 1997). Apparently, biofilms provide the nutritional (abundance of prey bacteria) and environmental conditions suitable for survival of the HBLO at relatively high levels under the harshest of conditions. This likely holds true for the terrestrial predatory organisms as well.

The HBLOs do show a seasonal distribution in the water column and sediment that has been correlated with temperature (Williams, 1988). At temperatures below 10°C, the numbers of the organisms were observed to decline rapidly in both the water column and sediments, although the numbers remaining in sediments were higher. Frequently at water temperatures below 5°C, the predatory HBLO could not be detected by culture. As the water temperature warmed in the spring, the numbers of the predators were first observed to increase in sediments and then in the water column. The effect of temperature on fluctuations in the numbers of HBLO was not nearly as dramatic in surface biofilms, where the organisms remained fairly constant, as that observed in water and sediments (Williams et al., 1995a, b). Rice et al. (1998) observed that a large majority of the bacteria recovered from the water, sediment, and biofilm in the Chesapeake Bay region was susceptible to predation by HBLO.

Clearly not all habitats are equal in their capacity to support the growth and maintenance of the HBLO and the other intraperiplasmic predatory bacteria (IPPB). In aquatic ecosystems, the predators do exhibit a preference for surface habitats over planktonic habitats.

The IPPB have been consistently isolated from animals and humans (Schwudke et al., 2001), including the blue crab, *Callinectus sapidus* (Kelley and Williams, 1992). HBLOs were recovered consistently from the gills of animals taken from estuarine waters and from seafood markets (Kelley and Williams, 1992; Schwudke et al., 2001).

For isolation of HBLO from environmental sources, samples are cultured in the same manner as their terrestrial counterparts except that a salt-containing (1–3%) medium such as Pp20[4] (Williams and Falkler, 1984) or MPY/10[5] (Marbach et al., 1976) is substituted for NB/500[6] (Staples, 1973) and DNB[7] (Stolp, 1973). The medium most often reported in the literature is Pp 20 (Williams et al., 1976; Schoeffield, 1990; Kelley et al., 1997) with *Vibrio parahaemolyticus* P-5 or other *Vibrio* sp. as prey. These species were observed to most consistently yield recovery of the greatest number of HBLO from the Chesapeake Bay (Schoeffield, 1990). However, when sampling other types of bodies of water, various species should be examined as prey. This may require using other media formulations such as MPY/10 that may be more suitable for production of confluent growth of the prey lawns required to maximize HBLO recovery (Marbach et al., 1976). The prey bacteria typically require salt, and they are grown on seawater yeast extract agar (SWYE[8]), or Marine broth (Difco). The colonies are harvested by flooding the plate with approximately 5 ml of sterile artificial seawater (ASW).

For initial recovery of HBLO, a solid agar or broth may be used. For samples in which HBLOs are expected to be abundant, recovery and isolation may be accomplished by direct plating on a solid medium using the double-agar overlay technique as described for the *Bdellovibrio*. This procedure has been used extensively for recovery from samples from rivers, estuaries, oceans, and marshes (Williams and Falkler, 1984; Williams, 1987; Williams et al., 1995a; Kelley et al., 1997; Rice et al., 1998). In addition, direct plating of samples should be considered when the water temperature is below 10°C, since it has been reported that the numbers of predatory bacteria are reduced at low temperatures (Williams, 1988). For the HBLO, plated samples are typically incubated at 22–25°C for up to 1 week, although plaques typically appear within 48–72 h. Individual plaque may be subcultured to obtain pure cultures. Samples thought to have numbers of HBLO too low to be readily detected by direct plating should be enriched. The typical enrichment procedure is to add a portion of the sample to a liquid medium containing prey cells. Good results have been observed for recovery of the HBLO using as culture medium filtered and sterilized natural seawater or estuarine water with no added nutrients or salts other than the

4. Pp20 is polypeptone 20 medium and consists of (g/l) polypeptone (Bacto), 1.0 g, and agar (Difco), 18.0 g. These ingredients are dissolved in 1 l of 70% artificial sea water. The 70% artificial sea water (ASW) consists of 26 g of Instant Ocean dissolved in 1 l of distilled water; the pH is adjusted to 8.0 with 1 M NaOH.

5. MPY/10 is a basal salt medium and consists of (per l basal salt solution) peptone (Bacto), 0.5 g; yeast extract, 0.3 g. The pH is adjusted to 7.4. Basal salt solution consists of (g/l) $MgSO_4 \cdot 7H_2O$, 6.92; NaCl, 28.15; $MgCl_2 \cdot 6H_2O$, 5.51; $CaCl_2 \cdot H_2O$, 1.45; KCl, 0.67.

6. NB/500 is nutrient broth (Difco) at 1/500 normal strength (equals 0.016 g of dehydrated broth/l).

7. DNB is a dilute nutrient broth, consisting of (per l) nutrient broth (Difco), 0.8 g; yeast extract (Difco), 0.1 g; vitamin-free casamino acids, 0.5 g; 2 mM $CaCl_2$; and 1 mM $MgCl_2$. The pH is adjusted to 7.2 with 1 M NaOH.

8. SWYE is salt water yeast extract medium and consists of (per l) peptone (Bacto), 10 g; yeast extract, 3.0 g dissolved in 1 l of 70% artificial seawater (ASW).

prey. In the previous edition of the *Manual*, the MPY medium (Taylor et al., 1974; Marbach et al., 1976) was cited for isolation, enrichment, and maintenance of HBLO. More recently, other media formulations have been used. For short-term maintenance in culture, satisfactory results have been obtained using prey–seawater medium consisting of prey cells suspended in either natural, filtered, or autoclaved seawater diluted to 70% or 70% artificial seawater (Instant Ocean, 26 g/l of distilled water) (personal observation). Estuarine water may be used undiluted. *V. parahaemolyticus* is a preferred prey for the growth and maintenance of the HBLO (Williams et al., 1976; Schoeffield, 1990). This method maintains cultures for 1–2 weeks only. For long-term maintenance, HBLO cultures may be pelleted as described for the terrestrial isolates, suspended in marine broth or other suitable medium containing 20% glycerol, quick-frozen in liquid nitrogen, and stored at −70°C. Storage for 6 months or less has been successful at −20°C.

Major phenotypic differences between *B. bacteriovorus* and the halophilic bdellovibrios are listed in Tables BXII.δ.46 and BXII.δ.47.

The taxonomy of the HBLO remains in a primitive state. In the first edition of the *Manual*, it was recommended that all halophilic and other low mol% G + C isolates be placed in the group designated *Bdellovibrio* sp. None of the HBLO organisms has been sufficiently characterized and defined to warrant designation as a taxonomic species. This lack of information has made it impossible to investigate the diversity of the organisms and the abundance and distribution of various species in nature. It is apparent that differences in the metabolic, genetic, and cultural properties between the HBLO and *Bdellovibrio* are sufficient to preclude them from belonging to the same genus (see Baer et al., 2004 in Further Reading section in this chapter).

Genus II. **Bacteriovorax** *Baer, Ravel, Chun, Hill and Williams 2000, 222*[VP]

Henry N. Williams and Marcie L. Baer

Bac.te.ri.o.vo′rax. Gr. dim. n. *bacterion* small rod; L. n. *vorax* devourer; M.L. n. *Bacteriovorax* devourer of bacteria.

Members of the genus *Bacteriovorax* exhibit the same general morphological and life cycle features as described for the genus *Bdellovibrio*. However, genetically the two genera vary considerably, with *Bacteriovorax* sp. having a lower **mol% G + C content, little to no DNA–DNA hybridization (<4%), and <82% rDNA similarity with *Bdellovibrio*.**

The mol% G + C of the DNA is: 41–43.5.

Type species: **Bacteriovorax stolpii** (Seidler, Mandel and Baptist 1972) Baer, Ravel, Chun, Hill and Williams 2000, 223 (*Bdellovibrio stolpii* Seidler, Mandel and Baptist 1972, 216.)

Further descriptive information

To reflect the molecular genetic heterogeneity and biochemical and cultural diversity within the genus *Bdellovibrio*, a new genus, *Bacteriovorax*, was established and includes the organisms classified in the last edition of *Bergey's Manual of Systematic Bacteriology* (Burnham and Conti, 1984) as *Bdellovibrio stolpii* and *Bdellovibrio starrii*. Details of how the new genus came to be are discussed under Taxonomic Comments.

Like most *Bdellovibrio* strains, *Bacteriovorax* strains are capable of preying upon Gram-negative enteric bacteria and other bacteria with similar LPS structure. *Bacteriovorax stolpii* appears to be unaffected by changes in the LPS composition of bacteria but instead recognizes protein receptors in the outer membrane of the prey cell (Schelling and Conti, 1986). Gram-positive bacteria cannot serve as prey, presumably because of the lack of outer membrane receptors.

The physical and morphological features of *Bacteriovorax* have been confirmed to be as described for the *Bdellovibrio*. However, most of the physiological studies involving utilization of prey macromolecules, enzyme production at various stages of entry into prey cells, and development have been done on *Bdellovibrio bacteriovorus* 109 and other strains. It is presumed at the current time, but not yet confirmed experimentally, that *Bacteriovorax* species are similar or identical in these characteristics. However, further study on the new genus is warranted.

Genetics The genome sizes for the two species of *Bacteriovorax* has been reported to be in the range of 2.0–2.6 Mb (Torrella et al., 1978; Scognamiglio and Tudor, 1996; Baer, 1998), which is higher than that reported by Seidler et al. (1972).

Prey-independent mutants of *Bacteriovorax* have been isolated by the procedure described by Seidler and Starr (1969) and are available through the ATCC. These mutant strains were derived as described in the chapter on the genus *Bdellovibrio*.

Phages Several phage types among the predatory intraperiplasmic bacteria have been reported. Group V consists of *Bacteriovorax stolpii* and group VI, *Bacteriovorax starrii*. Groups V and VI are unrelated to *B. bacteriovorus* strains, which comprise groups I–IV. Further study involving additional phages may make phage typing a useful technique for distinguishing between *Bdellovibrio* and *Bacteriovorax* species.

Antigenic structure *Bacteriovorax stolpii* and *Bacteriovorax starrii* have been reported to be antigenically distinct from each other (Schoeffield, 1990). Both species were distinct from the *B. bacteriovorus* strains (Schelling et al., 1977).

Antibiotics The use of antibiotic sensitivity patterns has revealed some differences between the species of *Bacteriovorax* (Guether and Williams, 1993). Both species as well as the related organism *Bdellovibrio bacteriovorus* were susceptible by the disk diffusion method to ampicillin (20 μg and 2 μg), carbenicillin (100 μg), gentamicin (10 μg), kanamycin (30 μg), and penicillin (10 U, BBL) and were resistant to colistin (10 μg). Only *Bacteriovorax stolpii* was susceptible to metronidazole (80 μg), nalidixic acid (5 μg), and vancomycin (30 μg). *Bacteriovorax starrii* was resistant to nalidixic acid (5 μg) and vibriostatic agent 0/129.

Pathogenicity Other than the infection of susceptible bacteria, *Bacteriovorax* are not known to be pathogenic to other species including plants and animals. The *Bacteriovorax/Bdellovibrio* group of organisms has been recovered from the gut of humans and animals (Schwudke et al., 2001); whether these organisms

are transient or permanent members of the intestinal flora is not known.

Ecology The ecology of the predatory, intraperiplasmic bacteria *Bacteriovorax/Bdellovibrio* has revealed the ubiquitous distribution of the group. However, past studies typically have not distinguished between the two genera or species within them. Currently the distribution and potential role of these predators in nature is presumed to be similar to that reported for the *Bdellovibrio* as described in the previous chapter of this volume since many of the isolates may have been of the *Bacteriovorax* species.

Enrichment and Isolation Procedures

Conditions for the enrichment and isolation of *Bacteriovorax* are the same as described for the genus *Bdellovibrio.* The essential conditions consist of a heavy prey cell suspension (10^8–10^9 cells/ml) in a medium such as a buffered salts solution with few or no added nutrients. These conditions retard growth of many heterotrophic bacteria and typically enable the rapid proliferation of the *Bacteriovorax*. Attention should be given to the selection of the prey bacterium. Although the *Bacteriovorax* species were initially isolated on *P. aeruginosa* and are maintained on *E. coli* ML35, other species may be more efficient as prey, producing a greater yield of the predators and should be tested.

Maintenance Procedures

The procedures for maintaining *Bacteriovorax* in the laboratory are the same as those described in the chapter on *Bdellovibrio.*

Procedures for Testing Special Characters

Bacteriovorax species, like *Bdellovibrio* species, cannot be characterized by commonly used laboratory tests, because the organisms grow in dual culture and typically do not yield reactions in pure culture on artificial media. Tests that do not require growth of the organism may be useful, such as the API-Zym system (BioMereiux, France). These tests have revealed differential reactions between the *Bacteriovorax* and *Bdellovibrio* strains tested (Table BXII.δ.48). Prey-independent mutants—isolated from wild-type strains—have been useful in determining some biochemical reactions and other properties of the organisms. Based on limited data, it appears that the prey-independent mutants are identical in most properties to the wild type.

Differentiation of the genus *Bacteriovorax* from other genera

Bacteriovorax is most closely related to *Bdellovibrio*, the genus in which they were previously placed. Although the two groups of organisms share the same general distinct intraperiplasmic lifestyle, they may be differentiated by a number of properties, biochemical and molecular. Restriction analysis by pulsed field gel electrophoresis revealed differences in sensitivity to restriction enzymes and in restriction patterns. When treated with the enzymes *Asc*I, *Fse*I, *Sfi*I, and *Not*I only DNA of *Bdellovibrio bacteriovorus* strains was cut and produced banding patterns, whereas DNA of *Bacteriovorax* strains remained uncut. All the strains were cut with *Sma*I, *Sac*II, and *Xba*I. Other fingerprinting techniques such as AP-PCR and ribotyping yielded distinct separation of *Bacteriovorax* species from *Bdellovibrio bacteriovorus* strains. The halophilic strains previously considered to be a part of the *Bdellovibrio* genus clustered closer to *Bacteriovorax* species than to strains of *Bdellovibrio bacteriovorus. Bacteriovorax* is also differentiated from *Bdellovibrio* based on certain biochemical, physiological, genetic, and cultural properties presented in Table BXII.δ.49.

Key biochemical reactions of *Bacteriovorax* species on the API-Zym system is presented in Tables BXII.δ.48 and BXII.δ.49. This system allows differentiation between *Bacteriovorax stolpii* and *B. starrii* by their respective reactions to trypsin. The system is also useful for differentiating *Bacteriovorax* from *Bdellovibrio.* Fatty acid analysis has revealed that differentiation is possible among the *Bacteriovorax* species as well as between *Bacteriovorax* and *Bdellovibrio.* A few key biochemical reactions were also reported in the last edition of the *Manual.*

Taxonomic Comments

When initially described as predatory bacteria in 1962 (Stolp and Petzold, 1962) and later as intraperiplasmic invaders (Starr and Baigent, 1966), bdellovibrios were the first bacteria reported to exhibit such features. For a time thereafter, all predatory bacteria isolated with similar morphology and a biphasic life cycle consisting of a free motile phase and an intraperiplasmic growth and reproductive phase were assigned to the genus *Bdellovibrio*, with a single species, *B. bacteriovorus.* Initially all isolates were considered to be a taxonomically homogeneous group, although important differences in their tolerance to sodium chloride and mol% G + C had been reported. In 1972, a report of molecular heterogeneity (based on DNA–DNA hybridization values among different isolates) resulted in the division of the genus into three species, *Bdellovibrio bacteriovorus*, *Bdellovibrio stolpii*, and *Bdellovibrio starrii* (Seidler et al., 1972). This was reflected in the previous edition of *Bergey's Manual of Systematic Bacteriology* (Burnham and Conti, 1984).

Based on the recent analysis of complete 16S rDNA sequences from *Bdellovibrio bacteriovorus* 100^T, *B. stolpii* Uki2^T, and *B. starrii* A3.12^T, and DNA–DNA hybridization studies (Baer et al., 2000), a single genus is no longer appropriate for this collection of molecularly diverse microorganisms. The 16S rDNA sequence similarities between *B. bacteriovorus* 100^T and *B. stolpii* Uki2^T and *B. starrii* A3.12^T were 81.7% and 81.2%, respectively. These similarity values are comparable to or lower than those between *B. bacteriovorus* 100^T and other organisms that phylogenetically group in the same clade but are considered to be members of separate genera (Fig. BXII.δ.54). The similarity between the rDNA sequences from *Bdellovibrio stolpii* Uki2^T and *Bdellovibrio starrii* A3.12^T is significantly higher (90.0%).

Comparison of the 16S rDNA sequences of *B. bacteriovorus* 100^T, *B. starrii* A3.12^T, and *B. stolpii* Uki2^T (M34125) revealed substantial sequence differences between all three organisms. *B. bacteriovorus* 100^T had 224 and 230 bp different from *B. stolpii* Uki2^T and *B. starrii* A3.12^T, respectively. Only 127 bp differences were found when *B. stolpii* Uki2^T and *B. starrii* A3.12^T sequences were compared to each other.

The distant relationship between the three *Bdellovibrio* species is also apparent from the rooted evolutionary tree (Fig. BXII.δ.54) based on the Jukes-Cantor distance model and the neighbor-joining methods. *B. bacteriovorus* 100^T clustered more closely with members of the *Desulfomonile*, *Desulfuromonas*, *Myxococcus*, *Geobacter*, and *Desulfuromusa* genera. *B. stolpii* Uki2^T and *B. starrii* A3.12^T clustered together but outside of the *B. bacteriovorus* 100^T clade. The nucleotide sequence data were also confirmed with three other tree-making algorithms: maximum parsimony, maximum likelihood, and Fitch-Margoliash methods. It is clear from the 16S rDNA sequence data that *B. bacteriovorus*

[c]Results with *B. starrii* were inconclusive.

[d]As determined using the MIDI Sherlock Microbial Identification System, Newark, DE.

100^T belongs in a separate clade with only a distant relationship to *B. stolpii* and *B. starrii*.

Results from investigations into the degree of DNA–DNA hybridization between *Bdellovibrio* strains have been inconsistent. Baer et al. (2000) reported very low hybridization values between *B. stolpii* Uki2^T and *B. starrii* A3.12^T (<4%). A previous study (Seidler et al., 1972) reported a slightly higher degree of hybridization (16%) between these same strains. Hybridization values between Uki2^T and A3.A3.12^T and *Bdellovibrio bacteriovorus* were 1% or less, and the investigators of that study suggested that the low level of hybridization was sufficient to warrant the separation of the genus *Bdellovibrio* into three species, *B. bacteriovorus*, *Bacteriovorus stolpii*, and *Bacteriovorus starrii*. Low hybridization values were also observed between halophilic *Bdellovibrio* strains and their terrestrial counterparts (Baer, 1998).

This evidence, taken in conjunction with additional studies demonstrating the diversity among the organisms previously in the genus *Bdellovibrio*, has resulted in a taxonomic separation between *B. bacteriovorus* and the other two species, *B. stolpii* and *B. starrii*. *Bdellovibrio stolpii* Uki2^T and *Bdellovibrio starrii* A3.12^T have been reclassified into a new genus, *Bacteriovorax* gen. nov. as *Bacteriovorax stolpii* comb. nov. and *Bacteriovorax starrii* comb. nov. (Baer et al., 2000). *Bacteriovorax* also clusters within the *Deltaproteobacteria*. The two *Bacteriovorax* species, *B. starrii* and *B. stolpii*, are distinct from *Bdellovibrio bacteriovorus* based on 16S rDNA sequence comparison, pulsed field gel electrophoresis macrorestriction patterns, other genetic “fingerprint” techniques (arbitrarily primed PCR and ribotype patterns), fatty acid content (Guether et al., 1993), antibiotic sensitivity patterns, phage typing, antigenicity, and prey range (Althauser et al., 1972; Varon and Levisohn, 1972; Kramer and Westergaard, 1977; Nguyen et al., 1997; Schelling and Conti, 1983). Currently, the genus is composed of two species; however, molecular evidence reveals that the halophilic strains of the genus *Bdellovibrio* are more ge-

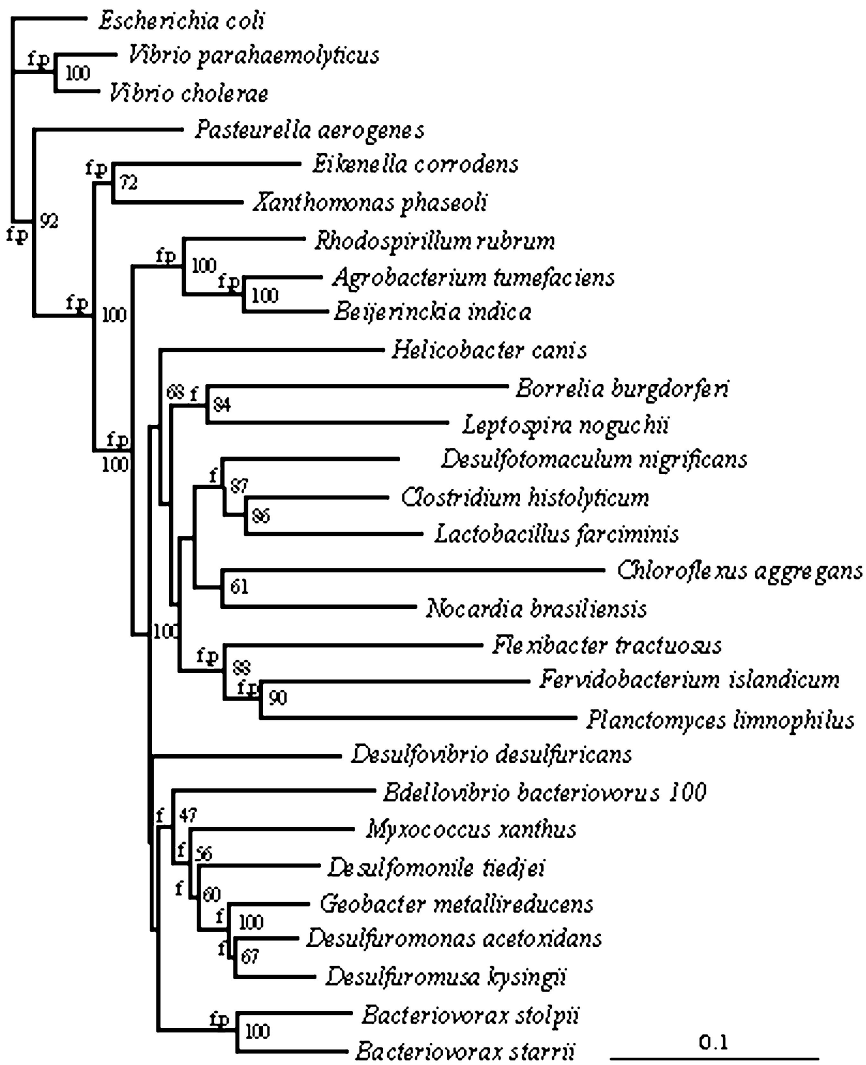

FIGURE BXII.δ.54. A neighbor-joining tree based on 16S rRNA sequences demonstrating the phylogenetic relationship between the *Bdellovibrio* and *Bacteriovorax* genera. *m*, *f*, and *p* indicate branches that were also found using the FastDNAml, Fitch-Margoliash, and maximum parsimony methods, respectively.

netically related to the genus *Bacteriovorax*. Fig. BXII.δ.53 in the section on the genus *Bdellovibrio* shows the phylogenetic relationships between different, unclassified, environmental isolates and known *Bdellovibrio* and *Bacteriovorax* sp. *B. bacteriovorus* strains 100, 109J, and E clustered together in one group. *Bacteriovorax stolpii* and *Bacteriovorax starrii* grouped into a separate clade, which included all the other environmental isolates. *B. stolpii* grouped most closely with the terrestrial environmental isolate Gunpowder, both of which formed a larger group with *B. starrii.* All marine isolates fell into three different groups within this same clade. The halophilic *Bdellovibrio* species were reclassified to the genus *Bacteriovorax* (see Baer et al., 2004 in Further Reading section below) after the cut-off date for inclusion in this edition of the *Manual.* It is expected, therefore, that the number of species and strains of the genus will increase, as more information on the diversity of new isolates from nature is uncovered.

The establishment of the genus *Bacteriovorax* represents an advancement in the taxonomy and classification of the bacterial intraperiplasmic predatory bacteria and recognizes significant differences within this group of organisms that share a similar lifestyle.

Baer, M.L., J. Ravel, S.A. Pineiro, D. Guether-Borg and H.N. Williams. 2004. Reclassification of salt-water *Bdellovibrio* spp. as *Bacteriovorax marinus* sp. nov. and *Bacteriovorax litoralis* sp. nov. Int. J. Syst. Evol. Microbiol. *54:*: 1011–1016.

List of species of the genus Bacteriovorax

1. **Bacteriovorax stolpii** (Seidler, Mandel and Baptist 1972) Baer, Ravel, Chun, Hill and Williams 2000, 223[VP] (*Bdellovibrio stolpii* Seidler, Mandel and Baptist 1972, 216.)

   stolp'i.i. M.L. gen. n. *stolpii* of Stolp, named after Heinz Stolp, discoverer of the bdellovibrios.

The characteristics are as described for the genus and as listed in Tables BXII.δ.48, BXII.δ.49, and BXII.δ.50.

The mol% G + C of the DNA is: 42 (Bd).

Type strain: Uki2, ATCC 27052, DSM 50722, ICPB 3291.

GenBank accession number (16S rRNA): M34125.

2. **Bacteriovorax starrii** (Seidler, Mandel and Baptist 1972) Baer, Ravel, Chun, Hill and Williams 2000, 223[VP] (*Bdellovibrio starrii* Seidler, Mandel and Baptist 1972, 216.)
starr' i.i. M.L. gen. n. *starrii* of Starr, named after M.P. Starr, an investigator of the bdellovibrios.

The characteristics are as described for the genus and as listed in Tables BXII.δ.48, BXII.δ.49, and BXII.δ.50.

The mol% G + C of the DNA is: 43.5 (Bd).

Type strain: A3.12, ATCC 15145.

GenBank accession number (16S rRNA): AF084852.

TABLE BXII.δ.50. Differential characteristics of the species of the genus *Bacteriovorax*[a]

Characteristic	*B. stolpii*	*B. starrii*
Facultatively predatory[b]	+	−
Sensitive to vibriostatic agent 0/129 150[c,d]	+	−
Mol% G + C of DNA	42	43.5
Growth at 35°C	+	−
Enzyme activities detected:[d]		
Trypsin	+	−
Protease production	High	Moderate
N-acetyl β-glucosaminidase	−	+
Catalase[e]	+	−
Nitrate reduced to nitrite	+	−

[a]Symbols: see standard definitions.

[b]Defined to mean that any individual comma-shaped cell may complete its life cycle either prey-dependently or prey-independently.

[c]O/129 = 24 diamino-6-7-disopropylpteridine phosphate. Test done on prey-independent mutants.

[d]Based on API Zym system using prey-independent mutants of *Bacteriovorax*.

[e]Cultures may be initially positive but become variable with subsequent transfer (Seidler and Starr, 1969).

Genus III. Micavibrio *Lambina, Afinogenova, Romai Penabad, Konovalova and Pushkareva 1989, 93[VP] (Effective publication: Lambina, Afinogenova, Romai Penabad, Konovalova and Pushkareva 1982, 105)*

MARCIE L. BAER AND HENRY N. WILLIAMS

Mi.ca.vib' ri.o. M.L. fem. n. *mica* a tiny thing; L. v. *vibrio* to move rapidly to and fro; M.L. masc. n. *vibrio* that which vibrates; M.L. masc. n. *Micavibrio* a tiny vibrio.

Curved rods 0.25–0.4 × 0.5–1.0 μm. Occur singly. **Motile by a single, sheathless, polar flagellum** approximately 13–15 nm in diameter. Gram negative. Electron microscopy demonstrates the cell wall infrastructure to be consistent with Gram-negative bacteria (Lambina et al., 1982). **Exoparasitic on other bacteria.** Attach themselves to their bacterial prey by the end opposite the flagellum and position themselves parallel to the longitudinal axis of the prey cell. **They remain along the outside of the prey cell** (unlike the genus *Bdellovibrio*, which penetrates its prey). **After attachment, the cells lose their motility, multiply by binary fission, and eventually cause lysis of their prey cell. The organisms have an obligate requirement for prey cells for multiplication** and lack the ability to propagate themselves on nutrient rich media. **Initial prey susceptibility appears to be specific for members of the genus *Pseudomonas* and *Xanthomonas***, with different *Micavibrio* species having different prey requirements. Resistant to vibriostatic agent 0/129.

Initially isolated from wastewater in Pushchino.

The mol% G + C of the DNA is: 57.

Type species: **Micavibrio admirandus** Lambina, Afinogenova, Romai Penabad, Konovalova and Pushkareva 1989, 93 (Effective publication: Lambina, Afinogenova, Romai Penabad, Konovalova and Pushkareva 1982, 106.)

TAXONOMIC COMMENTS

Although *Micavibrio* has some characteristics that resemble those of the genus *Bdellovibrio*, it has several distinctive differences from this genus that warrant a separate taxonomic classification. Morphologically, bdellovibrios and micavibrios are similar in size and shape, but *Micavibrio* cells have a single unsheathed polar flagellum (Lambina et al., 1982). The flagellum of the *Bdellovibrio* sp. has a definite sheath, as shown by electron microscopy studies. Both genera are parasitic in nature; however, members of *Micavibrio* are exoparasites, while bdellovibrios are endoparasites. Prey specificity of *Micavibrio* species also appears to be much more narrow than the range observed for *Bdellovibrio* sp.

Micavibrio species also demonstrate morphological similarities to the *Chlorella* parasite, *Vampirovibrio chlorellavorus* (previously described as *Bdellovibrio chlorellavorus*). Both are exoparasites and are characterized by a high specificity with respect to their individual prey. However, *Micavibrio* spp. demonstrate an ability to lyse procaryotic bacterial cells while the chlorellavorus bacterium exclusively parasitizes eucaryotic algae (Lambina et al., 1982).

List of species of the genus Micavibrio

1. **Micavibrio admirandus** Lambina, Afinogenova, Romai Penabad, Konovalova and Pushkareva 1989, 93[VP] (Effective publication: Lambina, Afinogenova, Romai Penabad, Konovalova and Pushkareva 1982, 106.)
ad.mir.an' dus. M.L. adj. *admirandus* admirable.

The general morphological characteristics and parasitic nature are as described for the genus. Upon initial isolation, *M. admirandus* is characterized by a narrow species specificity for *Stenotrophomonas maltophilia*. However, studies have shown that upon repeated transfer and storage under laboratory conditions, *M. admirandus* loses its narrow prey specificity and becomes a parasite with a broad range of lytic ability against Gram-negative bacteria (Afinogenova et al., 1986).

The mol% G + C of the DNA is: 57.1 (analytical centrifugation in a CsCl density gradient).

Type strain: ARL-14, VKM B-1619.

Other Organisms

1. *"Micavibrio aeruginosavorus"* Lambina, Afinogenova, Romai Penabad, Konovalova and Andreev 1983, 777.

ae.ru.gi.no.sa'vo.rus. M.L. adj. *aeruginosus* pertaining to the bacterium *Pseudomonas aeruginosa*; L. v. *voro* to devour; M.L. adj. *aeruginosavorus* devouring *P. aeruginosa*.

The general morphological characteristics and parasitic nature are as described for the genus *Micavibrio*. *"M. aeruginosavorus"* exhibits a narrow prey range and specifically requires *P. aeruginosa* for growth and multiplication (Lambina et al., 1983).

An electrophoretically homogeneous lytic proteinase of molecular weight 39,000 ± 1500 Da was isolated from the *M. admirandus* by means of ion-exchange chromatography and gel chromatography (Severin et al., 1987). The proteinase lyses autoclaved *E. coli* cells.

The mol% G + C of the DNA is: 53.8 (analytical centrifugation in a CsCl density gradient).

Deposited strain: ARL-13.

Genus IV. **Vampirovibrio** *Gromov and Mamkaeva 1980a, 676*[VP] *(Effective publication: Gromov and Mamkaeva 1980b, 165)*

MARCIE L. BAER AND HENRY N. WILLIAMS

Vam.pi.ro.vib'ri.o. Fr. n. *vampire* vampire; L. v. *vibrio* to move rapidly to and fro; M.L. masc. n. *vibrio* that which vibrates; M.L. masc. n. *Vampirovibrio* a vampire-like vibrio.

Cell shapes range from vibrios to wider curved rods to cocci and range from 0.3–0.6 µm wide. Cell size and shape vary with life cycle form. **Gram negative.** Cell wall ultrastructure is consistent with that of Gram-negative bacteria. Electron micrographs indicate the presence of extracellular appendages **including a single, unsheathed polar flagellum** and fibrils. **Require viable cells of the algal genus** *Chlorella* for growth and development; reproduction occurs via binary fission. **Extracellular parasites**; penetration of the prey cell has never been observed, although the *Chlorella* cells are killed and the cell contents are digested (Coder and Starr, 1978).

The mol% G + C of the DNA is: 50 (Coder and Starr, 1978).

Type species: **Vampirovibrio chlorellavorus** Gromov and Mamkaeva 1980a, 676 (Effective publication: Gromov and Mamkaeva 1980b, 165.)

FURTHER DESCRIPTIVE INFORMATION

The cell wall ultrastructure is consistent with that of Gram-negative bacteria. Prey susceptibility appears to be limited to alga cells of the genus *Chlorella*, as no degradation was observed when lysates of the "chlorellavorus bacterium" were tested with suspensions of a variety of Gram-negative bacteria, other eucaryotic algae, or the cyanobacterium *Anacystis* (Mamkaeva, 1966; Coder and Starr, 1978).

Coder and Goff (1986) examined 76 algal strains to see whether they could serve as prey for *Vampirovibrio*. The bacterium attacked all 31 strains of the species *Chlorella vulgaris*, *Chlorella sorokiniana*, and *Chlorella kessleri* but only two of 39 strains of nine other *Chlorella* species. Neither of two strains of another algal genus, *Prototheca*, was susceptible to attack. It was suggested that this narrow host specificity may be related to cell surface properties.

TAXONOMIC COMMENTS

Although *Vampirovibrio* has similar characteristics to the genus *Bdellovibrio* including morphology, predatory ability, and DNA base composition, there are important differences between the two genera. *Vampirovibrio* demonstrates an obligate requirement for viable algal cells in order to grow and reproduce, whereas bdellovibrios are much more flexible in their developmental cycle, utilizing active prey cells, growing axenically in liquid/solid media, or growing saprophytically on heat-killed cellular extracts. The prey for *Vampirovibrio* is eucaryotic, not procaryotic, and the prey range is limited to one algal type (*Chlorella*), whereas bdellovibrios demonstrate the ability to parasitize a wide range of susceptible prey bacteria. The shape of the *Vampirovibrio* flagellum resembles that of *Bdellovibrio*, but it lacks a flagellar sheath. Finally, *Vampirovibrio* lacks the typical dimorphic life cycle observed for *Bdellovibrio* sp., i.e., there is an absence of long, spirillar forms, and the organisms never penetrate the selected prey cells. This type of parasitism is unlike its *Bdellovibrio* counterpart, in which the bacteria penetrate and lodge within the periplasmic space of the prey cell. These reasons support the creation of a new genus containing the "chlorellavorus bacterium".

Vampirovibrio, in fact, may be taxonomically closer to members of the genus *Micavibrio* (Lambina et al., 1982). Micavibrios have a similar morphology—small curved rods with a single non-sheathed polar flagellum—and reproductive cycle—multiplication by binary fission that is dependent upon the presence of prey cells. More importantly, micovibrios have an exoparasitic lifestyle like that of vampirovibrios: they never penetrate their prey, yet eventually destroy the prey organism. The major differences between these two genera are that micavibrios have a procaryotic prey (*Stenotrophomonas maltophilia*) and the mol% G + C of the DNA is higher (57% vs. 50%).

List of species of the genus Vampirovibrio

1. **Vampirovibrio chlorellavorus** Gromov and Mamkaeva 1980a, 676[VP] (Effective publication: Gromov and Mamkaeva 1980b, 165.)

chlo.rel.la'vo.rus. M.L. fem. n. *Chlorella* a genus of algae; L. v. *voro* to devour; M.L. adj. *chlorellavorus Chlorella*-devouring.

The characteristics are as described for the genus.

The mol% G + C of the DNA is: 50 (method uncertain).

Type strain: ATCC 29753.

Order VIII. **Myxococcales** Tchan, Pochon and Prévot 1948, 398[AL]

Hans Reichenbach

My.xo.coc.ca'les. M.L. fem. pl. n. *Myxococcaceae* type family of order; *-ales* ending to denote an order; M.L. fem. pl. n. *Myxococcales* the *Myxococcaceae* order.

Rod-shaped, Gram-negative bacteria that move by gliding, produce fruiting bodies, and desiccation-resistant myxospores. Although these organisms are extremely fascinating because of their intricate life cycles, which are unique among procaryotes, they have been studied by relatively few scientists. In consequence, almost nothing is known about most species other than *Myxococcus xanthus* and *Stigmatella aurantiaca*. The considerable interest that the organisms have gained recently because of their rich secondary metabolism may change that situation. Since the last edition of the *Manual*, a number of comprehensive reviews have appeared that summarize much of our present knowledge of the organism. These reviews can be consulted for further details (Shimkets, 1990b; Reichenbach and Dworkin, 1992; Dworkin and Kaiser, 1993; Dworkin, 1996; Dawid, 2000).

Type genus: **Myxococcus** Thaxter 1892, 403.

Further descriptive information

Cytology of the vegetative cell It was observed long ago that there are two different basic and species-specific shapes of myxobacterial cells: long slender cells with tapering ends and cylindrical cells with rounded ends (Krzemieniewska and Krzemieniewski, 1928). This difference in cell shape was an essential argument, among others, for removing *"Chondromyces aurantiacus"* from the genus *Chondromyces* and returning it to its original genus, *Stigmatella* (McCurdy and Khouw, 1969; Reichenbach and Dworkin, 1969; McCurdy, 1971a). The real taxonomic significance of the two basic cell shapes, however, is that they distinguish two suborders, the *Cystobacterineae* and the *Sorangineae*, which thus can be recognized by microscopic examination. This subdivision of the myxobacteria into suborders is clearly supported by 16S rRNA sequence comparisons (Ludwig et al., 1983; Shimkets and Woese, 1992; Spröer et al., 1999). In fact, there is still another cell type that is characteristic of a third suborder, the *Nannocystineae*: short, often almost cube-shaped cylindrical cells with rounded or truncated ends. In each case, the distinguishing cell type occurs together with other exclusive features. Thus, for example, the colony morphologies also differ in characteristic ways, and colonies of members of the *Cystobacterineae* adsorb Congo red, while those of the *Sorangineae* and *Nannocystineae* do not (McCurdy, 1969b).

Additional variation within each of the three cell types helps distinguish certain taxonomic groups at the genus or family level. Thus, all species of the family *Myxococcaceae* have cells of moderate length (3–6 μm), which are cigar-shaped or slightly boat-shaped; *Cystobacter* species have long (8–15 μm) needle-shaped cells; *Stigmatella* cells are boat shaped and of moderate length, resembling the cells of *Myxococcus fulvus*, etc.

Besides normal cells, aberrant cells are occasionally observed, e.g., branched cells (Krzemieniewska and Krzemieniewski, 1928; Reichenbach, 1965c) or screw-shaped cells (Reichenbach, 1965c). The significance of the latter will become apparent when gliding motility is discussed.

Most myxobacteria have relatively large, slender cells measuring typically 0.6–1.2 × 3–15 μm depending both on the species and, to a certain degree, on the medium and the age of the culture. Some genera, however, have much smaller cells; for example, *Nannocystis exedens* cells are 1.4–1.5 × 1.75–3.5 μm, and some new myxobacteria have decidedly small, delicate cells, clearly a novel myxobacterial cell type.

Electron microscopic thin sections show a typical Gram-negative cell surface, with a thin peptidoglycan layer between outer and cytoplasmic membrane (Abadie, 1967, 1971; Voelz, 1967; Voelz and Reichenbach, 1969; MacRae and McCurdy, 1975; Lampky, 1976). The DNA region is clearly visible in electron micrographs. The early investigators were able to visualize several nucleoids within myxobacterial cells—variously called nucleus-like, nuclear, or chromatin bodies—under the light microscope after suitable staining. Growing vegetative cells may contain one, two, or four such bodies; myxospores apparently have only one (e.g., Thaxter, 1897; Vahle, 1910; Krzemieniewska and Krzemieniewski, 1928; Loebeck and Ordal, 1957; Reichenbach, 1965c).

Cell division is by septum formation (MacRae and McCurdy, 1975). Within the cells can be seen mesosomes (Voelz, 1965; Abadie, 1967, 1971; Lampky, 1976; Hirsch et al., 1978); polysomes, sometimes arranged in a helical pattern (Voelz 1966b; Abadie, 1971); polyphosphate bodies (Voelz, 1965; Voelz et al., 1966; Reichenbach et al., 1969; Abadie, 1971; Lampky, 1976); and various granules of reserve material, perhaps polysaccharide (Reichenbach et al., 1969; Schmidt-Lorenz and Kühlwein, 1969; Lampky, 1976) and certainly polyhydroxybutyric acid. In the myxospores, the polysaccharide granules may be surrounded by a dense monolayer of tiny electron dark particles (Voelz and Reichenbach, 1969; Galván et al., 1992). In addition, rather extended crystal-like structures may occur in the cytoplasm, which probably consist of protein (Voelz, 1968; Burchard et al., 1977a; Galván et al., 1992). Occasionally long filaments or tubules have been observed running lengthwise through the interior of the cell (Schmidt-Lorenz and Kühlwein, 1968; Abadie, 1971; MacRae and McCurdy, 1975; Burchard et al., 1977a; Galván et al., 1987). These tubules have been interpreted by some as the structural basis of gliding motility, but, in light of their rather irregular distribution, this hypothesis does not seem likely. There is, however, a regular structure just below the outer membrane that may be the still-unknown apparatus of gliding motility (Lünsdorf and Reichenbach, 1989; Freese et al., 1997). This structure will be discussed in more detail below.

The intracellular location of certain enzymes can be established by cytochemical methods. There is an ATPase in the cytoplasm and in the periplasmic space (Voelz, 1964; Abadie, 1971), acid phosphatase in the cytoplasm (Abadie, 1971), and alkaline phosphatase in the periplasm and, to a minor extent, in the cytoplasm (Voelz and Ortigoza, 1968; Abadie, 1971). In addition, the distribution of the stress protein SP21 was studied in indole-induced or heat-shocked cells of *Stigmatella aurantiaca* (Lünsdorf et al., 1995).

As shown by various electron microscopic techniques, the surface of myxobacterial cells is rather smooth. Sometimes small vesicles, or blebs, can be seen rising from the surface, perhaps connected with slime extrusion. There are also long filaments, probably composed of excreted slime or lipopolysaccharide (Abadie, 1967, 1971; McCurdy, 1969a; Schmidt-Lorenz and Kühlwein, 1969; MacRae and McCurdy, 1975, 1976; Lampky, 1976; MacRae et al., 1977; Galván et al., 1987, 1992). After fixation with glutaraldehyde, large polygonal holes have been observed in the

surface and interpreted as collapsed slime vacuoles (Schmidt-Lorenz and Kühlwein, 1969).

Various appendages are produced by myxobacteria. Slime threads may be seen under the light microscope after treatment with India ink (Fluegel, 1963). Three types of fibers have been discovered in images obtained in the electron microscope. Long, thin fimbriae with a diameter of 7–8.5 nm are found at the cell poles of 12 species of myxobacteria; the only exception was *Nannocystis*. They appear to arise from holes with a collar surrounded by 12 spikes and have hypothetically been connected with gliding motility, because they are absent from nonmotile mutants (MacRae and McCurdy, 1975, 1976; MacRae et al., 1977). Even thinner fibrils have been seen in *Myxococcus* that have to do with slime (MacRae and McCurdy, 1976). Thick, flaccid fibrils of 30–50 nm diameter arise all over the cell and appear to be responsible for cell cohesion and thus for S-, or social, gliding. These fibrils are absent from nonmotile mutants and from cells made noncohesive by treatment with Congo red (Arnold and Shimkets, 1988); the fibrils form an extracellular network, or matrix, that bears a specific antigen, FA-1 (Behmlander and Dworkin, 1991). Their formation seems to be stimulated by cell–cell contact. In liquid cultures, such fibrils are responsible for keeping the cells together in tight spherules and help to ensnare cyanobacteria for lysis (Burnham et al., 1981). For a review of fibrils on myxobacteria, see Dworkin (1999).

Chemical composition Some data on the chemical composition of various myxobacteria are available. The main fatty acids are C_{15} and C_{17} isobranched and monounsaturated C_{16} fatty acids. There appear to be differences between the suborders with respect to hydroxy fatty acids. Bacteria of the *Cystobacterineae* (*Myxococcus*, *Corallococcus*, *Archangium*, *Stigmatella*, *Cystobacter*) contain substantial amounts of 2-hydroxy fatty acids (mainly iso $C_{17:1\ iso\ 2OH}$) and smaller quantities of 3-hydroxy fatty acids. Bacteria of the other two suborders (*Sorangium*, *Nannocystis*) appear to be free of such hydroxy fatty acids. The main fatty acid of *Sorangium* was $C_{16:0}$. *Sorangium* species contain appreciable amounts of isobranched fatty acids (Schröder and Reichenbach, 1970; Ware and Dworkin, 1973; Rosenfelder et al., 1974; Fautz et al., 1979, 1981; Yamanaka et al., 1988). While 3-OH fatty acids are well-known constituents of lipopolysaccharide, 2-hydroxy fatty acids may come from phospholipids and sphingolipids. Ceramides and cerebrosides have indeed been demonstrated in *Cystobacter fuscus* (Eckau et al., 1984; Dill et al., 1985). The respiratory quinone is always menaquinone MK-8. In *Myxococcus fulvus*, it occurs in rather large quantity (9.1 µmoles/g membrane protein) (Kleinig, 1972; Yamanaka et al., 1987; M.D. Collins, personal communication). Various phospho- and glycolipids have been found in myxobacteria. The main phospholipid is phosphatidylethanolamine. In membrane fractions of *Myxococcus fulvus*, it comprises 72% of total phospholipid; the rest consists of phosphatidylglycerol, phosphatidylinositol, phosphatidic acid, and unknown components (Kleinig, 1972; Yamanaka et al., 1988). The fatty acid patterns of the individual phospholipids differ in their composition. Inner and outer membranes of *Myxococcus xanthus* can be separated (Orndorff and Dworkin, 1980). In both, phosphoethanolamine constitutes 60–80% of total phospholipid, but the outer membrane contains three times as much phospholipid as the inner membrane and consequently has a lower buoyant density (1.166 vs. 1.221 for the inner membrane). Both features are unusual for Gram-negative bacteria, and, together with branched fatty acids, may give the outer membrane a high flexibility required for gliding motility. Practically all phosphatidylserine and cardiolipine is found in the inner membrane. About 40 proteins have been separated from the total membrane fraction of *Myxococcus xanthus*; about 65% originated from the inner membrane. Succinate dehydrogenase and CN-sensitive NADH oxidase activities were found in the inner membrane, while four times as much NADH dehydrogenase activity was found in the outer membrane. A plasmalogen, i.e., a monoalkylether monoacylester, has been identified in *Myxococcus stipitatus* (Stein and Budzikiewicz, 1987). In *Stigmatella aurantiaca* phosphatidylinositol is a major component and comprises 18–25% of total phospholipid. It occurs exclusively as dialkylether (Caillon et al., 1983). In *Cystobacter fuscus* two isomers of a glycolipid were found: 1- or 2-acyl 3-glucosyl glycerol (Scherer et al., 1992). The carotenoid glycosides, which are the main pigments of myxobacteria, are also glycolipids. They are mostly glucosides of the myxobacton and myxobactin type, which in addition bear an ester-bound fatty acid residue on the glucose, in contrast to the overall fatty acid pattern of mostly $C_{14:0}$, $C_{16:0}$, and $C_{18:0}$ (Kleinig et al., 1970; Reichenbach and Kleinig, 1971; Kleinig and Reichenbach, 1973). A nonesterified carotenoid rhamnoside was found in *Sorangium* (Kleinig et al., 1971).

Myxobacterial chromophores are always acyclic or monocyclic C_{40} carotenoids (Reichenbach and Kleinig, 1972). In *Myxococcus fulvus* carotenoids constitute 0.03% of the dry weight of acetone-extracted cells grown in the light, and 0.003% of cells grown in the dark (Reichenbach and Kleinig, 1971). The carotenoids are exclusively located in the membrane fraction, where they constitute up to 0.14% of the dry weight (Kleinig, 1972). They act as photoprotective agents. Some myxobacterial strains produce a deep violet pigment, e.g., *Cystobacter violaceus* (formerly *"Archangium violaceum"*), which probably consists of melanin-like compounds (Reichenbach, 1965c). A red pigment of *Cystobacter violaceus* is probably a dopachrome (Mayer, 1967). Liquid cultures of *Stigmatella aurantiaca* in peptone liquid media become pitch black within 1 to 2 h after reaching stationary phase, presumably because melanin-like pigments are produced by phenol oxidases set free from lysing cells (Reichenbach and Dworkin, 1969). Many myxobacteria produce brown, water-soluble, diffusing, melanin-like pigments on plates of peptone media. Several myxococci, especially *Myxococcus virescens*, excrete a greenish-yellow diffusing pigment that appears to be myxochromid (Trowitzsch-Kienast et al., 1993). Plate cultures of *Myxococcus stipitatus* show a bright yellow fluorescence under the UV lamp at 366 nm (Lampky and Brockman, 1977) that is caused by phenalamides or stipiamides (Kim et al., 1991; Trowitzsch-Kienast et al., 1992). This author has never observed fluorescence at that wavelength with any other myxobacterium (hundreds of strains tested).

Several but not all myxobacteria synthesize squalene (0.1–0.3% of dry cell mass) and, very unusually among procaryotes, true steroids. *Nannocystis* strains contain 1.5–2.2% (by dry weight) cholestenols and cholestadienols; *Polyangium* strains, 0.3% lanosterol; and *Cystobacter* strains, lanosterol-like compounds. Squalene is produced by *Corallococcus*, but neither squalene nor steroids are found in *Myxococcus*, *Chondromyces*, and *Sorangium*. In contrast to secondary metabolites, steroids are present in all strains of the species. Hopanoids have never been detected (Kohl et al., 1983; Zeggel, 1993).

Typical lipopolysaccharide (3–4% of cell dry weight) with lipid A, core region, and O-antigen side chains is found in the following myxobacteria: *Myxococcus fulvus*, *Myxococcus virescens*, *Myxococcus xanthus*, *Corallococcus exiguus*, *Cystobacter fuscus*, *Cystobacter ferrugineus*, *Cystobacter violaceus*, *Sorangium cellulosum* (Kleinig, 1972; Sutherland and Smith, 1973; Rosenfelder et al., 1974; Suth-

erland and Thomson, 1975; Sutherland, 1979b; Orndorff and Dworkin, 1980; Fink and Zissler, 1989). Lipid A contains glucosamine and 3-hydroxy fatty acids; the core region contains 2-keto-3-deoxyoctonate but no heptose. The main sugars are mannose, D-galactose, D-glucose, rhamnose, and galactosamine. Smaller amounts of ribose, D-xylose, and arabinose are found along with the unusual but characteristic sugar 3-O-methyl-D-xylose (Weckesser et al., 1971).

The peptidoglycan of *Myxococcus xanthus* (0.6% of cell dry weight) contains *N*-acetylglucosamine, *N*-acetylmuramic acid, glutamic acid, diaminopimelic acid, and alanine. It is unusual in that it does not form a continuous layer but is organized in patches interrupted by trypsin-sensitive areas (White et al., 1968). This arrangement may make the wall more flexible, which could be essential for gliding motility. In *Myxococcus fulvus* undecaprenol required for peptidoglycan synthesis is present in substantial amounts (Beyer and Kleinig, 1985).

In general, and in spite of being referred to as slime bacteria, myxobacteria do not excrete large quantities of slime. In liquid cultures in sugar-containing media, some myxobacteria produce a slightly viscous solution. The slime is difficult to analyze because it is normally contaminated by products of cell lysis and may consist of several macromolecules that are difficult to separate. All investigators agree, however, that it is composed of polysaccharide. The slime of *Cystobacter violaceus* can be removed from culture plates as a tough layer (Reichenbach, 1965c). If it is boiled for some time in a dilute NaOH solution, some material is removed, but the sheet from the older parts of the swarm colony remains. Under the electron microscope, this material shows a fibrillar structure, and it exhibits birefringence in polarized light. The material remains intact in 17.5% NaOH solution, but it is quickly hydrolyzed in concentrated HCl or 17% H_2SO_4. In addition, it dissolves in Schweizer's reagent (ammoniacal copper oxide used for dissolving cellulose), from which solution it precipitates in the form of loose flakes upon the addition of acid. The main components in the hydrolysate are glucose and an unidentified disaccharide, exactly as in hydrolysates of cotton wool. The slime hydrolysates contain two more components, one of which may be a uronic acid. Thus, the slime of this organism appears to be a cellulose-like polysaccharide. The extracellular slime of liquid cultures of *Myxococcus virescens* variants that grow in either a dispersed or a nondispersed manner can be precipitated with ethanol (Stahl, 1973). The yields are 120–260 mg lyophilized material per liter of medium. The composition of the slime differs between the dispersed and the nondispersed variants. While the crude precipitate mainly contains proteinaceous material, including 25% of the proteolytic activity of the culture, the purified high molecular weight slime is a polysaccharide of 20 million Da. The compositions of the exopolysaccharides of vegetative cultures, myxospores, and fruiting bodies of *Myxococcus* (Sutherland and Thomson, 1975) and of *Cystobacter*, *Archangium*, *Stigmatella*, and *Sorangium* species (Sutherland, 1979b) have been analyzed. *Cystobacter* and *Archangium* expolysaccharides contain glucose, rhamnose, and mannose as the main components (20–50% of the total); *Stigmatella aurantiaca*, glucose and galactose; and *Sorangium*, galactose and mannose but no rhamnose. *Myxococcus* exopolyaccharide contains mainly glucose, galactose, and mannose. The yields are 5–30% of the dry weight of the cell mass.

A lectin (MBHA) with hemagglutinin activity is found in *Myxococcus xanthus*. It is a protein located in the periplasmic space and on the cell surface in appreciable quantity; it increases 4-fold during development (Cumsky and Zusman, 1981a, b; Nelson et al., 1981).

A peculiar DNA–RNA hybrid, msDNA, was discovered first in *Myxococcus xanthus* and later in almost all other myxobacteria investigated (*Corallococcus coralloides*, *Cystobacter violaceus*, *Stigmatella aurantiaca*, *Nannocystis exedens*); the exceptions were *Cystobacter fuscus* and *Cystobacter ferrugineus* (Dhundale et al., 1985, 1987). The hybrid consists of a single-stranded DNA linked at its 5′ end by a 2′,5′-phosphodiester bond to a specific rG residue in a single-stranded RNA. The free end of the DNA hybridizes with the 3′ end of the RNA. In *Myxococcus xanthus* 500–700 copies of msDNA are found per chromosome. A second, smaller such hybrid also exists in this organism (Dhundale et al., 1988). The length of both nucleic acids varies somewhat with individual strains between 65 and 163 bases for the DNA and 49–77 bases for the RNA. The DNA is part of the chromosomal DNA. The gene is transcribed into an RNA approximately 375 bases long, from which msDNA is synthesized by a reverse transcriptase (Hsu et al., 1989; Inouye et al., 1989, 1990; Lampson et al., 1991). The msDNA gene can be inactivated by mutation without any adverse effect on growth and development of *Myxococcus xanthus* (Dhundale et al., 1988). Of course, there may be an adverse effect under natural conditions. (For a review of retroelements, see Lampson, 1993).

Motility Myxobacteria move by gliding, or creeping, along interfaces, e.g., along the surface of the culture vessel, the surface of agar plates, even the surface of liquids. They also are able to penetrate the substrate and move within it, e.g., agar plates at normal gel strength. Cells suspended in liquid are nonmotile, but when they attach themselves by one pole to the substrate they perform a gyrating movement (shown in films about myxobacteria: Reichenbach et al., 1965c, b). Gliding motility is also observed in many other, unrelated bacteria, e.g., the *Cytophaga–Flavobacterium* group, *Lysobacter*, *Herpetosiphon*, and many cyanobacteria, but its mechanism is not yet understood. There are many hypotheses about it. As there is an excellent review on gliding in myxobacteria (Spormann, 1999), this topic is not discussed here. Recently a complex apparatus has been discovered just below the outer membrane of *Myxococcus fulvus* and *Myxococcus xanthus* (Lünsdorf and Reichenbach, 1989; Freese et al., 1997). It consists of strands of tiny rings connected by two longitudinal elements and arranged in a densely packed helical belt running from pole to pole. The system occurs in two conformational states: either the rings stand on edge, or they are tilted, in which case the whole structure shrinks by 40% in width. Unfortunately, the apparatus is difficult to demonstrate *in situ* within the cell, but a helical structural element is clearly present in myxobacteria as well as in other gliding bacteria, because, first, as already mentioned, degenerating cells may develop a helical shape, and second, upon shock freezing a helical structure can be seen running from pole to pole (Lünsdorf and Schairer, 2001). Perhaps the conformational change starts at one cell pole and moves along the belt, thereby creating a contraction wave that propels the cell. The flexibility of the cell wall mentioned above would certainly be helpful. Some mechanism at the cell poles must be responsible for starting the movement and determining its direction. The gliding speed of myxobacteria is usually too slow to be readily seen under the microscope, but under optimal conditions it may reach 13–15 μm/min. Gliding cells always deposit a slime trail (Reichenbach et al., 1965a, b, c; Abadie, 1968), which may have a guiding effect on following cells (Reichenbach, 1965a, b). The role of the slime is probably simply to keep the cells on the surface, as has been shown for *Flexibacter*

(Humphrey et al., 1979). The movements may be directed by tactic behavior. Phototaxis has been demonstrated in myxobacteria, the mechanism of which is somewhat difficult to comprehend (Aschner and Chorin-Kirsch, 1970). Chemotaxis is clearly at work when sporangioles of *Chondromyces apiculatus* germinate, and the released small swarm colonies move like pseudoplasmodia and are attracted by each other (Reichenbach, 1965c). *Myxococcus xanthus* cells show directed movements toward latex or glass beads (Dworkin, 1983), but do not respond to chemical gradients (Dworkin and Eide, 1983). The movement toward the beads could in fact be due to elasticotaxis, the movement along stress lines in the agar (Stanier, 1942). If chemical gradients are steep enough, *Myxococcus xanthus* exhibits both positive (e.g., toward nutrient-rich areas) and negative chemotaxis (e.g., away from nutrient-poor regions or away from repellents like DMSO or short chain alcohols) (Shi et al., 1993). This response is under the control of *frz* genes, which are homologues of chemotaxis genes of *Escherichia* and *Salmonella*. The response is correlated with methylation (positive) or demethylation (negative response) of the FrzCD protein. Chemotaxis plays an essential role in fruiting, as can be shown with *frz* mutants. The compounds responsible for myxobacterial autochemotaxis are not known, but in *Stigmatella aurantiaca*, stigmolone, a pheromone of unknown function, is produced during fruiting body formation and has been characterized (Morikawa et al., 1998; Plaga et al., 1998).

Genetic studies have identified a large number of genes involved in gliding and reversal of movement (*frz* genes). There are two movement systems, A- (for adventurous) and S- (for social) gliding; the former controls movement of single cells, and the latter controls movement of groups of cells (Hodgkin and Kaiser, 1979). Pili (Kaiser, 1979) and surface agglutinins (Shimkets, 1986) appear to be required for S-gliding. The situation is rather complex and is not discussed here, as several reviews are available (e.g., Shimkets, 1990b; McBride et al., 1993).

Swarm colonies Because of gliding motility, the colonies of myxobacteria are film-like, spreading swarms. Swarms may cover an 8.5-cm plate within a week, which translates into a spreading speed of approximately 4 μm/min. The spreading is linear, indicating that expansion is essentially due to movement (Reichenbach, 1965c; Grimm and Kühlwein, 1973a). Growth and movement can be artificially separated by blocking the former with 200 μg/ml nalidixic acid (Shi et al., 1993). Swarming and gliding motility both depend on the composition of the medium. Rich media, especially media having high peptone concentrations, prevent spreading—if they allow growth at all—in which case round, compact, convex, slimy colonies are produced resembling those of nonmotile bacteria. A narrow fringe of swarming cells may still be present. The distribution of cells within the swarm is rarely uniform, and the swarms usually are structured by a more or less prominent pattern of veins. In addition, a concentration of cells along the edge in the form of a ridge or a band may develop. Flares emerge from the edge and sometimes become very long and filament-like. This behavior is typical of gliding bacteria in general.

Swarm morphology can be characteristic for certain taxonomic groups. Thus, swarms of the *Myxococcaceae*, including *Pyxicoccus*, usually are soft and slimy with flat knobs and snaking, undulating veins, or without any structure. Those of the *Cystobacteraceae* always have well-developed, often branching, radial veins, usually in a very tough slime sheet. Swarms of *Polyangium* and *Chondromyces* normally produce shallow depressions in the agar surface, tend to deeply penetrate the plate, and often etch the surface of the plate in radial or irregular patterns. Often there is a dense, orange band of cells along the edge. Swarms of the genus *Sorangium* often develop prominent branched veins and may penetrate the culture plate. *Nannocystis* swarms corrode the agar plate and, on certain media, transform it into a spongy mass.

Swarm morphology may change dramatically when strains are transferred from plate to plate for some time or when variant strains adapted to dispersed growth in liquid medium are plated (Reichenbach, 1965c; Reichenbach and Dworkin, 1969; Grimm and Kühlwein, 1973a): The speed of spreading may be reduced substantially, the colonies may become soft and slimy, and structural features may be lost, so that the colony is no longer typical for the species. The cause of this phenomenon is not fully understood. In *Cystobacter violaceus*, for example, swarming "S" cells produce normal swarms, excrete less slime, and are up to four times more sensitive to NaCl than "K" cells that grow as compact colonies, are clearly impaired in motility, and grow more easily in suspension in liquid media. K and S cells convert into each other (Grimm and Kühlwein, 1973b, c). *Byssophaga cruenta*, which grows as pseudoplasmodia-like cell associations, forms homogeneous swarms after some months of transfers from plate to plate.

Because they are so thin, swarms usually are colorless in spite of striking pigmentation of the accumulated cell mass. Swarms of *Myxococcus virescens* and *Myxococcus xanthus* often become greenish yellow to orange; whereas those of *Myxococcus fulvus*, *Myxococcus stipitatus*, *Cystobacter*, and *Stigmatella* species may develop a deep brown color, particularly on peptone media. Swarms of *Cystobacter violaceus* and of some *Sorangium* strains are intensely violet. Light may stimulate carotenoid production, so that cultures kept in the light may become pink or red. Color variation has been observed in *Myxococcus xanthus* strain FB2 (Burchard et al., 1977b). When the strain is plated, tan and yellow colonies arise. While most yellow colonies yield only yellow colonies on repeated plating, tan colonies always produce both tan and yellow colonies. The conversion can be stimulated by UV irradiation, nalidixic acid, or cultivation at 36.5°C. The phase variation of pigmentation is paralleled by a variation in swarm morphology. Yellow colonies are rough and swarming; tan ones are mucoid with smooth edges. A genetic study showed that there is a specific promoter for yellow pigmentation, which apparently is controlled by a transcriptional regulator that in turn is regulated by a switch, the biochemistry of which is not known. A block in the switch leads to stable tan mutants with an extremely low conversion rate to yellow (Laue and Gill, 1994).

A peculiar feature of myxobacterial swarms is the occasional appearance of oscillating waves (Reichenbach, 1965b): Tiny, concentric ridges are arranged in a densely packed regular pattern, usually in the periphery of the swarm. In most myxobacteria, the waves occur in extended fields resembling ripples at the seashore. *Stigmatella* strains tend to produce isolated trains of waves, which is very typical for those organisms. When time-lapse movies of myxobacteria are made, the waves are seen to oscillate synchronously, and the whole pattern seems to vibrate. The vibration even may speed up and down, so that a second rhythm overlays the primary oscillation of the waves (Reichenbach et al., 1965b, c). The movements of the waves can be seen under the microscope by a patient observer. At high magnification, it becomes apparent that the waves consist of rows of cells arranged strictly parallel and in a radial direction. The movement of individual cells cannot be followed, because the cells are so densely packed. However, it appears that they really oscillate back and forth. This interpretation is suggested by a branching of the ridges at in-

tervals and by the fact that the speed of the waves is faster than the spreading of the swarm. Neither the mechanism nor the biological importance of the phenomenon is understood. It may be an artifact in the unnatural environment of cultures. Perhaps pili play a role in this phenomenon. There is no experimental proof that the phenomenon is connected with fruiting body formation; indeed fruiting often takes place in total absence of oscillating waves. In *Myxococcus xanthus*, oscillating waves can be induced by peptidoglycan and certain components of it (Shimkets and Kaiser, 1982), but this is not a general rule. Lack of a reliable induction system and of optical resolution of the movements of individual cells still impedes the investigation of the phenomenon. Mathematical models have been developed to describe the behavior of moving myxobacterial cells in the swarm, e.g., during aggregation or rippling (e.g., Pfistner, 1990; Stevens, 1990; Deutsch, 1999). Of course, such analyses can only be schematic and cannot explain the biochemical mechanisms behind the phenomena.

When freshly isolated myxobacteria are inoculated into a liquid medium and the cultures shaken, the bacteria usually grow first along the glass wall of the flask and then as nodules and flakes in the medium. Until the 1960s, it was generally believed that myxobacteria cannot be made to grow dispersed in liquid medium. This belief was disproved first for a strain of *Myxococcus xanthus* (Mason and Powelson, 1958a). Later it was found that many strains of other myxobacteria of the suborder *Cystobacterineae* can also grow dispersed in liquid medium when several transfers are made from liquid medium to liquid medium, although occasionally a strain may refuse to do so even after many transfers. Strains that grow dispersed in liquid medium continue to do so after being frozen at −80°C and thawed. Suitable media are based on tryptic digests of casein, such as Difco Casitone. This transformation is more difficult to achieve in strains of the other two suborders. Several *Sorangium* strains have been made to grow dispersed in liquid medium, however, only after months of serial transfers (Irschik et al., 1987; Gerth et al., 1994). Fully dispersedly growing cultures of strains of *Chondromyces*, *Polyangium*, and *Nannocystis* have never been obtained to the author's knowledge. Various strategies have been proposed to prevent clumping and to stimulate dispersed growth, e.g., adding 0.04% agar to the medium (Schürmann, 1967), but no one trick leads to success in all cases. Homogenizing the inoculum mechanically only leads to more and smaller flakes and nodules. Grimm and Kühlwein (1973b) observed that variants of *Cystobacter violaceus* that produce more slime grow more readily in suspension, but those cultures were not agitated. It is not understood which factors determine clumping. A good guess is that the composition of the slime plays a role; the composition of the slime indeed differs between strains that grow dispersed in liquid medium and those that do not (Stahl, 1973). In addition, the presence of agglutinins on the cell surface (Arnold and Shimkets, 1988) may be crucial.

Plating for single-cell colonies as required for cloning and mutant selection depends, of course, on the availability of homogeneous cell suspensions. It is also a problem to get individual cells to grow into colonies (e.g., Grimm, 1967). Media that allow excellent growth when inoculated with copious amounts of cells often do not give high yields of single cell colonies, if the organisms grow at all. An efficient plating medium has to be developed for every strain by optimizing media components and their concentrations. The problem has been solved in many cases and a 100% plating efficiency obtained, although usually after months of experimentation, because colonies can be seen only after 8–14 days. Sometimes it helps to add spent medium from old liquid cultures to the plating medium (Jaoua et al., 1992). The reasons for this failure of single cells to grow are not understood; perhaps some quorum-sensing mechanism is involved.

Nutritional requirements There are two nutritional types among myxobacteria. Whereas most species are proteolytic/bacteriolytic, the genera *Sorangium* and *Byssophaga* are cellulose decomposers. Both types can be cultivated on agar—and often also in liquid medium—containing autoclaved baker's yeast (e.g., VY/2-agar). The proteolytic species grow well on media containing a suitable peptone, e.g., tryptic digests of casein. Concentrations should not be too high, normally 0.3% to 1%. The inhibitory effect of higher concentrations is probably caused by an excess of phosphate, to which myxobacteria are rather sensitive. In addition, production of ammonia may become a limiting factor, especially with the genera *Myxococcus*, *Corallococcus*, and *Nannocystis* that do not utilize glucose or other mono- and disaccharides (Watson and Dworkin, 1968; Reichenbach, 1970). The situation with the latter genera may be more complex. *Myxococcus* and *Corallococcus* species always break down autoclaved yeast cells, and *Nannocystis* does the same with agar. It seems unlikely that the organisms do not make use of the degradation products. It has indeed been shown that a strain of *Corallococcus coralloides* decomposes starch into trisaccharides, and that the latter can be taken up and utilized, while mono- and disaccharides remain in the medium (Irschik and Reichenbach, 1985). A *Myxococcus fulvus* strain has been found to excrete a laminarinase that cleaves β-1,3-glycosidic bonds; this enzyme also produces trisaccharides (Borchers, 1982). However, the direct utilization of glucose and other sugars has been demonstrated for many other proteolytic myxobacteria, so that the addition of, for example, glucose or starch to the medium has a growth-stimulating effect. Yet those organisms usually do not grow faster with a carbohydrate in the medium, but only for a longer time and to a higher cell density. It appears that they utilize the sugars more as a source of building blocks than for energy. The cellulose degraders grow on very simple media, e.g., with nitrate (which they prefer to ammonium ion) as the nitrogen source and glucose as the carbon source. Many strains actually require a carbohydrate in the medium and do not grow on a pure peptone medium. In addition, those organisms grow better if an organic nitrogen source is available. Development of a defined amino acid medium for proteolytic myxobacteria is a tedious and time-consuming procedure, because not only the amino acid composition but also the concentrations of the individual amino acids must be carefully adjusted. Essential amino acids usually include the branched and the aromatic amino acids, glycine, and methionine. Defined media have been published for *Myxococcus xanthus* (Dworkin, 1962; Witkin and Rosenberg, 1970; Bretscher and Kaiser, 1978), *Cystobacter violaceus* (Mayer, 1967), *Cystobacter fuscus*, and *Cystobacter ferrugineus* (Reichenbach and Dworkin, 1992). In the latter case, the organisms become dependent on biotin and/or thiamine when the number of amino acids is reduced to three or four, or when amino acids are replaced by their respective keto acids. Every strain requires its own defined medium. Occasionally a myxobacterial strain depends on vitamin B_{12}. Many myxobacteria can be cultivated on technical substrates, such as soy meal or flour, skim milk, single-cell protein, or corn steep powder, a characteristic that may be useful for mass fermentations (Gerth et al., 1984). The mineral requirements are the usual ones (e.g., Coucke and Voets, 1967). Relatively high concentrations of Mg^{2+}

(0.15% $MgSO_4 \cdot 7H_2O$) are often beneficial; some strains require Ca^{2+}. Sensitivity of many myxobacteria to high phosphate concentrations above 0.5 mM has already been mentioned. This concentration is reached in a 0.2% Casitone solution, so that usually no phosphate need be added to media with a peptone or a technical substrate. The phosphate problem may be mitigated by adding polyphosphate rather than salts of phosphoric acid. Many details on media recipes can be found in Reichenbach and Dworkin (1992).

Physiology The biochemistry and physiology of myxobacteria cannot be discussed here in detail; the review articles mentioned above provide that information. Myxobacteria are strictly aerobic organisms. Their temperature range for optimal growth is normally between 26° and 34°C, but some strains grow up to 40°C, and most probably also grow at much lower temperatures (e.g., Janssen et al., 1977). This author observed one strain of *Myxococcus fulvus* with a temperature optimum around 30°C still slowly growing at 6°C in the refrigerator. Psychrophilic myxobacteria were isolated from Antarctica that did not grow at 18°C (Dawid et al., 1988). The pH range for growth is usually 6.8–7.8. Cellulose degraders may grow at pH 5.8–6.4. There is rarely growth beyond pH 8.0. However, alkalophilic myxobacteria that grow at pH 9.5, but not at 7.2, have been found in an alkaline lake in East Africa (Dawid, 2000). Acidophilic myxobacteria have not been found so far. Salt tolerance of myxobacteria is usually low. The number of myxobacteria from terrestrial samples decreases dramatically when 0.8% NaCl is added to isolation media; usually only *Myxococcus virescens* (Rückert, 1978) and sometimes *Nannocystis* strains are obtained. At 1% NaCl, only a rare *Myxococcus virescens* strain may show up. While most myxobacteria grow well on yeast agar (VY/2) with 0.3% NaCl, only a few grow at 2% NaCl; these are mainly *Myxococcus* strains. Some *Myxococcus virescens* strains prefer a low salt concentration, while others grow well at 2% (Iizuka et al., 1998). Truly halotolerant and halophilic myxobacteria growing best at NaCl concentrations between 2% and 3% and not at all below 1% have been obtained from marine samples off Japan (Iizuka et al., 1998). In addition, 16S rRNA sequences typical of myxobacteria were discovered in samples from a deep-sea vent near Hawaii (Moyer et al., 1995). These two examples are both from the Pacific; efforts of several investigators to isolate marine myxobacteria from samples from the Atlantic were not successful. Myxospores seem to survive in a marine environment for some time, so that nonhalotolerant strains can be isolated from marine sediments (Rückert, 1984).

Myxobacteria efficiently decompose a number of biomacromolecules (Dworkin, 1966). All species degrade casein (e.g., in skim milk), gelatin, other proteins, starch, and dextrin, and all, with the exception of *Sorangium*, degrade RNA and DNA (e.g., Jahn, 1924; McCurdy, 1969b). Several myxobacteria hydrolyze chitin (always reprecipitated material and not natural chitin); this trait is typical of certain taxa and thus is of taxonomic relevance. Thus, all *Stigmatella* and several *Cystobacter* species, *Myxococcus stipitatus*, *Kofleria flava*, *Jahnia thaxteri*, and most *Sorangium* strains produce a complete clearing in a chitin layer. Most or all species appear to degrade xylan. Degradation of crystalline cellulose is probably restricted to the genera *Sorangium* and *Byssophaga*, and seems always to be found with the ability to utilize inorganic nitrogen compounds. In the older literature, cellulose decomposition is occasionally mentioned for *Myxococcus*, *Stigmatella* (*Podangium*), and *Angiococcus* species (Mishustin, 1938; Pronina, 1962). However, this author has not encountered cellulose-degrading *Myxococcus*, *Stigmatella*, or *Angiococcus* strains in 30 years of isolating cellulolytic myxobacteria and is inclined to believe that those "cellulose degraders" were myxobacterial contaminants of other cellulolytic bacteria. In fact, one always finds many noncellulolytic myxobacteria in enrichment cultures for cellulose-degrading organisms. Many myxobacteria decompose the β-glucans of yeast cell walls, and at least some excrete a laminarinase (Borchers, 1982). Agar degradation is rare among myxobacteria. Some *Sorangium* strains soften or even liquefy agar, and all *Nannocystis* strains digest holes and channels in an agar layer without liquefying it (Reichenbach, 1970). It is an open question whether *Nannocystis* can utilize agar as a substrate because in liquid media there seems to be no growth stimulation by agar. Perhaps the enzymes are directed against some other polysaccharide, e.g., some microbial products in the soil, where agar is absent.

The degrading enzymes are only partly known. They are mostly diffusing exoenzymes that thus can act far away from the swarm. The cellulases may be an exception, for it seems that cellulose fibers are only attacked when cells are in direct contact with them. While proteolytic activity has often been reported, relatively few studies deal with the enzymes responsible for this activity. *Myxococcus virescens* produces at least three extracellular proteases: a serine protease that has a molecular weight of about 26 kDa and shows activity on casein, hemoglobin, and, under alkaline conditions, on elastin. It cleaves preferentially near nonpolar amino acids (Gnosspelius, 1978). Three serine proteases are found in the culture supernatant of *Myxococcus xanthus*. Different strains show different protease patterns (Coletta and Miller, 1986). In addition, a 39 kDa extracellular metalloprotease with elastase activity can be isolated from *Myxococcus xanthus* (Dumont et al., 1994). A study of intracellular proteases in *Myxococcus xanthus* revealed mainly metalloproteases and traces of a serine protease. The intracellular enzymes of the strain are different from the extracellular ones (Orlowski and White, 1974). Initiation of the excretion of proteases when cells are growing on a protein substrate like casein requires a certain cell density (Rosenberg et al., 1977). An exocellulase with a pH optimum around 5.6 is released from *"Sorangium compositum"* by heating the culture at 100°C. This cellulase produces cellobiose, which is then cleaved into glucose by a heat-labile cellobiase. The cellulase also attacks carboxymethylcellulose with production of reducing sugars (Coucke and Voets, 1968). Addition of starch to the medium induces synthesis and excretion of amylase by *Corallococcus coralloides* (Farez-Vidal et al., 1990). A laminarinase (molecular weight 12 kDa, pH optimum 5.0–5.5) and an enzyme releasing trisaccharides from starch have already been mentioned. Nothing is known about myxobacterial xylanases and agarases. Restriction endonucleases have been demonstrated in various *Myxococcus* species, in *Cystobacter velatus*, and in *Archangium* (Morris and Parish, 1976; Mayer and Reichenbach, 1978). These enzymes are apparently located in the periplasm. They can have different specificities even if they come from the same species. Not all myxobacteria seem to contain endonucleases. Non-specific DNases (and RNases) have been observed in many myxobacteria (McCurdy, 1969b; Mayer and Reichenbach, 1978). A single cell-bound DNase can be isolated from several myxobacteria; it has an apparent molecular weight of about 200 kDa (Muñoz et al., 1989). A more careful study of a *Corallococcus coralloides* strain revealed three cellular DNases (Martinez-Cañamero et al., 1991). The purified enzymes have different temperature optima (between 25° and 37°C), require Mn^{2+} and Mg^{2+} for good activity, and have molecular weights of 39, 44, and 49 kDa. While DNases seem to be cell-bound in liquid cultures, they are excreted and

diffuse through the agar in plate cultures. Several other degradative enzymes have been reported from myxobacteria. A coagulase (myxocoagulase) has been isolated in pure form from a strain of *Myxococcus fulvus* (Bojary and Dhala, 1989). It has a molecular weight of 57 kDa, is highly active on rabbit plasma, and is clearly different immunologically from *Staphylococcus aureus* coagulase. Esculin-cleaving glucosidases appear to be present in most myxobacteria, although not in *Myxococcus* (McCurdy, 1969b).

The potential of myxobacteria to lyse bacteria and yeasts was observed early, and the older literature is full of such reports (e.g., Beebe, 1941c; Singh, 1947; Nolte, 1957; Margalith, 1962; Bender, 1963; Raverdy, 1973; Yamanaka et al., 1993). The cocktail of hydrolases mentioned above, perhaps with the addition of antibiotics, is used for this activity. Among the bacteriolytic enzymes those that attack peptidoglycan play a special role. Six enzymes have been characterized in the culture supernatant of *Myxococcus xanthus* that have amidase, glucosaminidase, and peptidase activity and thus would be able to cleave the polysaccharide backbone as well as the cross-links (Sudo and Dworkin, 1972). An extracellular cell-wall-degrading enzyme has been isolated from *Cystobacter violaceus* in addition to three proteases (Hüttermann, 1969). Several *Myxococcus xanthus* and *Myxococcus fulvus* strains have been shown to control populations of the cyanobacterium, *"Phormidium luridus"*, with predator-prey cycles of 9 days under experimental conditions. As few as 50 *Myxococcus* cells per 100 ml containing 10^7 cells of the prey were sufficient to start a lytic cycle (Burnham et al., 1984). The myxobacteria produced an enzyme resembling lysozyme (Daft et al., 1985). However, it appears that myxobacteria cannot control natural blooms of cyanobacteria, probably because of an insufficient supply of inorganic nutrients (Fraleigh and Burnham, 1988). It has been observed that myxobacteria digest holes in the cell wall of two fungi, *Cochleobolus* and *Rhizoctonia* (Homma, 1984), and of the green alga, *Cladophora* (Geitler, 1925), respectively. The myxobacteria enter the cells and produce fruiting bodies inside.

Most myxobacteria of the suborder *Cystobacterineae*, but not those of the other two suborders, autolyze soon after reaching the growth maximum, so that there is hardly a stationary phase. Five different autocides have been isolated from *Myxococcus xanthus*. AM I is a mixture of fatty acids (Varon et al., 1986); AM V consists of phosphoethanolamine containing unsaturated fatty acids (Gelvan et al., 1987). In the latter case, it appears that the cell population releases the fatty acids through the action of a phospholipase. In AM I unsaturated fatty acids are the most efficient autocides. While AM I and AM V act specifically on *Myxococcus* species, the other autocides act on a variety of myxobacteria. Mutants that are resistant to autocides can no longer produce fruiting bodies. In fact, during fruiting body formation in *Myxococcus xanthus* autolysis of part of the cell population takes place before sporulation begins (Wireman and Dworkin, 1977). During sporulation, cells reorganize the cell wall and become particularly prone to autolysis (Kottel and White, 1974). A unique feature of certain *Myxococcus xanthus* strains is their high sensitivity to monovalent cations; Na^+ (0.03 M) or NH_4^+ (0.03 M) induce rapid lysis at 45°C. Bulges arise at the sides or ends at the cell, gradually blow up, and transform the cell into an empty sphere (Mason and Powelson, 1958b). This course of cell degeneration is also seen in other species of the suborder *Cystobacterineae*.

The primary metabolism of myxobacteria resembles that of other aerobic Gram-negative bacteria. The catalase reaction is always positive. Oxidase is variable and often delayed or negative; oxidase production also depends on culture age and growth medium. The respiratory chain of myxobacteria appears to be the usual one. Cytochromes of the *a*, *b*, and *c* type, but not of the *o* type have been demonstrated in membrane preparations of *Myxococcus xanthus*, *Myxococcus fulvus*, *Sorangium cellulosum*, and *Stigmatella* (Dworkin and Niederpruem, 1964; McCurdy and Khouw, 1969; Kleinig, 1972; Sarao et al., 1985). NADH:cytochrome *c* reductase, cytochrome *c* oxidase, NADH oxidase and reductase activity, and flavoprotein are present. Cytochrome *c* reductase activity is 10 times higher in *Myxococcus xanthus* myxospores than in vegetative cells. The respiratory quinones are menaquinones, almost exclusively MK-8. A 27-kDa apoprotein of a FMN enzyme has been identified as the product of gene *fprA*, formerly *spoC* (Shimkets, 1990a). Acid and alkaline phosphatases have already been mentioned. Their activity in *Myxococcus xanthus* increases during sporulation (González et al., 1991). The enzymes are also present in *Corallococcus coralloides* (González et al., 1987; 1989). Two extracellular and two intracellular activities are produced constitutively. Carbohydrate metabolism has been studied in several myxobacteria. In *Myxococcus xanthus* a deficient Emden–Meyerhof pathway is present that lacks hexokinase and pyruvate kinase; this fact explains why the organism does not utilize glucose (Watson and Dworkin, 1968). The pathway may mainly be used for gluconeogenesis. A complete tricarboxylic acid cycle is present and is probably supplied with acetate from amino acids via pyruvate. The initial enzymes of the pentose phosphate pathway and of polysaccharide synthesis are also present. There is a glyoxylate shunt (Orlowski et al., 1972). During sporulation the key enzyme, isocitrate lyase, is downregulated. However, this pattern of sugar metabolism is not typical for myxobacteria in general. *Stigmatella aurantiaca* utilizes glucose with acid production (Reichenbach and Dworkin, 1969; Gerth and Reichenbach, 1978) as do *Cystobacter* strains (Reichenbach and Dworkin, 1992); *Sorangium cellulosum* (formerly *Polyangium cellulosum*) even grows on glucose and nitrate. Hexokinase is present in *Stigmatella erecta* (or *"Stigmatella brunnea"*), but, while growth is stimulated by sugars and starch, these substrates are not utilized (McCurdy and Khouw, 1969). *Corallococcus coralloides* contains both polyphosphate and ATP glucokinases with molecular weights of 61 kDa and 47 kDa, respectively (González et al., 1990). As mentioned before, *Corallococcus coralloides* does not utilize glucose or maltose, but degrades starch into trisaccharides, which it can take up and metabolize. This strain, too, has a hexokinase and other enzymes of glucose catabolism but seems to use glucose mainly to produce ribose and deoxyribose via the pentose phosphate pathway . The fact that starch does not speed up but only prolongs growth supports this interpretation (Irschik and Reichenbach, 1985). The enzymatic complement differs somewhat between individual *Sorangium cellulosum* strains, a situation that leads to different, strain-specific nutrient requirements. One strain carries out glycolysis, with a normal hexokinase, the TCA cycle (including the glyoxylate shunt), and the pentose phosphate pathway (Sarao et al., 1985). Strain So ce12 has the same pathways except for the glyoxylate shunt (Hofmann, 1989). Glucose is introduced into metabolism by glycolysis and the pentose phosphate pathway in a ratio of 95% to 5%. This strain can produce acetyl-CoA either from PEP with a pyruvate dehydrogenase or from external acetate with an acetyl-CoA synthetase; it can produce oxaloacetate from PEP with a PEP carboxylase. It is not capable of gluconeogenesis, or only carries out this process at a very low level, a fact that explains its dependence on a hexose, pentose, starch, or cellulose as a carbon source; glycerol or intermediates of the TCA cycle would not suffice. While enzyme activities in So ce12

are highest in early log phase, lactate dehydrogenase, glucose-6-phosphate dehydrogenase, and α-ketoglutarate dehydrogenase have their maxima in stationary phase. Growth of *Byssophaga cruenta*, the other myxobacterial cellulose degrader, is repressed by glucose at concentrations of more than 0.1%.

For most myxobacteria the only acceptable nitrogen sources are amino acids, which also supply carbon and energy. This fact clearly reflects their lifestyle as micropredators (Singh, 1947). The cellulose degraders, which grow on nitrate or ammonium, are an exception. They too can utilize amino acids, but usually cannot grow on them alone. Myxobacteria prefer peptones and proteins to free amino acids, which are acceptable only if their concentrations are carefully balanced in a narrow range. The enzymes involved in amino acid metabolism are as would be expected. A number of these enzymes have been characterized, e.g., aspartokinase in *Myxococcus xanthus* is regulated by feedback inhibition and feedback stimulation (Filer et al., 1973). Details may be found in the reviews mentioned above. A DOPA decarboxylase of unknown function was recently discovered in *Sorangium cellulosum* by gene sequence analysis (Müller et al., 2000); this enzyme was previously unknown in bacteria. Total dependence on amino acids, as is seen in *Myxococcus* species, has the consequence that substantial amounts of ammonia are produced during growth, which can become a serious problem in large-scale fermentations because ammonium ions have strong regulatory effects. Intracellular ammonia pools can be quite high: e.g., 80–140 mM in a *Myxococcus virescens* strain (Gerth and Reichenbach, 1986).

Other enzymatic activities of myxobacteria that have been studied include a DNA-dependent RNA polymerase, which in *Myxococcus xanthus* (Rudd and Zusman, 1982) and *Stigmatella aurantiaca* (Heidelbach et al., 1992) has the typical eubacterial α,β,β′ core enzyme (molecular weights 38, 140, and 145 kDa for *Myxococcus xanthus*; 40, 146, and 146 kDa for *Stigmatella aurantiaca*). The holoenzyme of *Myxococcus xanthus* may combine with two σ-factors (around 86 kDa); that of *Stigmatella aurantiaca* has one major σ-factor of 195 kDa. The major vegetative σ-factor of *Myxococcus xanthus*, σ-80, has high homology to σ-70 of *E. coli* and σ-43 of *Bacillus subtilis* (Inouye, 1990). Patterns of posttranslational phosphorylation and methylation of proteins and of DNA methylation change both with the growth stage and during conversion into myxospores (Komano et al., 1982; Yee and Inouye, 1982). Several kinds of kinases are also known from myxobacteria. For example, a serine/threonine protein kinase, the first example of this type of kinase in a procaryote, has been found in *Myxococcus xanthus* (Muñoz-Dorado et al., 1991). The enzyme is autophosphorylated and changes during development. A histidine protein kinase seems to be inserted in the membrane of *Myxococcus xanthus* and probably transduces starvation and cell density signals required for induction of development (Yang and Kaplan, 1997). A nucleoside diphosphate kinase from *Myxococcus xanthus* has been studied with its nucleotide in place by high-resolution X-ray crystallography (Williams et al., 1993), the first time that such an enzyme could be analyzed in this way.

Isoprenoids appear to be produced by the mevalonate pathway (Horbach et al., 1993). C_{15} to C_{60} polyprenols can be synthesized *in vitro* using cell free extracts of *Myxococcus fulvus* (Beyer and Kleinig, 1985). Polyketide synthases and peptide synthetases play an essential role in secondary metabolism; often both are combined in one enzyme complex (e.g., Paitan et al., 1999; Silakowski et al., 2001). Regulatory cyclic nucleotides are also known from myxobacteria. Adenylate and guanylate cyclases (Devi and McCurdy, 1984b), cyclic GMP- and cyclic AMP-binding proteins (Devi and McCurdy, 1984a), and both cyclic AMP and cyclic GMP (Campos and Zusman, 1975; Passador and McCurdy, 1985) are found in *Myxococcus xanthus*. Concentrations of these components change during myxospore and fruiting body formation. A GTP-binding membrane G-protein—unusual for a procaryotic organism—exists in *Stigmatella aurantiaca* and may be involved in signal transduction (Dérijard et al., 1989). *Corallococcus coralloides* produces ppGpp beginning in stationary phase, but the observed kinetics do not support a role in a stringent response (Fernandez-Vivas et al., 1983). *Myxococcus xanthus* has an S-adenosylmethionine synthetase, which is gradually inhibited after glycerol induction of sporulation, so that the S-adenosylmethionine pool is reduced from 0.5 μmol/g dry weight—several times higher than the methionine pool—to 0.28 μmol/g (Jones and Wells, 1980). Myxobacterial ribosomes have the expected 30S/50S subunits, but conditions for their dissociation are not the same as in *E. coli* (Foster and Parish, 1973). Initiation factor IF2 of *Stigmatella aurantiaca* shows considerable homology to other bacterial IF2s, especially in the GTP-binding region, but is longer than the *E. coli* IF2 by 160 amino acids at the N-terminal end. The extension is rich in Ala, Pro, Glu, and Val residues and contains nine repetitive sequences. The function of the extension is unknown (Bremaud et al., 1997).

Relatively little is known about transport mechanisms in myxobacteria. In *Sorangium cellulosum* strain So ce12, glucose and fructose appear to be transported by a common uptake system that has a higher affinity for glucose and does not involve phosphorylation (Hofmann, 1989). Myxobacteria have been investigated as potential nonpathogenic expression hosts. Acid phosphatase and β-lactamase, which are typically located in the periplasm in Gram negative bacteria, have been cloned in *Myxococcus xanthus*. The enzymes are produced and excreted into the medium by *Myxococcus xanthus* (Breton and Guespin-Michel, 1987). Excretion is strictly regulated. This regulation can be ablated by Tn5 insertion mutagenesis. Mutants exhibit increased excretion (Nicaud et al., 1984). While native proteins are excreted directly into the medium, the foreign proteins appear to be actively transported first into the periplasmic space, from which they diffuse into the environment; the latter is the rate-limiting step (Letouvet-Pawlak et al., 1993). Iron transport may be mediated by iron chelators. Myxochelins were discovered in *Angiococcus disciformis*, *Myxococcus fulvus*, and *Stigmatella aurantiaca* (Kunze et al., 1989) and nannochelins in *Nannocystis exedens* (Kunze et al., 1992). The chelators are produced at high levels only when the iron concentration in the medium is low (10^{-7} M). The genes responsible for the biosynthesis of myxochelins in *Stigmatella aurantiaca* have been characterized (Silakowski et al., 2000b). Unexpectedly, a nonribosomal peptide synthetase appears to be involved.

Myxobacteria have an elaborate secondary metabolism. To date, 90 different basic structures and 350 structural variants of secondary metabolites have been characterized. Most are new compounds. Many are electron transport inhibitors (e.g., myxothiazol, stigmatellin). Epothilone efficiently stabilizes microtubuli, like paclitaxel (Taxol®). The ability to produce a certain compound is usually a strain and not a species characteristic. Many of these compounds are found in different species, genera, and even families, but rarely in different suborders. The genetic basis of myxobacterial secondary metabolism has been intensively studied (e.g., Silakowski et al., 2000a; Gaitatzis et al., 2001). Details may be found in the following reviews: Dworkin and Kaiser (1993); Reichenbach and Höfle (1993), Höfle and Reichenbach (1995), and Reichenbach and Höfle (1999).

Many myxobacterial cultures have an earthy odor that is due to geosmin, among other compounds Trowitzsch et al., 1981). *Chondromyces crocatus* produces a very characteristic odor that is unique among myxobacteria and that reminds one faintly of pyridine; it is produced by a mixture of pyrazine derivatives (Fuhlendorf and Schulz, personal communication).

It may be mentioned in passing that myxobacteria possess several features that are more characteristic of eucaryotes than of procaryotes, e.g., sterol, ceramide and cerebroside synthesis, a Ser/Thr protein kinase, DOPA decarboxylase, a G-protein, and calmodulin-like S-protein. This finding suggests that analysis of base sequences of the myxobacterial genome may contribute to a better understanding of sequences in genes of higher animals.

Antibiotic resistance varies with different myxobacteria (McCurdy, 1969b), but as a rule resistance varies among the strains of a species and not among species. *Sorangium cellulosum* is an exception. Almost all strains grow on yeast agar (VY/2-) containing 1000 μg/ml kanamycin sulfate; this characteristic can be used for isolation. Usually kanamycin resistance is found together with resistance to neomycin and gentamicin, but streptomycin resistance is rarely tolerated (50 μg/ml each). In contrast, the cellulose degrader *Byssophaga cruenta* does not grow in the presence of concentrations of kanamycin above 20 μg/ml. Not one of 81 tested *Myxococcus* strains belonging to all known species grows on yeast agar containing 250 μg/ml kanamycin sulfate, but about 50% of 95 tested *Corallococcus* strains do so. The opposite behavior was seen with streptomycin sulfate (50 μg/ml): 297 out of 306 *Corallococcus* strains do not grow, while 119 of 201 *Myxococcus* strains do. There is no antibiotic for which an occasional resistant isolate cannot be found. Practically all myxobacteria are resistant to β-lactam antibiotics, although not always to every one of the tested compounds (ampicillin, carbenicillin, cephalotin, cephalosporin C, 50 μg/ml each, all the following inhibitors are also at 50 μg/ml). An intracellular β-lactamase is found in *Myxococcus xanthus* DZ1 (Breton and Guespin-Michel, 1987). Many strains are insensitive to ribostamycin, kasugamycin, phosphomycin, polymyxin, cycloserine, and bacitracin, while resistance to paromomycin, spectinomycin, tobramycin, dibecacin, erythromycin, oxytetracycline, chloramphenicol, and rifampin is rare or exceptional. Kanamycin (and gentamicin) resistance of *Sorangium cellulosum* is apparently a property of ribosomal proteins, as the compounds are taken up and are not modified chemically, and the relevant portion of the 16S rRNA sequence is identical in *Myxococcus xanthus* and *E. coli*. Curiously, *in vitro* translation with *Sorangium cellulosum* ribosomes is only marginally inhibited by high concentrations of kanamycin, perhaps because it is inefficient. However, radioactive gentamicin clearly binds less strongly to *Sorangium* ribosomes than to those of *E. coli* (Pöhl, 1996). Myxobacteria are much more sensitive to actinomycin D (Dworkin, 1969) and acriflavin (Grimm, 1980) than ordinary Gram-negative bacteria. This sensitivity may mean that their outer membrane is more permeable to these compounds.

Intercellular communication Myxobacteria are decidedly social organisms. The reason may be found in their nutritional specialization. Because they depend on the degradation of various biomacromolecules, they must first produce exoenzymes, which diffuse into the environment and act on their substrates; the lysis products then diffuse in all directions. Consequently, only a small portion of the invested energy, if any, is returned to an individual cell. However, if a population is at work, the cells profit mutually from individual exertions, and the energy loss is minimized. As already mentioned, cell-to-cell communication occurs beginning at the swarm stage, and the mechanisms of communication are both mechanical and chemical in nature. Initially defined by genetic analyses, several signaling systems have been identified with various biochemical events; e.g., A-factor is a mixture of 8 amino acids, and C-factor is a 20-kDa surface-bound protein. Excellent reviews are available on this topic (Shimkets, 1990b; Kaiser and Kroos, 1993; Sager and Kaiser, 1994; Dworkin, 1996; Kaiser, 1998, 2000; Plaga and Schairer, 1999).

Morphogenesis Myxobacteria are the most sophisticated procaryotes with regard to morphogenesis. Under starvation conditions, hundreds of thousands to millions of cells aggregate, and if conditions are right, differentiate into fruiting bodies (cooperative morphogenesis). These fruiting bodies may be very simple structures, like the soft, slimy knobs produced by *Myxococcus* species. But many species surround the cell mass with a tough wall—often after a subdivision of the original mass into portions of approximately equal size—thus creating sporangioles, either singly or in clusters. The sporangiole wall is very thin, about 30 nm in *Chondromyces crocatus* (Abadie, 1971) and 200–300 nm in *Cystobacter* (Vahle, 1910; Jahn, 1924). It dissolves in potassium hypochlorite solution (eau de Javelle-Vahle, 1910) and is intensely colored by pigments that are not identical with those of the cells and that cannot be extracted by any of the normal solvents (Vahle, 1910). The chemical composition and the origin of the sporangiole wall are not known. It has been suggested that it is excreted by the cells lying at the surface (Jahn, 1924). Alternatively, it may be formed by fusion of the cells forming the top layer. In *Melittangium boletus* the cells in the developing sporangiole are arranged in a regular pattern in rows of parallel rods perpendicular to the surface. Thus, in this case, it seems that the wall would be excreted from one cell pole only (Jahn, 1924). How the subdivision of the sporangioles is determined within the undifferentiated cell mass is one of the many unsolved questions in myxobacterial morphogenesis. During germination the sporangiole wall is ruptured mechanically, and an empty husk remains after the cells leave.

The most elaborate fruiting bodies have white slime stalks, which are branched in *Chondromyces crocatus* and consist of fine tubules in *Stigmatella aurantiaca* and *Chondromyces* (McCurdy, 1969a; Voelz and Reichenbach, 1969; Abadie, 1971). The stalk bears at the end either a soft, slimy, globose head (*Myxococcus stipitatus*) or one or several sporangioles. Stalked fruiting bodies were apparently selected for independently in the suborders *Cystobacterineae* (*Myxococcus*, *Melittangium*, *Stigmatella*) and *Sorangineae* (*Chondromyces*). The stalks arise in a different way in the two suborders, however. In the *Cystobacterineae*, the piled-up and rotating cell mass differentiates morphologically into stalk and head, and the cells later simply leave the stalk region; in *Chondromyces* the stalk is excreted by the spherical cell mass, which sits initially on the substrate, is lifted upward as a whole by the developing stalk, and only differentiates into sporangioles at the end of the process (Thaxter, 1892; Jahn, 1924). The intricate designs of fruiting bodies made 19th century investigators believe that they were dealing with fungi.

The size of myxobacterial fruiting bodies varies between 10 and 1000 μm or more depending on the species, and many can be seen with the naked eye, especially since they are normally produced in large numbers and often are brightly colored in hues of yellow, orange, red, brown, or black. The distribution of fruiting bodies over the swarm is usually random, but sometimes fruiting bodies arise in concentric rings, along radial veins, or

in various patterns controlled by elasticotaxis (Stanier, 1942). Fruiting proceeds in the swarm from center to periphery. The shape, structure, and color of fruiting bodies is species specific. In fact, myxobacterial species are mainly defined by their fruiting bodies, but similar shapes are developed by completely unrelated species, e.g., *Stigmatella* and *Chondromyces*, or *Cystobacter*, *Polyangium*, *Jahnia*, and *Sorangium*. In addition, shape and color of fruiting bodies may vary substantially within the species. During cultivation, fruiting bodies often degenerate quickly into shapes and structures that are no longer typical and resemble *Archangium* fruiting bodies, i.e., masses of myxospores and slime of ill-defined shape and size. This problem particularly affects *Cystobacter*, *Stigmatella*, and *Melittangium* species.

The fruiting bodies of myxobacteria may be interpreted as resting colonies. The function of fruiting bodies is probably to guarantee that a new life cycle is started with a population rather than a single cell, for the reasons discussed above in the section on intercellular communication. Fruiting bodies may also facilitate distribution into another habitat. Thus, some species produce fruiting bodies only in the light, a behavior that ensures that they arise on the surface of the substrate. This phenomenon has been demonstrated for *Chondromyces apiculatus* (Reichenbach et al., 1974) and *Stigmatella aurantiaca* (Qualls et al., 1978). No rearrangement of the genome appears to be connected with fruiting. The induction of fruiting body formation is a complex process and clearly more complicated than a mere response to starvation. Fruiting of *Myxococcus xanthus* (and other myxobacteria) takes place above and below dialysis membranes or cellophane sheets at exactly the same spot, suggesting a fruiting signal (McVittie and Zahler, 1962; Reichenbach., 1966). Fruiting bodies may arise in the middle of an active population of cells that do not participate in fruiting, which seems to indicate that the cells must be competent before they enter the fruiting process (Reichenbach et al., 1965b, c).

Within the maturing fruiting body, a cellular morphogenesis takes place: the production of myxospores. In the suborder *Cystobacterineae*, this process always involves a rather dramatic shortening and fattening of the vegetative rods into spheres or at least into short, fat rods. The myxospores surround themselves with a capsule that may be rather thin and recognizable only under the electron microscope. In addition, they become optically refractile. In the suborders *Sorangineae* and *Nannocystineae* the shape change is less extensive. The vegetative cells may become somewhat shorter and slightly constricted in the middle. Often they also become optically refractile and may (e.g., in *Chondromyces crocatus*; Abadie, 1971) or may not develop a thin capsule. The fine structure of myxospores, formerly also called microcysts, has been studied in six organisms: *Myxococcus xanthus* (Voelz and Dworkin, 1962; Voelz, 1966a; Bacon and Eiserling, 1967; Kottel et al., 1975), *Stigmatella aurantiaca* (Reichenbach et al., 1969; Voelz and Reichenbach, 1969), *Stigmatella erecta* (Galván et al., 1987), *Archangium gephyra* (Galván et al., 1992), *Sorangium cellulosum* (Lampky, 1976), and *Chondromyces crocatus* (McCurdy, 1969a; Abadie, 1971). *Myxococcus xanthus* has a very thick, layered capsule, which can be seen under the light microscope, especially after contrast staining with India ink. The capsule appears to be reduced in thickness during germination and is left behind as an empty shell by the emerging vegetative cell. The cell wall is retained intact during sporulation. An interesting but open question is what happens to the gliding apparatus during shape change. Polyphosphate and polysaccharide granules can be seen in the cytoplasm. Artificially induced myxospores fold their outer membranes into vesicular and tubular structures. About 75% of the capsule is a polysaccharide that consists entirely of galactosamine and glucose. In *Stigmatella aurantiaca* fruiting body myxospores, the outer membrane becomes ruffled or folded; in artificially induced myxospores, these folds form densely packed membrane bodies between the cytoplasmic membrane and the capsule. It is assumed that the outer membrane cannot be melted in during cell conversion and therefore is conserved in this way. As artificially induced cells change their shape much faster than cells in developing fruiting bodies, the phenomenon is more pronounced in the former. Polyphosphate and polysaccharide granules can be seen in both types of myxospores; the surface of the latter is densely covered by small, dark, ribosome-like particles. Essentially the same type of myxospore is found in fruiting bodies of *Stigmatella erecta* and *Archangium gephyra*. The latter may contain large, fusiform bodies with a crystalline internal structure; these bodies are probably composed of protein crystals. Fruiting body myxospores of *Sorangium cellulosum* seem to be devoid of a capsule. They are full of large, electron translucent granules, probably composed of polysaccharide. Polysaccharide is also found near the poles of vegetative cells. In fact, phase bright pole regions are observed under the phase contrast microscope in older vegetative cells. Mesosome-like membrane stacks are seen deep in the interior of the myxospores. Fruiting body myxospores of *Chondromyces crocatus* are found with and without a capsule. In addition, mesosomes are present in *Chondromyces crocatus*. Furthermore, polysaccharide granules, slime vesicles, a ruffled outer membrane, and areas of vesicular or tubular outer membrane structures occur. The arrangement of myxospores within the sporangioles is normally random, but in *Melittangium boletus*, myxospores are oriented strictly perpendicularly to the outer wall (Jahn, 1924). In *Cystobacter fuscus* sporangioles, a pattern of surface-parallel myxospores can be seen impressed on the inner face of the wall (Jahn, 1924). In culture, myxospores are often also produced outside of fruiting bodies. A well-defined experimental system for the study of morphogenesis in myxobacteria became available with the discovery that the addition of glycerol to suspension cultures of *Myxococcus xanthus* induces the vegetative cells to convert synchronously into myxospores within 90 minutes (Dworkin and Gibson, 1964). This discovery made the organisms attractive as research subjects and led to a host of studies on the events during induction and conversion. However, no coherent picture of the involved biochemistry and genetics has been obtained thus far. Details can be found in the reviews mentioned in the beginning of this article and at the end of this section.

Many other myxobacteria can also be induced to sporulate by adding chemicals to suspension cultures. *Stigmatella aurantiaca* can be induced to sporulate by 40 different chemicals acting on at least three different receptors, as suggested by studies of reciprocal induction-resistant mutants (Gerth et al., 1993; Gerth and Reichenbach, 1994). Induction in *Stigmatella aurantiaca* is also triggered by high temperatures just below the temperature maximum, and induction by heat and by chemicals that complement each other. These observations could mean that stress receptors and heat shock proteins play a role in myxospore induction and possibly within fruiting bodies (Heidelbach et al., 1993). Myxospores are clearly designed for survival in unfavorable environmental conditions. Myxospores of *Myxococcus xanthus* are much more resistant to elevated temperatures (60°C), ultraviolet light, and sonic vibration than vegetative cells (Sudo and Dworkin, 1969). In contrast to vegetative cells, myxospores are completely desiccation resistant and can be lyophilized. Dry myxospores can survive for at least 20 years at room temperature.

The temperature resistance of dry myxospores is especially impressive. Myxospores of strains of *Myxococcus*, *Corallococcus*, *Angiococcus*, *Archangium*, *Cystobacter*, *Polyangium*, and *Sorangium* survive for 30 min at 140°C; myxospores of *Corallococcus*, *Archangium*, *Polyangium*, and *Sorangium* strains survive for 45 min; and myxospores of *Archangium* and *Polyangium* strains survive for 60 min. Exposure to 140°C for 240 min, or to 145°C for a short time kills all myxobacteria. Heat resistance of myxospores is often useful for the isolation of pure strains. Fruiting body suspensions can be heated at 58°C for 15 or 40 min to eliminate contaminants. In *Myxococcus xanthus* myxospore resistance to heat and desiccation appears to be effected by the accumulation of trehalose up to 1.100 μg/mg protein (McBride and Zusman, 1989). Details of numerous studies on myxobacterial morphogenesis can be found in several of the reviews mentioned at the beginning of this article (see also Sudo and Dworkin, 1973; Shimkets, 1987, 2000; Ward and Zusman, 2000; White and Schairer, 2000).

Genetics The DNA of myxobacteria has a mol% G + C content between 67 and 72; the species of the suborder *Cystobacterineae* tend to have lower values in this range (Mandel and Leadbetter, 1965; McCurdy and Wolf, 1967; Behrens et al., 1976). More than 90% of the codons have a G or a C in position 3 (Bremaud et al., 1997). The myxobacterial genomes are among the largest known in procaryotes, viz., 9.45 Mbp in *Myxococcus xanthus* (Chen et al., 1990b), 9.4 Mbp in *Stigmatella aurantiaca*, 9.7 Mbp in *Stigmatella erecta* (Neumann et al., 1992), and 12.2 Mbp in a strain of *Sorangium cellulosum* (Pradella et al., 2002). These sizes indicate a coding capacity of 8000–11,000 genes, or ¼ to ⅓ the number of human genes. Repetitive sequences have been identified in *Myxococcus xanthus* (Fujitani et al., 1991), *Stigmatella aurantiaca* (Bremaud et al., 1997), and *Nannocystis exedens* (Lampson and Rice, 1997). Physical maps of the chromosomes of *Myxococcus xanthus* (Chen et al., 1991a) and *Stigmatella aurantiaca* (Neumann et al., 1993) have been established. The chromosome is circular. Developmental and communication genes are found in all regions. The *Myxococcus xanthus* genome has been cloned in yeast artificial chromosomes (Kuspa et al., 1989). The complete base sequences of the genomes of three organisms, *Myxococcus xanthus*, *Stigmatella aurantiaca*, and *Sorangium cellulosum*, are about to be determined. *Myxococcus xanthus* DNA contains 5-methylcytosine, and the methylation pattern changes with culture development (Yee and Inouye, 1982).

Extrachromosomal DNA has been found in several *Myxococcus xanthus* and *Myxococcus fulvus* strains (Brown and Parish, 1976). Covalently closed plasmids were found in *Myxococcus xanthus* strain FBt after induction of chloramphenicol resistance. Chloramphenicol resistance could be transferred from *E. coli* via an R-plasmid, which also seemed to be retained free in the cytoplasm. However, plasmids normally seem to survive in myxobacterial cells only when inserted into the cellular DNA, perhaps because of efficient restriction systems.

Promoter regions (e.g., Inouye, 1984), genes for σ-factors (Inouye, 1990; Skladny et al., 1994), and for a number of enzymes (e.g., Muñoz-Dorado et al., 1991; Müller et al., 2000) were identified in several myxobacteria. A light-induced promoter controls carotenogenesis in *Myxococcus xanthus* (Balsalobre et al., 1987; Hodgson, 1993). In *Myxococcus xanthus*, induction of fruiting by starvation and of carotenogenesis by light are jointly controlled by gene *carD* (Nicolas et al., 1996). This gene appears to encode a transcription factor with high homology to nuclear proteins of plants and animals; it possesses four repeats of a DNA-binding domain.

Mutants of various myxobacteria can be obtained by UV irradiation and treatment with nitrosoguanidine (e.g., Grimm, 1978). Photorepair and perhaps other repair systems may become activated. In addition, insertional mutants have been obtained by introduction of transposons, mostly TN5, and plasmids and have been used in many studies (e.g., Starich et al., 1985; Jaoua et al., 1987; Glomp et al., 1988). Several gene transfer systems are available for myxobacteria. Chloramphenicol resistance, conferred by an R-factor, can be transferred from *E. coli* into several *Myxococcus* strains by ways not clearly established at the time of the initial studies (Parish, 1975). Later it was shown that gene transfer between *E. coli* and myxobacteria is possible through coliphage P1 as a suicide vector (Kaiser and Dworkin, 1975; Morris et al., 1978; Kuner and Kaiser, 1981; O' Connor and Zusman, 1983) and by conjugation (Breton et al., 1985; Glomp et al., 1988; Jaoua et al., 1992). Conjugal transfer also occurs from *Myxococcus xanthus* into *E. coli* and apparently also between *Myxococcus xanthus* strains. Gene transfer between *Myxococcus xanthus* strains is also possible using myxobacterial transducing phages (Campos et al., 1978; Geisselsoder et al., 1978), and with Mx alpha particles (probably a defective phage) (Starich and Zissler, 1989). More recently, electroporation has been used with good results (Hartzell and Kaiser, 1991; Silakowski et al., 2001). During the past 20 years many studies have been published making use of various gene transfer systems for the investigation of gliding motility, morphogenesis, carotenoid biosynthesis, and secondary metabolism. Methods and results are described in several reviews (see Zusman, 1980; Rosenberg and Dworkin, 1984; Kaiser, 1991; Dworkin and Kaiser, 1993; and reviews cited above).

Phages, Defective phages, Bacteriocins Phages are readily obtained for myxobacteria. Wild strains normally harbor prophage DNA inserted in the cellular genome and possess DNA restriction and modification systems, so that suitable indicator strains are required for the isolation of phages. *Myxococcus virescens* strain V2 is restrictive for *Myxococcus xanthus* phage MX-1 and contains two restriction endonucleases; this strain could be mutated to become phage-sensitive by loss of the restriction enzymes (Morris and Parish, 1976). The first myxophage to be isolated was *Myxococcus xanthus* phage MX-1 (Burchard and Dworkin, 1966), which came from a sample of cow dung and is a virulent phage resembling coliphage T2. MX-1 has a contractile tail sheath, a latent period of 2–2.5 h (30°C), a 2-h rise, and a burst size of about 100. MX-1 attacks *Myxococcus xanthus*, *Myxococcus virescens*, and *Myxococcus fulvus* strains. Two glycoproteins are found in its tail (Tsopanakis and Parish, 1976). The phage exhibits the classic pattern of infection and propagation known in *E. coli* phages (Voelz and Burchard, 1971) and survives during sporulation within myxospores; it induces lysis after germination (Burchard and Voelz, 1972). Many more phages have been isolated from *Myxococcus* species, mostly from *Myxococcus xanthus*, and from *Stigmatella aurantiaca* (e.g., Brown et al., 1976; Campos et al., 1978; Martin et al., 1978; Rodrigues et al., 1980). Many of them are temperate phages. In addition, several generalized transducing phages have been obtained (e.g., MX4, MX8). Myxophages do not differ in essence from other, comparable bacteriophages. All are DNA phages with double-stranded DNA of around 50 Kbp. Temperate MX8 of *Myxococcus xanthus* has DNA with terminal repetitions and circular permutation (Magrini et al., 1997). Its prophage DNA remains stably integrated in the cellular DNA for many generations and during development (Orndorff et al., 1983). It contains a gene of an adenine methylase that can be deleted, making room for cellular DNA to be

transduced (Magrini et al., 1997). Several morphological types of myxophages are known, all with polyhedral heads and with either long contractile tails (e.g., MX1, MX4), or very short tails (e.g., MX8, MX9); λ-like myxophages have also been obtained (Rodrigues et al., 1980). Defective phages are also known from myxobacteria. The first one was found in *Cystobacter violaceus*. Particles resembling rhapidosomes, as described in *Saprospira grandis*, turned out to be extended and contracted phage tails, cores, and polysheaths (Reichenbach, 1965a, 1967). No complete phage has been discovered in the strain, and the defective phage seems not to interfere with growth and development of the organism. Phage tails have also been found in cultures of *Myxococcus xanthus* (Burchard and Dworkin, 1966; Brown et al., 1976). In addition, the transducing Mx alpha particles of *Myxococcus xanthus* could be a defective phage (Starich and Zissler, 1989).

Bacteriocins have been described in myxobacteria. Fulvocin C, one of three substances with bacteriocin-like activity from *Myxococcus fulvus* Mx f16 (Hirsch, 1977a), is a protein consisting of 45 amino acid residues (molecular weight 4672 Da) with no lipid or carbohydrate attached. Disulfide bridges (probably four) make it a very compact molecule (Tsai and Hirsch, 1981). It was the first bacteriocin for which the complete structure was elucidated. Fulvocin C killed 16 out of 17 tested *Myxococcus fulvus* strains, the exception being the strain that produces the molecule. Some strains of other myxobacteria, but no other eubacteria, were inhibited by fulvocin C. The minimal inhibitory concentration was 0.1 to 0.25 μM. Fulvocin C appears to act on the membrane system. Vesicles and stacks of membranes can be seen within sensitive cells treated with the bacteriocin, and the outer membranes of neighboring cells fuse (Hirsch et al., 1978).

A nonparticulate bacteriocin has been obtained from *Corallococcus coralloides* (Muñoz et al., 1984); it inhibits *Corallococcus*, *Myxococcus*, and *Stigmatella aurantiaca* strains. Xanthacin is produced by *Myxococcus xanthus* (McCurdy and McRae, 1974); production is induced by mitomycin C. Xanthacin is active exclusively on a few myxobacteria. It consists of spherical bodies of somewhat variable size, resembles membrane vesicles and the Mx alpha particles mentioned above, and may in fact be a defective phage. Two further "bacteriocins" reported from *Myxococcus* strains do not fit the definition of bacteriocins, as they also kill *Cytophaga* and *Salmonella* strains unrelated to the producer (Brown et al., 1976); they may be antibiotics.

Ecology As there are two recent reviews of this topic (Reichenbach, 1999; Dawid, 2000), only some general information will be presented here in addition to the facts that have already been mentioned. Myxobacteria are ubiquitous organisms living in soil, on decomposing plant material, on the bark of living and dead trees, on the droppings of wild rabbits, hares, sheep, and other herbivores, in freshwater habitats, and, perhaps, in the oceans. There are very rich populations of myxobacteria on *Zostera* leaves in the drift line on the shores of the German and Danish coast of the Baltic Sea. Like normal terrestrial myxobacteria, the latter isolates are only mildly halotolerant (0.3% NaCl). Myxobacteria are inhabitants of all climate zones and vegetation belts; particularly rich floras occur in warm, semi-arid regions such as the Southwest of the USA, Egypt, or India. They have been isolated from slightly acid to alkaline soils, but seem to prefer a more or less neutral pH. Acidophilic, thermophilic, and anaerobic myxobacteria have not been found so far. Myxospores and fruiting bodies are desiccation resistant and survive in air dried soil at environmental temperatures for long periods; this author isolated *Sorangium cellulosum*, *Corallococcus*, *Nannocystis*, *Archangium*, and other myxobacteria from the same air-dried sample after 12 years of storage. Myxobacteria pathogenic for higher plants and animals have never been observed. (As a note of caution, it may be added that for some time *Cytophaga*-like bacteria were classified as myxobacteria and that among those organisms there are several serious fish pathogens and allergenic organisms. However, the two groups of organisms are not related and actually belong to different phyla.) In the older literature, there are several reports of symbiotic relationships between myxobacteria and other bacteria. While in some cases this conclusion may just have been a misinterpretation due to the inability to separate the bacteria with the then-available methods, there is indeed at least one case of a symbiosis, between *Chondromyces crocatus* strains and a *Sphingobacterium*-like organism, which always shows up with the *Chondromyces* regardless of where the latter has been isolated (Jacobi et al., 1997).

Isolation, Preservation, Cultivation Current methods and recipes can be found in *The Prokaryotes* (Reichenbach and Dworkin, 1992). Only some basic principles will be mentioned. Bacteriolytic myxobacteria can be enriched on spots or streaks of living *E. coli* on water agar. Swarms and fruiting bodies will be evident after 2–14 d at 30°C and can be transferred to new streaks for further enrichment. Cellulolytic myxobacteria are obtained on filter paper placed on a mineral salts agar with KNO_3 as the nitrogen source (ST21-agar). A selective cellodextrin-agarose medium is recommended for the isolation of cellulose degraders (Li et al., 1996). In both cases, it is advisable to suppress growth of fungi by adding a suitable antibiotic, e.g., cycloheximide, to which myxobacteria are completely resistant. The inoculum is taken from sources mentioned in the ecology section. Bark, rotting wood, and animal droppings, which are natural habitats or act as baits, can be incubated in a moist chamber. Fruiting bodies can be seen after a few days and can be used to inoculate streaks of *E. coli*. However, not all myxobacterial fruiting bodies are conspicuous enough to be easily seen on such substrates. Sterilized rabbit dung placed on top of collected soil in large dishes was a favored technique of the earlier investigators (Krzemieniewska and Krzemieniewski, 1926, 1927, 1930).

Some isolation methods are particularly useful for specific myxobacteria. *Myxococcus* species with their large and often colorful fruiting bodies are readily obtained if rabbit, sheep, or goat droppings are incubated in a moist chamber. *Stigmatella aurantiaca* seems to occur only on rotting wood. However, while the organism is very common in the Midwest of the USA, it seems to be exceedingly rare on the same substrate in Europe. Knowledge of exact habitats would certainly help to make the isolation of certain species more efficient. *Chondromyces crocatus* was isolated a hundred years ago from willow bark in the Prater in Vienna and was not obtained again from European samples until recently, when it was found in two samples from a compost heap near Basilea in Switzerland. Purification of strains is somewhat tedious and time consuming. Many strains are pure after a few transfers on living and autoclaved *E. coli*. If a series of transfers is not sufficient to purify a strain, antibiotics, treatment of suspended fruiting bodies at 58°C, or incubation of cultures at elevated temperature (up to 40°C) can be tried. Purity is tested on agar plates of a rich medium and in shaken liquid cultures, in which turbidity after 12 h usually indicates contamination.

Pure cultures can be propagated on yeast agar (VY/2-) or on peptone (CY-) agar. Transfers are necessary every 2–3 weeks at 30°C. Typical generation times at 30°C in liquid media range from 3 to 14 h. As mentioned above, *Chondromyces crocatus* re-

quires the presence of a symbiont. For preservation, fruiting bodies and myxospores can be dried on filter paper or in skim milk. Fruiting bodies stored dry on filter paper at room temperature can be reactivated after as long as 22 years. Vegetative cells appear not to survive lyophilization but can be preserved frozen in liquid nitrogen or in a freezer at −70° to −80°C. Frozen cultures remain viable for many years. In liquid nitrogen, they remain viable for decades.

Practical relevance The only practical application myxobacteria have found thus far is as producers of secondary metabolites. About 650 chemical structures and structural variants have been obtained from myxobacteria, which have become one of the richest sources of such compounds among bacteria. Those compounds can either be a source of structural ideas or can be produced directly by fermentation (Reichenbach and Höfle, 1993, 1999; Höfle and Reichenbach, 1995; Reichenbach, 1999). Several myxobacterial metabolites are now useful tools in basic research, e.g., the electron transport inhibitors myxothiazol and stigmatellin and the inhibitors of eubacterial RNA polymerase sorangicin, myxo- and corallopyronin, and ripostatin. Ratjadon inactivates the CMR-1 shuttle that exports proteins from the nuclear into the cytoplasmic compartment specifically and with high mimetic epothilone (Gerth et al., 1996) is being investigated clinically as an antitumor drug. Other practical aspects are more hypothetical. Myxobacteria produce a host of enzymes and are a potential source of enzymes that has hardly been tapped. One interesting enzyme is a milk-clotting protease excreted by *Myxococcus xanthus* (Petit and Guespin-Michel, 1992). An extracellular glycopeptide, myxalin, which acts as a blood-anticoagulant, has been obtained from the same organism (Masson and Guespin-Michel, 1988; Akoum et al., 1992). Geosmin produced by myxobacteria may contribute to the unpleasant earthy smell of drinking water from reservoirs (the main culprits, however, are cyanobacteria and actinomycetes). Finally, micropredators like myxobacteria could suppress wanted organisms, such as *Azotobacter*, in soil or could help control water blooms of cyanobacteria. Quantitatively both effects are probably of minor importance.

Taxonomy, Phylogeny The taxonomy and diagnostics of myxobacteria are based mainly on morphological characteristics: the shape and size of vegetative cells and myxospores; the morphology of the swarm colony; and especially the shape, size, color, and structure of the fruiting bodies. As mentioned above, the latter is a weak point in this endeavor, because the appearance of fruiting bodies may vary substantially from culture to culture, similar structures are produced by unrelated species, and fruiting body formation may degenerate or be lost during isolation or cultivation, so that atypical fruiting bodies or no fruiting bodies at all are found in pure cultures. All this led to much confusion in the past, and still is frustrating for everyone who tries to name new isolates. Lack of fruiting body formation also limits the usefulness of type strains. Sometimes altering laboratory conditions can help elicit fruiting. Most *Chondromyces* strains produce typical fruiting bodies when cultivated on filter paper with a crude mixture of cellulose-decomposing bacteria (no myxobacteria) and other organisms which can be obtained from enrichment cultures for *Sorangium cellulosum*. Other species of the suborder *Sorangineae* are sometimes stimulated to fruit under such conditions. Cultivation on pellets of (wild) rabbit feces may also be useful, probably because of the presence of a similar constellation of other organisms.

Efforts to find alternative characteristics for the classification of myxobacteria have not been particularly successful (e.g., McCurdy, 1969b). Cellulose degradation appears to be a reliable and stable feature and is probably always found together with the ability to use inorganic nitrogen sources, a character which is unusual for myxobacteria. This trait distinguishes the genera *Sorangium* and *Byssophaga* from all other myxobacteria. In addition, efficient chitin degradation appears to be rare and typical of certain species and genera, e.g., of all strains of the three *Stigmatella* species, of *Cystobacter fuscus*, *Cystobacter ferrugineus*, and *Cystobacter miniatus*, and of *Jahnia* and *Kofleria*. *Myxococcus stipitatus* cultures are supposed to show an intense yellow fluorescence under UV irradiation at 366 nm (Lampky and Brockman, 1977). This trait is found together with chitin degradation and poor swarming on chitin agar, perhaps due to inhibition by acetylglucosamine. Those characteristics are not found in typical *Myxococcus fulvus* strains, the closest relative of *Myxococcus stipitatus*. Yet there are many *Myxococcus fulvus* strains with small myxospores, which are typical of *Myxococcus stipitatus*, so that confirmation by the methods of molecular taxonomy would be desirable. There may be more phenotypic characteristics that would help distinguish between species, but they can be discovered only by a careful comparative study of many strains. In addition, the habitat may be helpful for diagnosis. For example, while *Stigmatella aurantiaca* appears to be restricted to rotting wood and bark, *Stigmatella erecta* and *Stigmatella hybrida* live in soil and on animal droppings. Analysis of 16S rRNA sequences largely supports classification by the procedures outlined above (Spröer et al., 1999). Groups of organisms remain that apparently represent several species—perhaps even several genera—that cannot be subdivided based on present knowledge. Such is the case with the genera *Corallococcus*, *Archangium*, *Sorangium*, *Polyangium*, and *Nannocystis*. DNA–DNA hybridization (Johnson and Ordal, 1969) and serological reactions (Grilione, 1968) have not been fully exploited for the classification of myxobacteria, but seem promising.

At the moment, about 50 species of myxobacteria are distinguishable and are classified in 16 genera, 5 families, and 3 suborders in the order *Myxococcales*. The order has changed its name three times during the author's scientific career, and one hopes that the present names will remain for some time to come. The suborders are easily recognizable by their characteristic vegetative cells, myxospores, and swarm patterns—the only problem arises with the genus *Kofleria* in the *Nannocystineae*—and are clearly separated in 16S rRNA similarity trees (Ludwig et al., 1983; Shimkets and Woese, 1992; Spröer et al., 1999). Still more so far undescribed species probably exist in nature, as is suggested by the many unusual organisms that have been isolated over the past 35 years, and the number of species may finally reach around 100.

Analysis of 16S rRNA sequences indicates that the myxobacteria are a phylogenetically coherent group and belong to the class *Deltaproteobacteria* (Stackebrandt et al., 1988b). Their nearest—if remote—relatives are, quite unexpectedly, *Bdellovibrio* and strictly anaerobic sulfate reducers (Oyaizu and Woese, 1985). The age of the group was estimated from 16S rRNA similarities to be 900–1000 million years (Shimkets, 1990b). Only a few strains of myxobacteria are found in most public collections. This author recently transferred a collection of roughly 7000 strains covering most of the described genera and species to the DSM (Deutsche Sammlung von Mikroorganismen und Zellkulturen, the German Culture Collection) in Braunschweig, so that ample material for all kinds of studies is now available.

Key to the suborders and families of the order Myxococcales

I. Vegetative cells with tapering ends. Myxospores much shorter and often fatter than vegetative cells, optically refractile when mature. Swarm colony adsorbs Congo red.
Suborder I. *Cystobacterineae*

A. Myxospores spherical or ellipsoidal. Swarm colonies soft, slimy, often with undulating, snaking veins and flat humps.
Family I. *Myxococcaceae*

B. Myxospores short, often relatively slender and curved rods. Swarm colonies with a tough slime sheet and long, often branching radial veins.
Family II. *Cystobacteraceae*

II. Vegetative cells cylindrical with rounded ends. Myxospores resemble vegetative cells but may be optically refractile. Swarm colony does not adsorb Congo red.
Suborder II. *Sorangineae*

C. Swarm colonies sometimes without a coherent slime sheet but often with veins and a ridge or band of cells along the edge. Agar may be etched, and there may be shallow depressions in the agar surface. Often the swarm penetrates deeply into the agar plate, or, in several species, breaks up into small, independently migrating cell clumps.
Family III. *Polyangiaceae*

III. Vegetative cells either short, cylindrical or broadly ellipsoidal, with rounded or truncated ends, sometimes almost cube shaped; or slender, cylindrical rods with rounded ends resembling vegetative cells of the *Polyangiaceae*, but more delicate. Myxospores, as far as known (*Nannocystaceae*), are spherical or short and ellipsoidal and optically refractile. Swarm colonies do not adsorb Congo red.
Suborder III. *Nannocystineae*

D. Swarm colonies without a slime sheet, tend to corrode the agar plate, on certain media very deeply so, transforming it into a spongy mass. Vegetative cells short rods. Fruiting bodies tiny to moderately sized sporangioles, solitary or aggregated.
Family IV. *Nannocystaceae*

E. Swarm colonies consist of a slime sheet with more or less prominent radial veins, do not etch the agar, resemble the swarms of the *Cystobacteraceae* but do not adsorb Congo red. Usually produce many small to large globular knobs all over the swarm surface and dense, spherical cell aggregates within the agar resembling sporangioles, but real sporangioles and myxospores have yet to be found. Vegetative cells delicate, slender cylindrical rods with rounded ends. Besides terrestrial organisms, some marine, halophilic myxobacteria also appear to belong to this group.
Family V. Kofleriaceae

Comments In general, affiliation of an isolate with one of the suborders is easy to recognize by the shape of vegetative cells, myxospores, and swarm colonies (Fig. BXII.δ.55). The Congo red reaction is normally not required to distinguish the suborders; but sometimes an additional test may be welcome (e.g., with *Kofleria*). As first observed by McCurdy (1969b), the swarm colonies of some myxobacteria adsorb Congo red while those of others do not. The swarms are covered with an 0.01% aqueous Congo red solution. A positive reaction occurs when the swarm becomes purple-red within 5 min at room temperature; also, the swarm sheet then tends to float off the substrate. This result is typical for species of the suborder *Cystobacterineae*, and is especially striking in the family *Cystobacteraceae*. Swarms of species of the other two suborders do not give this reaction. Sometimes their fruiting bodies stain red with Congo red, e.g., those of *Sorangium cellulosum*. This reaction takes a much longer time, and the color is rather blood-red than purple. The Congo red reaction indicates a difference in slime chemistry. Incidentally, chitin flakes in chitin agar also stain intensely with Congo red, so that somewhat hazy lysis zones are made more distinct. Myxobacteria were originally regarded as strictly aerobic organisms; however, facultatively anaerobic, halorespiring myxobacteria have recently been reported and classified in a new genus, *Anaeromyxobacter* (Sanford et al., 2002).

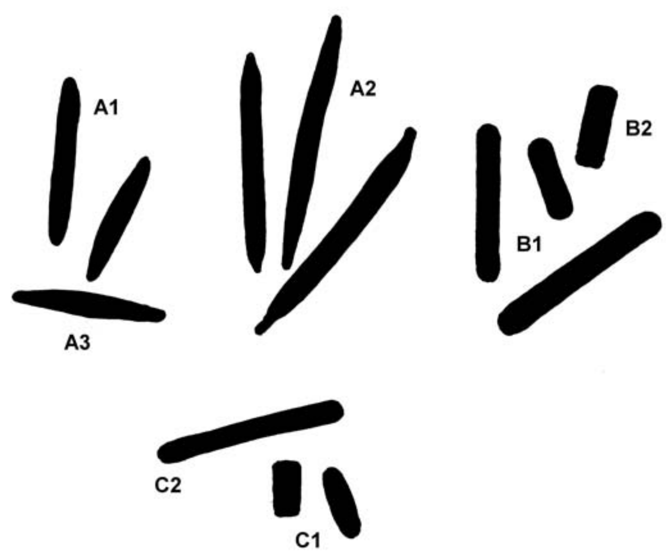

FIGURE BXII.δ.55. Many genera of myxobacteria may be recognized by their cell shape. A: Suborder *Cystobacterineae*. A1: *Myxococcus*, *Corallococcus*, *Pyxicoccus*; A2: *Archangium*, *Cystobacter*, *Melittangium*; A3: *Stigmatella*. B: Suborder *Sorangineae*. B1: *Polyangium*, *Byssophaga*, *Chondromyces*, *Jahnia*; B2: *Sorangium*. C. Suborder *Nannocystineae*. C1: *Nannocystis*; C2: *Kofleria*.

Family I. **Myxococcaceae** Jahn 1924, 84[AL]

HANS REICHENBACH

Myx.o.coc.ca'ce.ae. M.L. masc. n. *Myxococcus* type genus of the family; *-aceae* ending to denote a family; M.L. fem. pl. n. *Myxococcaceae* the *Myxococcus* family.

Vegetative cells slender rods with slightly tapering ends, cigar or boat-shaped. **Myxospores spherical or ellipsoidal with a thick capsule, optically refractile**. Fruiting bodies are naked masses of slime and myxospores or, in one genus, consisting of sporangioles with a wall. All species are of the proteolytic–bacteriolytic nutritional type.

Type genus: **Myxococcus** Thaxter 1892, 403.

Key to the genera of the family Myxococcaceae

I. Fruiting bodies are naked masses of slime and myxospores.
   A. Fruiting bodies are relatively large, soft and slimy, spherical knobs or heads with or without a stalk.
      Genus I. *Myxococcus*
   B. Fruiting bodies of cartilaginous consistency and very variable shape: pustules, ridges, often with horns or coralloid.
      Genus II. *Corallococcus*

II. Fruiting bodies consist of sporangioles with a wall. Sporangioles spherical or slightly elongated; arranged in packages and sheets.
      Genus III. *Pyxicoccus*

FURTHER DESCRIPTIVE INFORMATION

The family is well characterized by swarm morphology. The swarms are soft and slimy and have only rarely a thin, tough top layer. They are either without any structure, or develop snaking, undulating veins and flat humps, especially on peptone (CY-) agar. This normally allows for the recognition of members of the family at a glance. However, after prolonged cultivation, swarms of other myxobacteria may degenerate into unstructured, soft, slimy colonies, so that the initially clear difference from species of the *Myxococcaceae* becomes obscured. While the swarms of most species of the *Myxococcaceae* are unpigmented, swarms of two *Myxococcus* species may be intensely greenish yellow or orange. The Congo red reaction can be relatively weak and delayed but is usually clear. The second characteristic typical for all members of the family is the spherical or ellipsoidal myxospores. However, more or less spherical myxospores may also be produced by certain *Archangium* and *Cystobacter* species. With some experience, however, the two can be distinguished. Myxospores of the *Myxococcaceae* are more uniform and have a smoothly curved surface, probably because of their rather thick capsule, while those of the *Cystobacteraceae* are slightly angular and normally accompanied by more or less short, fat rods. Also, swarm morphology and shape of the vegetative cells differ. If for some reason a culture ceases development prematurely, cell conversion of the *Myxococcaceae* may stop at an intermediary stage of short, optically refractile rods. In this case, however, other cultures of the same strain usually have typical, spherical myxospores. Further, the vegetative cells of the *Myxococcaceae* are short to moderately long rods (3–6 μm), either cigar-shaped with slightly tapering ends or slender and boat-shaped, while vegetative cells of the *Cystobacteraceae* are often long, slender, needle-shaped rods (6–12 nm long).

In the last edition of the *Manual*, the species of the former genus *Chondrococcus* were incorporated in the genus *Myxococcus*. While the genus name *Chondrococcus* is not valid, because it was used earlier for a genus of red algae (Kützing, 1847; Papenfuss, 1940); this author wishes to propose a new genus, *Corallococcus*, for the organisms formerly known as *Chondrococcus* spp., because those species do indeed differ substantially and coherently in several respects from *Myxococcus* species. In general, fruiting cultures of the two genera can be differentiated by eye, and if there is doubt, a touch with a needle will show whether the fruiting body is soft, as is typical of *Myxococcus*, or of cartilaginous consistency, as is characteristic of *Corallococcus*. In addition, the shape of the fruiting bodies normally differs. *Myxococcus* fruiting bodies are relatively large globular masses, knobs, or heads, often with a constriction at the base or even a stalk. They may degenerate in culture into deliquescent flat mounts or plump ridges, rarely into finger-like projections, but they always remain soft. *Corallococcus* fruiting bodies, in contrast, are smaller and very irregular in shape; they form pustules, branched or unbranched ridges, ribbon- or disk-like structures, often with finger-like projections that may or may not be branched; they can also develop into coralloid, much-branched masses. In culture, they are conspicuous because they are usually produced in tremendous numbers. The two genera show other differences as well. As mentioned before, *Myxococcus* strains do not grow in the presence of 250 μg/ml kanamycin sulfate, but 50% of *Corallococcus* strains do. On the other hand, while 60% of *Myxococcus* strains grow with 50 μg/ml streptomycin sulfate, only 3% of *Corallococcus* strains do. *Corallococcus* strains produce squalene, not so for *Myxococcus* strains. The number of secondary metabolites obtained from *Corallococcus* is much lower than it is with *Myxococcus*, and the array of compounds produced differs. In addition, there is a difference in salt tolerance. While *Myxococcus* strains still grow, if hesitantly, on yeast agar (VY/2-) with 2% NaCl, *Corallococcus* strains do not. Finally, the 16S rRNA sequences of *Corallococcus* strains cluster together and clearly separate from those of *Myxococcus* species (Spröer et al., 1999).

The third genus of the family, which is now called *Pyxicoccus*, is somewhat confusing. The roots of the genus go back to a bacterium described by Thaxter (1904) as *Myxococcus disciformis*. Because the spherical myxospores of the species are enclosed in sporangioles with a wall, Jahn (1924) created a new genus, *Angiococcus*, for it, apparently without ever having seen the organism. In spite of the fact that the same organism had been reported from Poland (Krzemieniewska and Krzemieniewski, 1926), it was later concluded that *Angiococcus* did not exist (Peterson and McDonald, 1966). Then the bacterium was rediscovered in the

fossa of an alkaline bog (Hook et al., 1980). So the old species and genus names were revived, and a neotype strain of *Angiococcus disciformis* was deposited (ATCC 33172). The morphology of the organism suggests that it is really Thaxter's organism. However, it does not belong to the *Myxococcaceae*. In the last edition of this *Manual*, it was classified as *Cystobacter disciformis*. It has vegetative cells and a swarm morphology similar to those found in organisms of that genus. Its present classification is supported by 16S rRNA sequence data, which place the neotype strain close to *Cystobacter minus* (Spröer et al., 1999). There are, however, organisms with spherical myxospores, a swarm morphology characteristic of the *Myxococcaceae*, and 16S rRNA sequences that position them close to *Myxococcus* (Spröer et al., 1999). For organisms of this type, exemplified by strain An d1, a new genus name, *Pyxicoccus*, will be used here. This avoids confusion, especially as it is not yet established whether *Cystobacter disciformis* really belongs to the genus *Cystobacter*. If not, the genus name *Angiococcus* may have to be revived for it. It should be mentioned that *Pyxicoccus* fruiting bodies often degenerate into *Corallococcus*-like structures. The 16S rRNA study also proved that *Pyxicoccus* could be easily confused with other myxobacteria, as two of the three strains tentatively identified by the author as *Angiococcus disciformis* clustered in the *Archangium* group (Spröer et al., 1999).

Genus I. **Myxococcus** *Thaxter 1892, 403*[AL]

HANS REICHENBACH

Myx.o.coc'cus. Gr. fem. n. *myxa* mucus, slime; Gr. masc. n. *kokkos* berry; M.L. masc. n. *Myxococcus* slime coccus.

Vegetative cells are slender rods with tapering ends, either cigar-shaped or slender and boat-shaped, measuring about 0.8 × 3–6 μm. When typical, the fruiting bodies are soft, slimy globular masses, knobs, or heads, constricted at the base or on a slime stalk (but see comments on the family). Of the proteolytic–bacteriolytic nutritional type. Common organisms in soil, in freshwater, and on dung of herbivores. Readily obtained when rabbit, hare, or sheep droppings are incubated in a moist chamber at 30°C.

The mol% G + C of the DNA is: 68–71 (Mandel and Leadbetter, 1965), 67–68 (McCurdy and Wolf, 1967), 68–70 (Behrens et al., 1976), 65–67 (Yamanaka et al., 1987).

Type species: **Myxococcus fulvus** (Cohn 1875) Jahn 1911, 198.

FURTHER DESCRIPTIVE INFORMATION

Originally, the *Myxococcus* species were distinguished primarily by the color of the fruiting bodies. However, this color may vary quite considerably, depending on environmental factors such as light and growth media, and it may even be completely absent. A better feature appears to be the size of the myxospores, which seems to be fairly constant within each species. Yet questions remain, as the taxonomic significance of the observed variability between strains cannot be evaluated based on available data. The largest myxospores are those of *Myxococcus virescens*. *Myxococcus xanthus* has somewhat smaller myxospores; in addition, many strains produce a certain proportion of abortive, dark myxospores. *Myxococcus stipitatus* has small myxospores, which, in some strains, are decidedly ellipsoidal. In principle, the presence of a stalk should make it easy to recognize this species. However, well-developed stalks are normally only seen in crude cultures, when fruiting bodies develop on natural substrates. In culture, only rudimentary stalks or no stalks at all develop as a rule. Fruiting bodies often develop in groups or in lines on a common, cushion-like base; this behavior is not seen in *Myxococcus fulvus*, its nearest relative. Furthermore, it has been observed that cultures of *Myxococcus stipitatus* exhibit an intense yellow fluorescence under UV light at 366 nm (Lampky and Brockman, 1977). All such strains seem to degrade chitin and to spread very little on chitin agar; neither characteristic is seen in typical *Myxococcus fulvus* strains. However, the size of the myxospores of *Myxococcus fulvus* varies from mid-sized to small in different strains, so that in this respect there is an overlap with *Myxococcus stipitatus*. DNA–DNA hybridization of a critical number of strains would be desirable to establish whether the above-mentioned distinguishing characteristics are reliable. The small differences in the 16S rRNA sequences are clearly not sufficient to classify the various *Myxococcus* species (Spröer et al., 1999).

Several *Myxococcus* species of questionable validity appear in the literature. In part, the confusion is due to variability of characteristics that could not be evaluated properly at the time the species were described, especially if the organisms were not cultivated. In addition, in the early days organisms were named *Myxococcus* that do not correspond with today's definition of the genus, as has just been shown with the example of *Angiococcus*. For the moment, it appears that all variants can be classified in the four species outlined below. This is probably also the case with the most recent addition, *Myxococcus flavescens* (Yamanaka et al., 1987). The size of its myxospores, its yellow color, and the myxovirescin type antibiotics produced by it (here called megovalicins; Miyashiro et al., 1988) are a perfect fit with the description of *Myxococcus virescens*. This identity is also supported by 16S rRNA sequence comparison (Spröer et al., 1999).

As happened with several myxobacteria, a *Myxococcus* species was observed and named before Thaxter (1892) discovered the peculiar life cycle of those bacteria, which he then described as myxobacteria. It appears that in 1875 Cohn gave a description of fruiting bodies of *Myxococcus fulvus*, which he named *"Micrococcus fulvus"*. Thaxter's *"Myxococcus rubescens"* was later regarded as being identical to *"Micrococcus fulvus"* and was consequently renamed (Jahn, 1911). Ferdinand Cohn, however, did not realize what an extraordinary developmental cycle was performed by his organism.

The relative abundance of the four *Myxococcus* species may be approximately estimated from the number of strains that have been isolated over 30 years: *Myxococcus fulvus* (572), *Myxococcus virescens* (264), *Myxococcus xanthus* (173), and *Myxococcus stipitatus* (94).

Differentiation of the species of the genus Myxococcus

I. Myxospores middle-sized to small, 1.2–1.6 μm in diameter. Fruiting bodies pink, brownish, reddish, or white.

A. Myxospores middle-sized to small, spherical. Fruiting bodies often with a constriction at the base and a pedicle, but never with a stalk. No yellow fluorescence of cultures.

M. fulvus

B. Myxospores small, spherical, or ellipsoidal. Fruiting bodies with a long, white stalk. Cultures show a bright yellow fluorescence at 366 nm.

M. stipitatus

II. Myxospores large, 1.8–2.1 μm in diameter. Fruiting bodies often deep orange.

M. xanthus

III. Myxospores very large, 2.0–2.5 μm in diameter. Fruiting bodies often greenish yellow, or grayish and deliquescent.

M. virescens

List of species of the genus Myxococcus

1. **Myxococcus fulvus** (Cohn 1875) Jahn 1911, 198[AL]
ful′vus. L. masc. adj. *fulvus* reddish yellow, brown.

Vegetative cells are slender rods with tapering ends, often slightly boat-shaped, 0.6–0.8 × 4–8 μm (Fig. BXII.δ.56).

Fruiting bodies are spherical or slightly pear shaped, 50–250 μm and more in diameter (Fig. BXII.δ.57), often constricted at the base and on a pedicle or short stalk. In culture also plump ridges and deliquescent mounds may be found. Occur in a wide variety of colors: white, pink, red, brown. Myxospores spherical, optically refractile, 1.3–1.6 μm (range: 1.2—2.0 μm) in diameter, with a thick capsule (Fig. BXII.δ.58). Swarm colonies as are typical for the family (Fig. BXII.δ.59), rarely pigmented, sometimes greenish yellow when grown in the dark, pink to purplish red when cultivated in the light. A dark brown, diffusible pigment is often produced on peptone agar. Optimal pH 6.8–7.5. Temperature range 25–35°C (may be 6–38°C), optimal 26–32°C. Gelatin and casein are hydrolyzed. Does not utilize mono- and disaccharides.

Very common and readily obtained from dung of rabbits, hares, sheep, etc., but also from enrichment cultures with soil and rotting plant material on streaks of living *E. coli* or on plates for cellulose degraders. Also found in fresh water and samples from the marine littoral zone.

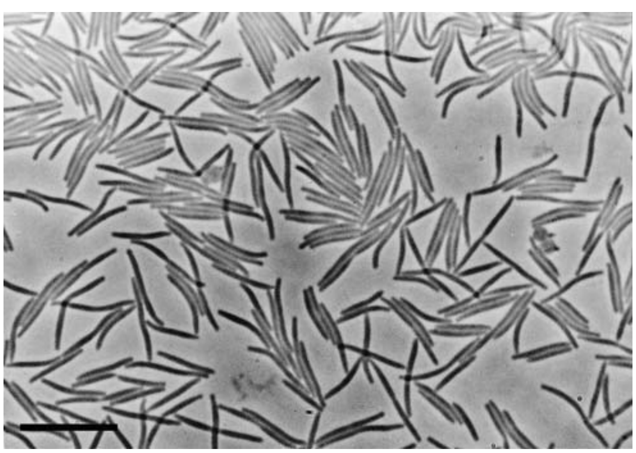

FIGURE BXII.δ.56. *Myxococcus fulvus*: vegetative cells from a liquid culture, in phase contrast. As the culture was already beyond its optimal, the cells are longer than usual. Bar = 10 μm.

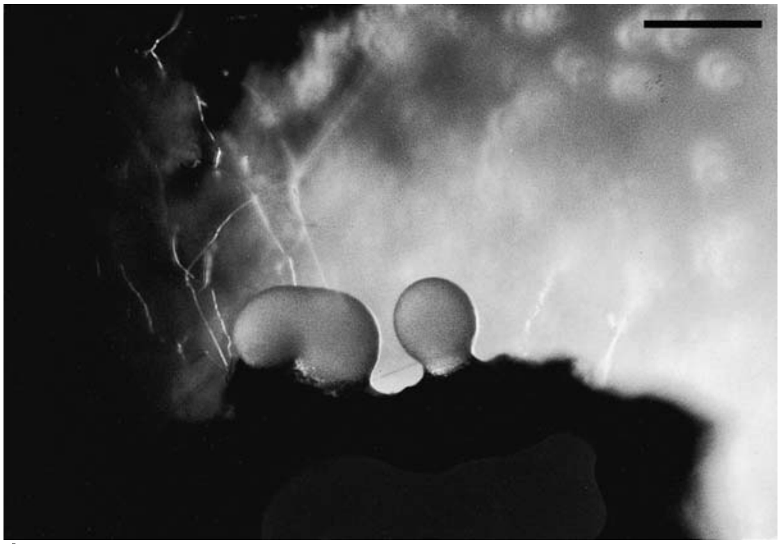
The wide range of myxospore diameters between individual strains may indicate that the species is not completely homogeneous.

The mol% G + C of the DNA is: 67–71 (Bd, T_m).



Type strain: ATCC 25199.

Additional Remarks: Reference strains include DSM 434 (Mx f2, isolated in 1967 from deer dung collected in Minnesota, USA).

2. **Myxococcus stipitatus** Thaxter 1897, 408[AL]
sti.pi.ta′tus. L. masc. n. *stipes,* gen. *stipitis* trunk, stalk; M.L. adj. *stipitatus* stalked.

Vegetative cells slender rods with tapering ends, 0.7–0.8 × 4–6 μm, normally shorter than those of *Myxococcus fulvus*. Fruiting bodies consist of a spherical mass of slime and myxospores, 40–140 μm and more in diameter, unpigmented or brownish, on a long, white slime stalk, 100–250 μm long and 30–60 μm wide (Fig. BXII.δ.60). While stalks usually are well developed in enrichment cultures with fruiting bodies sitting on the natural substrates, stalks may be mostly lacking in cultures on agar media, so that the fruiting bodies resemble those of *Myxococcus fulvus*. In contrast to *Myxococcus fulvus*, *Myxococcus stipitatus* fruiting bodies often arise in clusters or lines on a common, cushion-like base. In addition, in contrast to *Myxococcus fulvus*, *Myxococcus stipitatus* cultures show a bright yellow fluorescence under UV light at 366 nm, which is caused by phenalamide or stipiamide compounds. Further, *Myxococcus stipitatus* strains decompose chitin but spread very little on chitin agar plates. As mentioned above, it is not yet firmly established whether the latter two characteristics distinguish the two species reliably. Myxospores are spherical or sometimes ellipsoidal and rather small (1.3–1.5 × 1.5–1.6 μm in diameter) (Fig. BXII.δ.61). Swarm colonies as are typical for the family, unpigmented or yellowish. On peptone agar a brown, diffusible pigment is often produced. Nutritional requirements as for the other species of the genus.

Myxococcus stipitatus is common, especially on rotting plant material and in samples from the tropics, but may also be obtained from other sources. Strain Mx s8 was isolated at the Gesellschaft für Biotechnologische Forschung in 1982 from a soil sample collected near the Iguaçu waterfalls in Brazil, December 1981. Reference strain Mx s1 came from soil and rotting wood collected in Bangkok, Thailand, in August 1970 and was isolated at the University

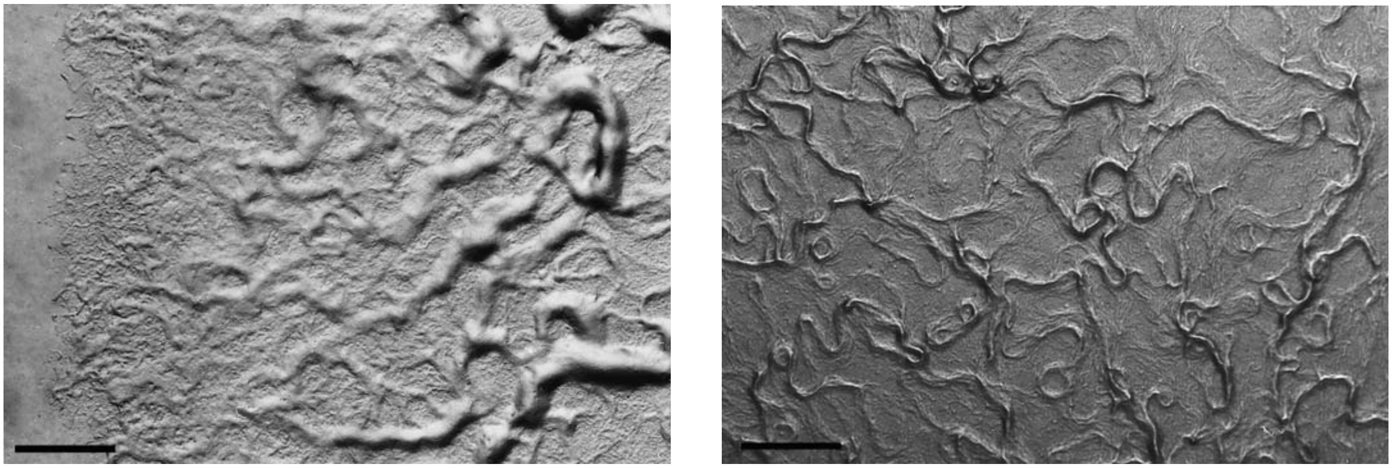
B

FIGURE BXII.δ.57. *Myxococcus fulvus*: fruiting bodies: (*A*) on the natural substrate, in this case rotting wood; (*B*) on an agar surface. Typical fruiting bodies show a constriction at the base and a short pedicle. Sometimes the soft heads of neighboring fruiting bodies fuse. Typical fruiting bodies of *Myxococcus xanthus* and *Myxococcus virescens* would have the same shape, but a different color. (*A*) Bar = 165 μm; (*B*) Bar = 200 μm.

A B

FIGURE BXII.δ.58. *Myxococcus fulvus*: myxospores from squashed fruiting bodies, in phase contrast; (*A*) a homogeneous suspension, (*B*) mixed with myxospores of *Myxococcus virescens* (the large, phase-bright cells): The size difference is recognizable at a glance through the microscope. (*A*) Bar = 8 μm; (*B*) Bar = 13 μm.

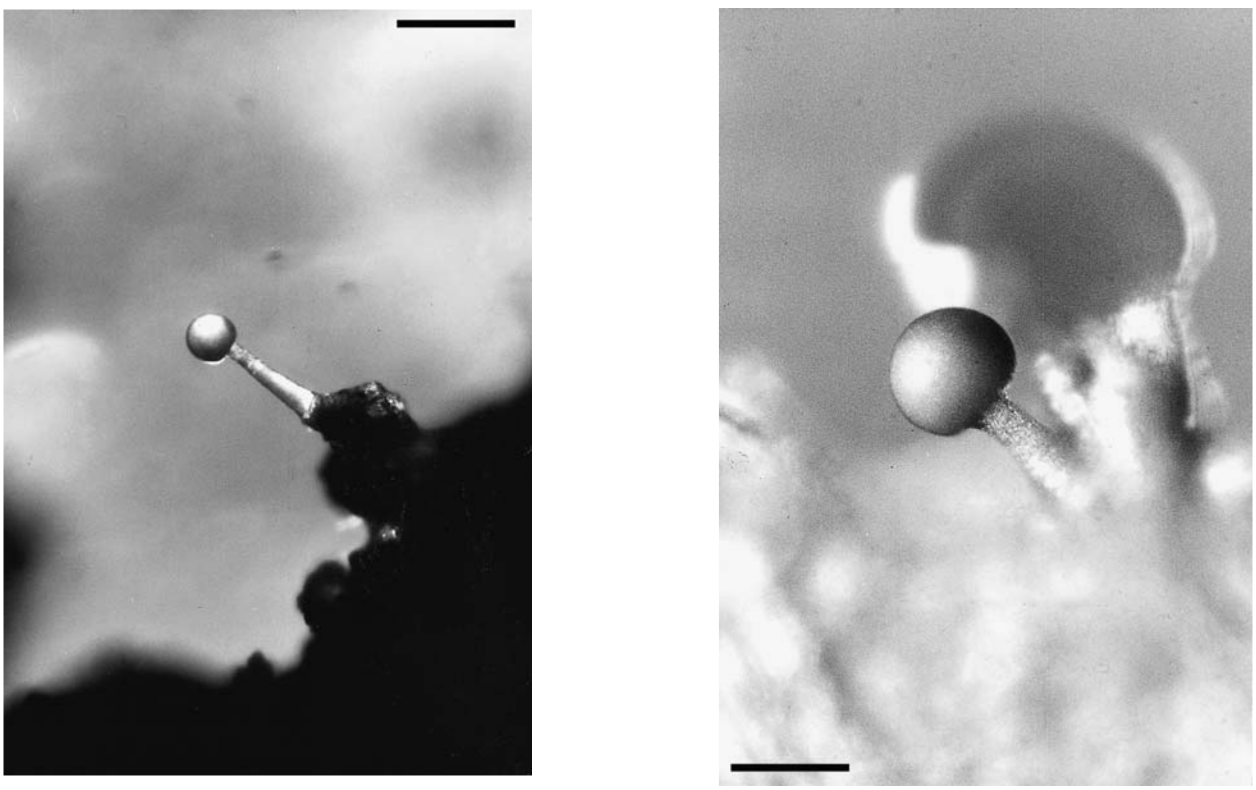
of Freiburg, Germany, in October 1970; reference strain Mx s2 was isolated in 1973, also in Freiburg, from a soil sample collected near the city.



The mol% G + C of the DNA is: 65 (T_m).

Type strain: Mx s8, DSM 14675, JCM 12634.

Additional Remarks: Reference strains include ATCC 29611, ATCC 29612, ATCC 29621, DSM 14676 (Mx s1), DSM 14700 (Mx s2).



3. **Myxococcus virescens** Thaxter 1892, 404[AL]
vi.res′ cens. L. part. adj. *virescens* becoming green.

Vegetative cells slender rods with shortly tapering ends, cigar-shaped, 0.7–0.8 × 4–8 μm. Fruiting bodies are globular or oval, rarely even finger-like (Fig. BXII.δ.62); on agar media also plump ridges and, very often, deliquescent mounds; greenish yellow when typical, but often yellow to orange, in cultures even unpigmented, gray. May become rather large, 150–500 μm. Myxospores are spherical, optically refractile, and very large, 1.9–2.4 μm in diameter (range: 1.7–2.6 μm) (Fig. BXII.δ.63), with a thick capsule. This large size is the most reliable distinguishing charac-

A B

FIGURE BXII.δ.59. Swarm colonies of *Myxococcaceae*. The swarms of all species of the family look alike and are quite different from those of other myxobacteria. If swarms are structured at all, snaking, undulating veins are typical; they are particularly prominent on peptone-containing agar media (*A*). Both examples show swarms of *Corallococcus coralloides*. (*A*) Bar = 600 μm; (*B*) Bar = 800 μm.

A B

FIGURE BXII.δ.60. *Myxococcus stipitatus*: fruiting bodies. (*A*) Long stalks are normally produced on the natural substrate, in this case a crumb of soil, but (*B*) on agar plates stalks often are only rudimentary or absent. (*A*) Bar = 125 μm; (*B*) Bar = 75 μm.

teristic of the species. Swarm colonies as characteristic of the family, unpigmented or greenish yellow, sometimes orange. Temperature and pH range and nutritional requirements as for the other species of the genus.

Myxococcus virescens is a common organism in soil, in rotting plant material and in samples from the littoral; it is easily obtained when rabbit or sheep dung is incubated in a moist chamber. The species appears to be more halotolerant than most myxobacteria (Rükert, 1978).

The mol% G + C of the DNA is: 68–71 (Bd, T_m).

Type strain: M22, ATCC 25203, DSM 2260.

4. **Myxococcus xanthus** Beebe 1941a, 195[AL]

xan' thus. Gr. adj. *xanthos* yellow; M.L. masc. adj. *xanthus* yellow.

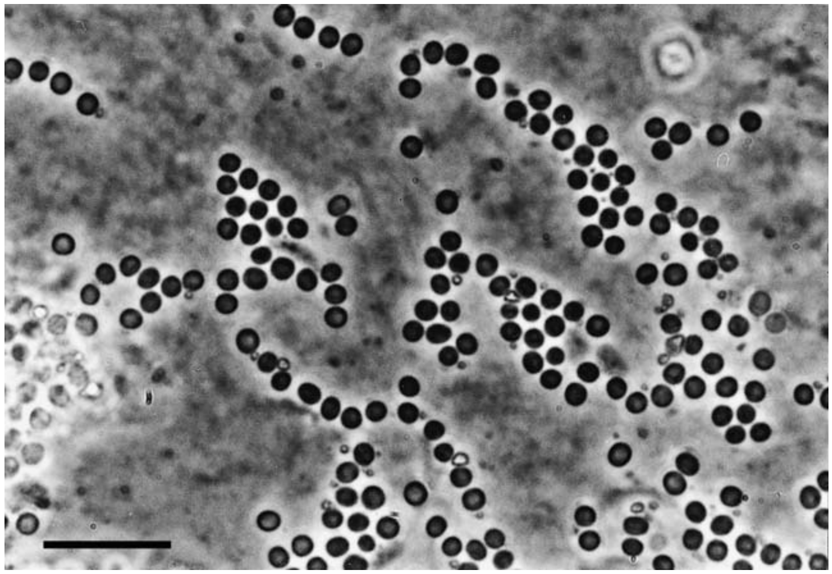


FIGURE BXII.δ.61. *Myxococcus stipitatus*: Myxospores from squashed fruiting body. At high magnification (100 × 2.0, phase contrast, oil immersion) the small myxospores do not show optical refractility which is readily seen using a 40× objective. Bar = 8 µm.

Vegetative cells slender rods with tapering ends, 0.7–0.8 × 4–8 µm. Fruiting bodies are spherical or oval; on agar plates plump ridges or deliquescent mounds are often formed, usually deep orange, but often yellow, greenish yellow, gray. or even unpigmented; 80–150 µm and up to 300–400 µm in diameter. Myxospores spherical, optically refractile, 1.7–2.2 µm in diameter. Often a subpopulation of dark, degenerate myxospores is seen among the typical ones. Swarm colonies as typical for the genus, unpigmented, orange or greenish yellow. Pigmentation of *Myxococcus xanthus* swarms overlaps with that of *Myxococcus virescens* and may change with cultivation. Temperature and pH range and nutritional requirements as for the other species of the genus.

Myxococcus xanthus appears to be somewhat less common than *Myxococcus fulvus* and *Myxococcus virescens* but it is still easily obtained from the usual sources, particularly when dung is incubated in a moist chamber.

The mol% G + C of the DNA is: 67–71. (Bd, T_m).

Type strain: FB, ATCC 25232, NCIB 9412, IFO 13542, DSM 6796.

Additional Remarks: Reference strains include DSM 435 (Mx x1, isolated in 1962 from a soil sample collected in 1961 in Liberia).

FIGURE BXII.δ.62. *Myxococcus virescens*. In agar cultures, the organism rarely produces atypical, finger-like fruiting bodies. Bar = 65 µm.

Other Organisms

A substantial number of additional *Myxococcus* species have been described, mainly in the early years of myxobacterial research. Most of them are synonymous with the above-listed species; others belong to other genera of myxobacteria, or are not myxobacteria at all. Almost none of the names are validly published and only in one case (*Myxococcus flavescens* DSM 4946, IAM 13189, JCM 6245) is a type strain still available.

The following species appear to be identical with *Myxococcus fulvus*: *"Myxococcus rubescens"* Thaxter 1892; *"Myxococcus pyriformis"* Smith 1901; *"Myxococcus ruber"* Baur 1905; *"Myxococcus ja-*

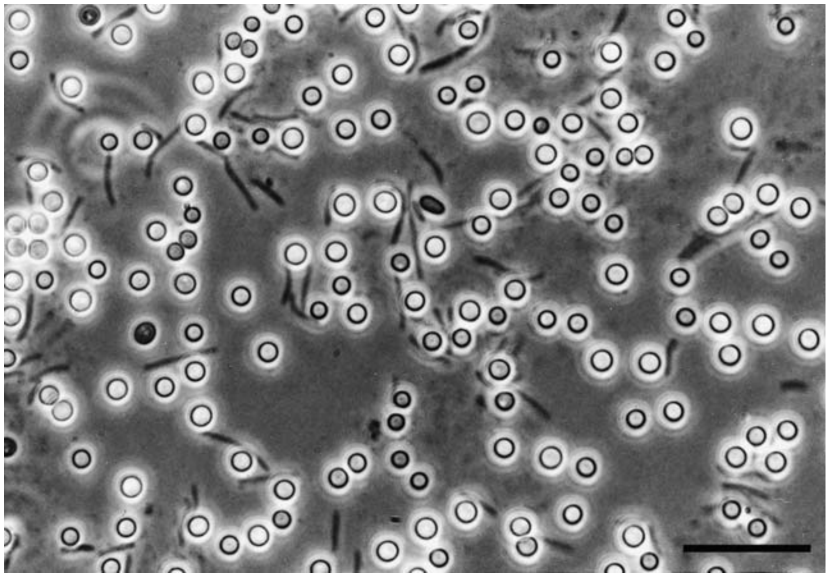

FIGURE BXII.δ.63. *Myxococcus virescens*: myxospores from squashed fruiting body, in phase contrast. Bar = 13 μm.

vanensis" de Kruyff 1908; perhaps also *"Myxococcus albus"* Finck 1950; *"Myxococcus brevipes"* Finck 1950; and most likely *"Myxococcus cellulosus"* Pronina 1962, which probably was not a cellulose degrader as stated (see Chapter on *Myxococcales*). *"Myxococcus ovalisporus"* Krzemieniewska and Krzemieniewski 1926 may have been *Myxococcus stipitatus*; the pale color of the fruiting bodies, the fact that they often arise in clusters on a common base, and oval myxospores would support this assumption. *"Myxococcus viperus"* Finck 1950 and *Myxococcus flavescens* Yamanaka et al., 1987 appear to be identical with *Myxococcus virescens* (see Further Descriptive Information). *"Myxococcus cirrhosus"* Thaxter 1897, *"Myxococcus digitatus"* Quehl 1906, and *"Myxococcus clavatus"* Quehl 1906 may have been *Corallococcus coralloides* strains. *"Myxococcus polycystus"* Kofler 1913 was probably *C. coralloides*, too. *Myxococcus disciformis* Thaxter 1904 is *Angiococcus disciformis* Jahn 1924 and now *Cystobacter disciformis* McCurdy 1989. *"Myxococcus cruentus"* Thaxter 1897 is a cellulose-degrader belonging to the suborder *Sorangineae* and is now called *Byssophaga cruenta*. *"Myxococcus cerebriformis"* Kofler 1913 was probably *Archangium gephyra*. *"Myxococcus filiformis"* Solntseva 1940 is *Flexibacter filiformis*. *Myxococcus macrosporus* Zukal 1897b was obviously not a myxobacterium at all, but a fungus.

Genus II. **Corallococcus** *gen. nov.* (*Chondrococcus Jahn 1924, 85*)

Hans Reichenbach

Co.ral.lo.coc' cus. Gr. neut. n. *korallion* coral; Gr. masc. n. *kokkos* berry; M.L. masc. n. *Corallococcus* coral-shaped coccus (i.e., with coral-shaped fruiting bodies).

Vegetative cells are slender rods with tapering ends, cigar-shaped, 0.6–0.8 × 3–8 μm. **Myxospores spherical or ellipsoidal**, often somewhat irregular, 1.3–2.4 μm in diameter. **Fruiting bodies very variable in shape and size** even within one culture: pustules, ridges, slabs, and irregular disks, often with finger-like projections, or raised and bizarre coralloid, **of cartilaginous consistency**. Swarm colonies as are typical for the family. The organisms do not utilize mono- and disaccharides, but may degrade polysaccharides, like starch, into tri- and oligosaccharides, which can be taken up and metabolized.

The mol% G + C of the DNA is: 66–68.

Type species: **Corallococcus coralloides** *comb. nov.* (*Myxococcus coralloides* Thaxter 1892, 404.)

Further descriptive information

The genus is readily distinguished from *Myxococcus* by the cartilaginous consistency of the fruiting bodies and their bizarre shape. In addition, *Corallococcus* fruiting bodies are usually much smaller and are produced in enormous numbers, even in agar cultures. There also are physiological differences, which are described in the Further Descriptive Information section of the description of the family *Myxococcaceae*. *Corallococcus* fruiting bodies can be distinguished from *Archangium* fruiting bodies (which also lack a firm outer wall), by their small size, and by the absence of the large, extended aggregates of fruiting bodies typical of *Archangium*. The swarm structure is also different. *Archangium* swarms produce a tough slime sheet with radial veins, that are the shape and size of the vegetative cells (which are long needles in *Archangium*) and myxospores (which are more heterogeneous and rarely exactly spherical in *Archangium*).

An unsolved problem, however, is the subdivision of the genus *Corallococcus* into species, because of the extreme variability of the fruiting bodies. *Corallococcus coralloides* strains regarded here as typical have relatively large, bizarre coralloid fruiting bodies loosely scattered over the surface of the culture plate and myxospores around 1.6 μm in diameter. There are, however, many variant strains with all kinds of fruiting bodies and myxospores of very different size. Strains with large myxospores can be separated as the species *Corallococcus macrosporus*, and strains with many tiny, brownish fruiting bodies produced in very dense pop-

ulations, as the species *Corallococcus exiguus*, but the remaining *Corallococcus coralloides* strains still must be regarded as forming a composite species. A further complication is that *Pyxicoccus* fruiting bodies may degenerate into *Corallococcus*-like structures, so that if typical *Pyxicoccus* fruiting bodies were not observed before degeneration occurred, *Pyxicoccus* strains would be classified in the *Corallococcus coralloides* complex.

Corallococcus strains are among the most common myxobacteria and are found in unfavorable habitats, such as high mountain or desert areas, where other myxobacteria are not found. They can be isolated from soil, rotting plant material, dung of herbivores, and samples from the drift line at the sea shore. They are difficult to recognize on the surface of natural substrates, as are the myxococci, because *Corallococcus* fruiting bodies are much smaller and do not rise much from the surface. However, they may be conspicuous by their sheer number.

The number of strains in the author's collection may give a rough estimate of the relative abundance of the species: *Corallococcus coralloides* (1624), *Corallococcus exiguus* (172), and *Corallococcus macrosporus* (22).

Key to the species of the genus *Corallococcus*

I. Myxospores spherical or slightly irregular, small to moderately sized, 1.2–1.9 µm in diameter.

A. Fruiting bodies are pustules or branched or unbranched ridges, often with long, finger-like projections or more or less coralloid; white, pale brown, pink, orange, or red; loosely to densely scattered over the agar plate.

Corallococcus coralloides

B. Fruiting bodies are small pustules or narrow ridges, only exceptionally with a short hump; brownish; in agar cultures very densely packed in extended fields. Myxospores large, 1.5–1.9 µm in diameter.

Corallococcus exiguus

II. Myxospores spherical or short, fat rods, large, 1.8–2.2 µm in diameter. Fruiting bodies are ridges, often with finger-like projections; yellow to orange; loosely scattered over the agar surface. Swarm colonies often yellow to orange.

Corallococcus macrosporus

List of species of the genus Corallococcus

1. **Corallococcus coralloides** *comb. nov.* (*Myxococcus coralloides* Thaxter 1892, 404.)
co.ral.lo.i'des. Gr. neut. n. *korallion* coral; Gr. neut. n. *eidos* shape, appearance; M.L. adj. *coralloides* coral-shaped.

Vegetative cells slender rods with tapering ends, 0.7–0.8 × 3–6 µm, tend to be shorter than *Myxococcus* cells.

Fruiting bodies 50–250 µm in size and extremely variable in shape (Fig. BXII.δ.64). May form pustules, ridges, or bands, with or without branches at the sides or at the ends, as well as star, staghorn, and anchor shapes that may end in a long, tapering tail of myxospores or in finger-like projections, which may themselves be branched or bizarrely coralloid and may extend root-like into the agar substrate. Fruiting bodies may be very different in color, depending at least partly on the culture conditions; occur singly or in dense clusters, loosely or densely scattered over the agar surface and normally produced in large numbers. Myxospores spherical, often somewhat deformed, optically refractile, with different strains of very different size, 1.5–1.7 µm in diameter (range: 1.2–1.8 µm); variability in size sometimes occurs within the same fruiting body.

Organisms of this kind are very common in nature, in fact, together with *Nannocystis*, the most common of all myxobacteria. However, the species as delineated here is probably a composite comprising several species. This conclusion is suggested by the very different sizes of myxospores among individual strains. In addition, differences in the specific shapes of fruiting bodies are seen among individual strains and could be a basis for a subdivision of the species. The problem, however, is that there is a considerable overlap of those characteristics, and that the shapes and patterns are not reliably stable. Clearly, molecular taxonomy has to be applied here. The reference strains Cc c1613 and Cc c1616 were chosen because of their typical, coralloid fruiting bodies. Cc c1616 was isolated in 2001 from a sample of rotting *Zostera* leaves in the drift line on the shore of the Isle of Poel off the German Baltic Sea coast; Cc c1613 in 2001 from soil and decaying plant material collected in San Diego, CA, USA.

The mol% G + C of the DNA is: 68 (T_m).

Type strain: M2, ATCC 25202, DSM 2259.

GenBank accession number (16S rRNA): M94278.

Additional Remarks: Reference strains include DSM 14687 (Cc c1613), DSM 14688 (Cc c1616).

2. **Corallococcus exiguus** (ex Kofler 1913) *nom. rev., comb. nov.* (*"Myxococcus exiguus"* Kofler 1913, 367.)
ex.i'gu.us. L. masc. adj. *exigus* small.

Vegetative cells slender rods with tapering ends, 0.7–0.8 × 3–6 µm. Fruiting bodies small pustules or more or less long, narrow ridges, rarely with a low hump or short projection, 20–50 µm wide; brownish; single but in very densely packed, extended fields (Fig. BXII.δ.65). Myxospores spherical, optically refractile, tend to be larger than those of *Corallococcus coralloides*, 1.5–1.9 µm in diameter.

This organism is distinguishable from *Corallococcus coralloides* by its delicate, brownish fruiting bodies, which always appear in enormous numbers, by the lack of projections, and by its relatively large myxospores.

The mol% G + C of the DNA is: not determined.

Type strain: Cc e167, DSM 14696.

GenBank accession number (16S rRNA): DSM 14720 (Cc e163).

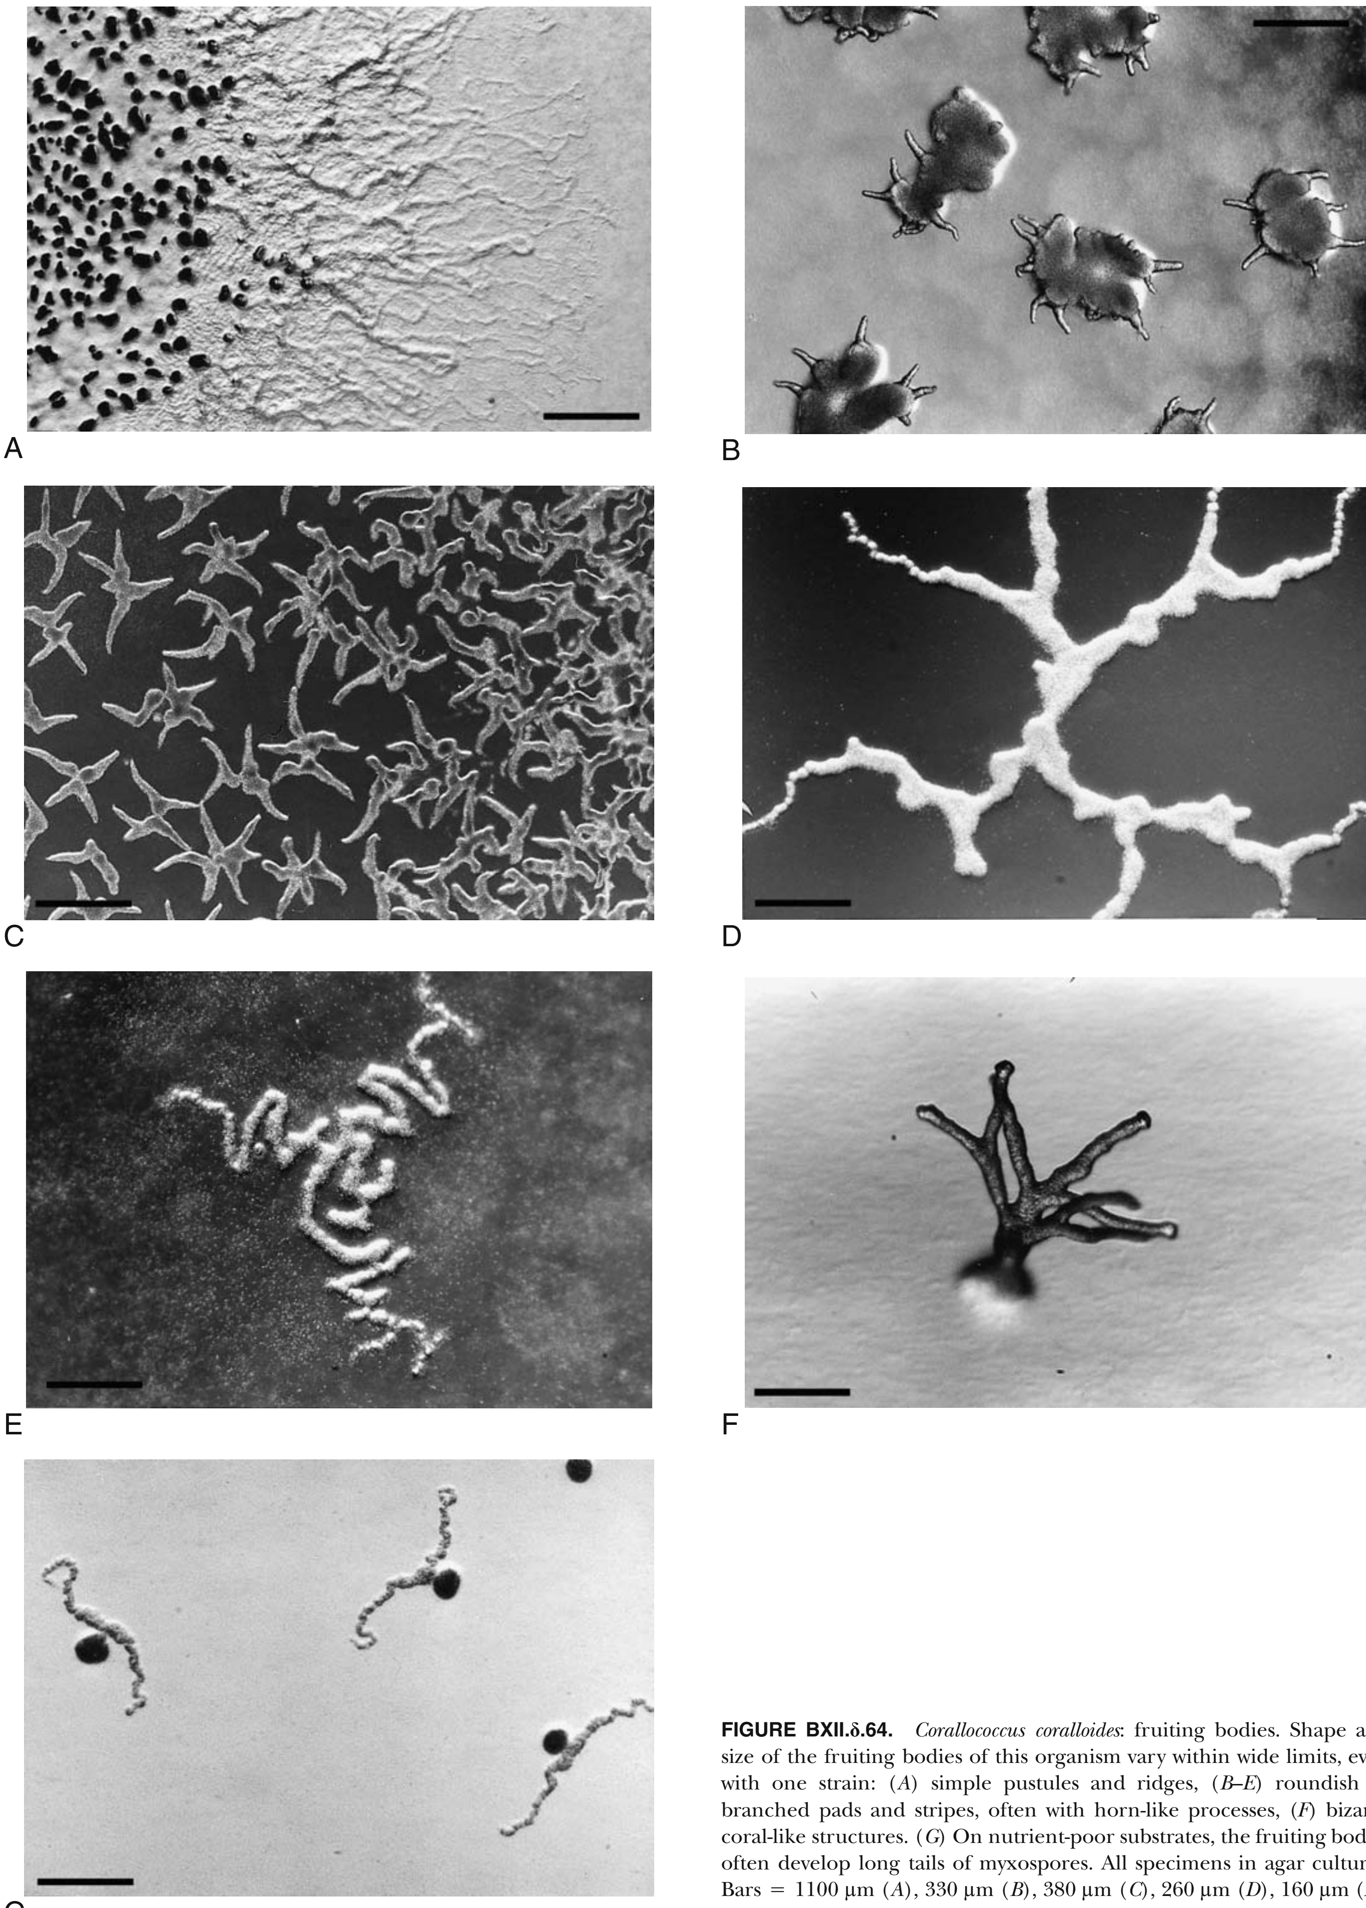

FIGURE BXII.δ.64. *Corallococcus coralloides*: fruiting bodies. Shape and size of the fruiting bodies of this organism vary within wide limits, even with one strain: (*A*) simple pustules and ridges, (*B–E*) roundish or branched pads and stripes, often with horn-like processes, (*F*) bizarre coral-like structures. (*G*) On nutrient-poor substrates, the fruiting bodies often develop long tails of myxospores. All specimens in agar cultures. Bars = 1100 μm (*A*), 330 μm (*B*), 380 μm (*C*), 260 μm (*D*), 160 μm (*E*), 200 μm (*F*), 130 μm (*G*).

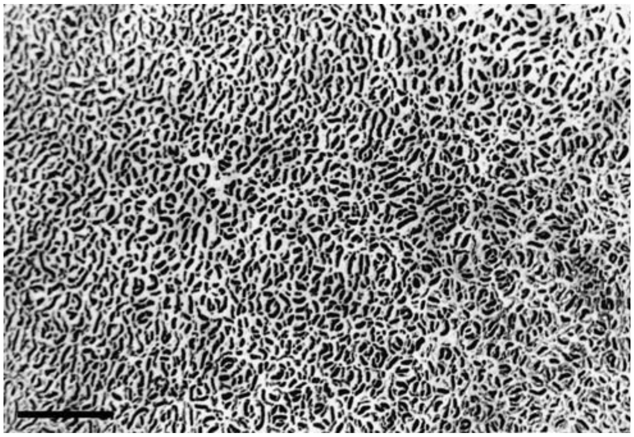

FIGURE BXII.δ.65. *Corallococcus exiguus*: fruiting bodies on agar surface, simple ridges in very dense populations. Bar = 940 μm.

Additional Remarks: While the general description of *Myxococcus exiguus* by Kofler (1913) fits the strains this text refers to quite well, the myxospores of this organism were much smaller, only 1–1.4 μm in diameter. However, measurements with microscopes of those days and of stained smears were perhaps not reliable. In any case, as no type material of Kofler's organism is available, there is no risk of confusion in defining the species anew. *Corallococcus exiguus* is found in the usual myxobacterial habitats and is moderately common. Strain Cc e167 comes from soil with decaying plant material collected in 1992 in Oranje Free State, Republic of South Africa, and was isolated in 1998; reference strain Cc c163 was isolated in 1998 from a soil sample collected in 1994 in Taiwan.

3. **Corallococcus macrosporus** *comb. nov.* (ex Krzemieniewska and Krzemieniewski 1926) *comb. nov.* (*Chondrococcus macrosporus* Krzemieniewska and Krzemieniewski 1926, 16.)
ma.cro.spor′ us. Gr. adj. *makros* long, large; Gr. masc. n. *sporos* seed; M.L. masc. adj. *macrosporus* with large spores.

Vegetative cells slender rods with tapering ends, 0.7–0.8 × 4–8 μm, usually longer than those of the other *Corallococcus* species. Fruiting bodies short to moderately long ridges, often with long, finger-like projections; yellow to orange brown; loosely scattered over the agar surface. Myxospores spherical, optically refractile, 1.8–2.2 μm in diameter. The conversion of vegetative cells into myxospores is often incomplete, and the resulting myxospores are short, fat rods. Swarm colonies as typical for the family, often yellow to orange. At least some strains degrade chitin, which is exceptional among *Corallococcus*. May require vitamin B_{12}.

The mol% G + C of the DNA is: not determined.

Type strain: Cc m8, DSM 14697, JCM 12621.

Reference strains include ATCC 29619, ATCC 29620, ATCC 29039, DSM 14690 (Cc m15).

Additional Remarks: Corallococcus macrosporus is easy to distinguish from the other *Corallococcus* species by the yellow color of its swarm colonies and fruiting bodies, and particularly by its large myxospores. It may be confounded with *Myxococcus virescens*, which sometimes also produces finger-like fruiting bodies, that are, however, soft and not firm. Further, *Corallococcus macrosporus* may be mistaken for a degenerate *Myxococcus virescens* strain if typical fruiting bodies are lacking. *Corallococcus macrosporus* may be found in the same habitats as the other two *Corallococcus* species, but it is much less common. Strain Cc m8 was isolated in 1982 from soil collected in 1981 in Ceylon, Sri Lanka; reference strain Cc m15 was isolated in 1991 from bear feces collected in 1980 in Ontario, Canada.

Other Organisms

Many more *Corallococcus* (= *Chondrococcus*) species have been described. It appears that in most cases investigators were misled by the extreme variability of fruiting body shapes and sizes, and that most of those species belong to the *Corallococcus coralloides* complex. However, some of them may be stable varieties of the species, or may even turn out to be separate species when the *Corallococcus coralloides* complex can finally be broken down. No reference strains are available for any of them, and the names have not been validly published.

"Chondrococcus coralloides" Jahn 1924 is a synonym of *Myxococcus coralloides* Thaxter 1892. *"Chondrococcus cirrhosus"* Jahn 1924 (= *"Myxococcus cirrhosus"* Thaxter 1897), *"Chondrococcus coralloides"* var. clavatus Jahn 1924 (= *"Myxococcus clavatus"* Quehl 1906), *"Chondrococcus coralloides"* var. digitatus Jahn 1924 (= *"Myxococcus digitatus"* Quehl 1906), *"Chondrococcus blasticus"* Beebe 1941b probably belong to the same species. In addition, *"Chondrococcus coralloides"* var. maximus Lièvre 1927 and *"Chondrococcus coralloides"* var. polycistus Jahn 1924 (= *"Myxococcus polycistus"* Kofler) appear to have been *Corallococcus coralloides*, with the distinguishing characteristic that the fruiting bodies are subdivided into parcels, which were called cysts even though an outer wall was lacking; such composite fruiting bodies are indeed seen with *Corallococcus coralloides* strains. *"Chondrococcus simplex"* Singh and Singh 1971 was most likely *Corallococcus coralloides*; the published figures would fit the species. *"Chondrococcus microsporus"* Singh and Singh 1971 had exceedingly small myxospores, 0.4–0.6 μm in diameter; the figure of the fruiting bodies seems to show walled sporangioles. The organism has been found only once, and its status must remain open for the moment. *"Chondrococcus cerebriformis"* Jahn 1924 (= *"Myxococcus cerebriformis"* Kofler 1913) looks more like an *Archangium*-type organism, as does *"Chondrococcus sorediatus"* Singh and Singh 1971 with its long vegetative cells and large, variably shaped myxospores. The same may be the case with *"Chondrococcus megalosporus"* Jahn 1924. *"Chondrococcus cruentus"* Krzemieniewska and Krzemieniewski 1927 and Krzemieniewska and Krzemieniewski 1930 was regarded as identical with *"Myxococcus cruentus"* Thaxter 1897; this is almost certainly not correct. Unfortunately, the description is very scanty, and the figures are not good enough to decide which species this was. *"Chondrococcus columnaris"* Ordal and Rucker 1944 (= *"Bacillus columnaris"* Davis 1921/1922) is not a myxobacterium but a fish-pathogenic *Cytophaga*-like bacterium, presently classified as *Flexibacter columnaris*.

Genus III. **Pyxicoccus** *gen. nov.*

HANS REICHENBACH

Py.xi.coc′cus. Gr. fem. n. *pyxis* box, case, container; Gr. masc. n. *kokkos* berry; M.L. masc. n. *Pyxicoccus* boxed coccus.

Vegetative cells are slender rods with tapering ends, 0.7–0.8 × 3–8 μm. **Myxospores spherical, often somewhat deformed, optically refractile**, 1.4–1.8 μm in diameter (sometimes up to 2.4 μm). **Fruiting bodies consist of more or less spherical sporangioles with a distinct outer wall, clustered in sori of variable size**. In culture, degenerate fruiting bodies resembling those of *Corallococcus coralloides* may be produced. Swarm colonies as are typical for the family: soft and slimy, with snaking, undulating veins, without striking pigmentation. Of the proteolytic-bacteriolytic nutritional type.

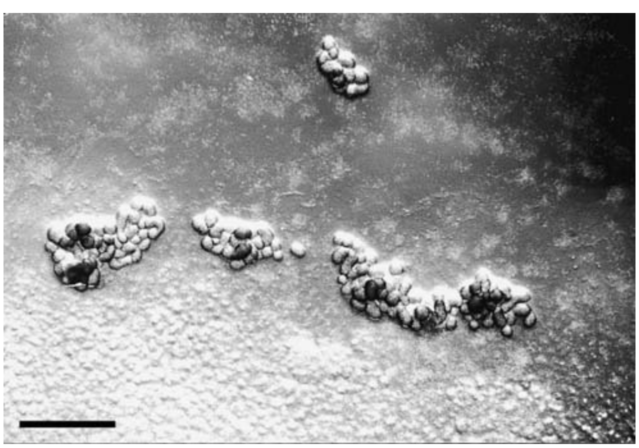
Type species: **Pyxicoccus fallax** *sp. nov.*

FURTHER DESCRIPTIVE INFORMATION

As already discussed, this organism is not identical with *Myxococcus disciformis* Thaxter (=*Angiococcus disciformis* Jahn = *Cystobacter disciformis* McCurdy). The sporangioles of the genus *Pyxicoccus* are smaller, not disk-shaped, and do not stand on edge. Its classification in the family *Myxococcaceae* is clearly supported by 16S rRNA sequence comparisons (Spröer et al., 1999): strain An d1 clusters with *Myxococcus* species. The same study shows, however, that strains belonging to the *Cystobacteraceae* can easily be mistaken for *Pyxicoccus fallax*, as strains An d4 and An d6, which were originally classified as *Pyxicoccus*, cluster with *Archangium*. In principle, the two species should be easy to distinguish, as *Archangium* has long, needle-shaped vegetative cells and swarm colonies with a tough slime sheet and conspicuous radial veins. However, strain degeneration during cultivation may obscure such clear characteristics. It is important to classify a strain as early as possible during isolation. The fruiting bodies of *Cystobacter disciformis* and *Cystobacter minus* could be mistaken for *Pyxicoccus*, as could those of *Hyalangium minus* gen. nov., sp. nov. This organism produces small, brownish sporangioles arranged in chains or sheets. However, they often are empty, translucent, glassy sporangioles among the mature ones, and vegetative cells, myxospores, and swarm structure are different.

List of species of the genus Pyxicoccus

1. **Pyxicoccus fallax** *sp. nov.*
fal′lax. L. masc. adj. *fallax* deceptive.



Vegetative cells, myxospores, and swarm colonies are as described for the genus. The fruiting bodies (Fig. BXII.δ.66) consist of golden brown, somewhat elongated or spherical sporangioles with a distinct wall containing the brown pigment, mostly 30–45 μm in diameter (range: 20–60 μm). The sporangioles are arranged as a monolayer or slightly piled up in sori of variable size, often around 450 × 200–250 μm on agar plates. The diameter of the myxospores (Fig. BXII.δ.67) averages 1.8 μm but varies from 1.5–2.1 μm. Some strains have larger (2.1–2.4 μm) myxospores, but otherwise look exactly like *Pyxicoccus fallax*. They could represent a different species.

Pyxicoccus fallax is found in the usual myxobacterial habitats but is only moderately common. Strain Py f1 was isolated in 1992 from soil with decaying plant material collected a few months earlier on the island of Crete, Greece. Reference strain Py f4 was isolated in 1995 from a similar sample collected in 1994 on Crete, and reference strain Py f5 (= An d1) was isolated in 1980 from soil collected from a city dump near St. Thomé Madras, India.

The mol% G + C of the DNA is: not determined.

Type strain: Py f1, DSM 14698, JCM 12639.

Additional Remarks: Reference strains include DSM 14689 (Py f4), DSM 14699 (Py f5 = An d1).

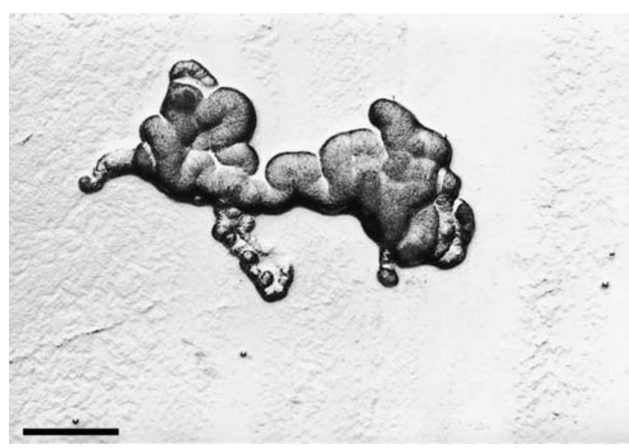


FIGURE BXII.δ.66. *Pyxicoccus fallax*: fruiting bodies on agar plates. *(A)* The fruiting bodies consist of sporangioles in piles or sori. In *B* an incompletely differentiated specimen is shown. The fruiting bodies in *D* and *E* are squeezed (see next page), in *E* more so than in *D*, so that the sporangiole walls can be seen more clearly; both in phase contrast. Bars = 320 μm (*A*), 130 μm (*B,C*), 80 μm (*D*), 40 μm (*E*).

(continued)

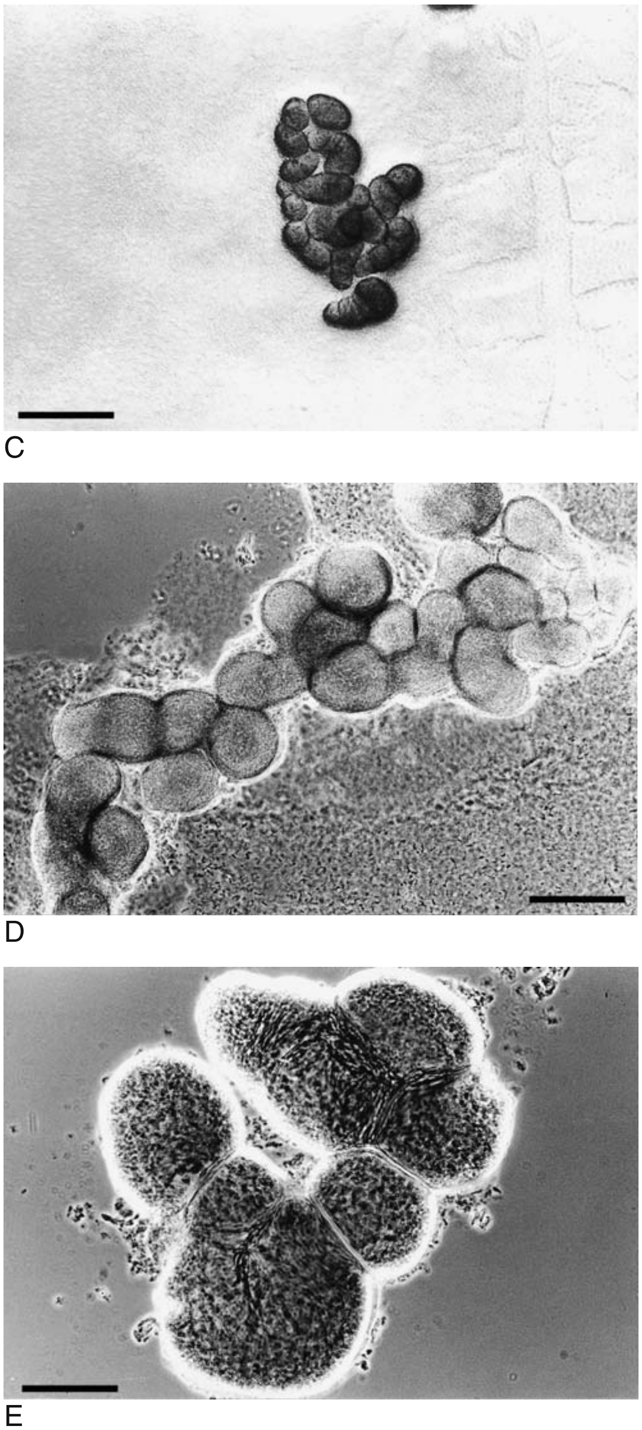

FIGURE BXII.δ.66 (Continued)
(for this figure legend see previous page)

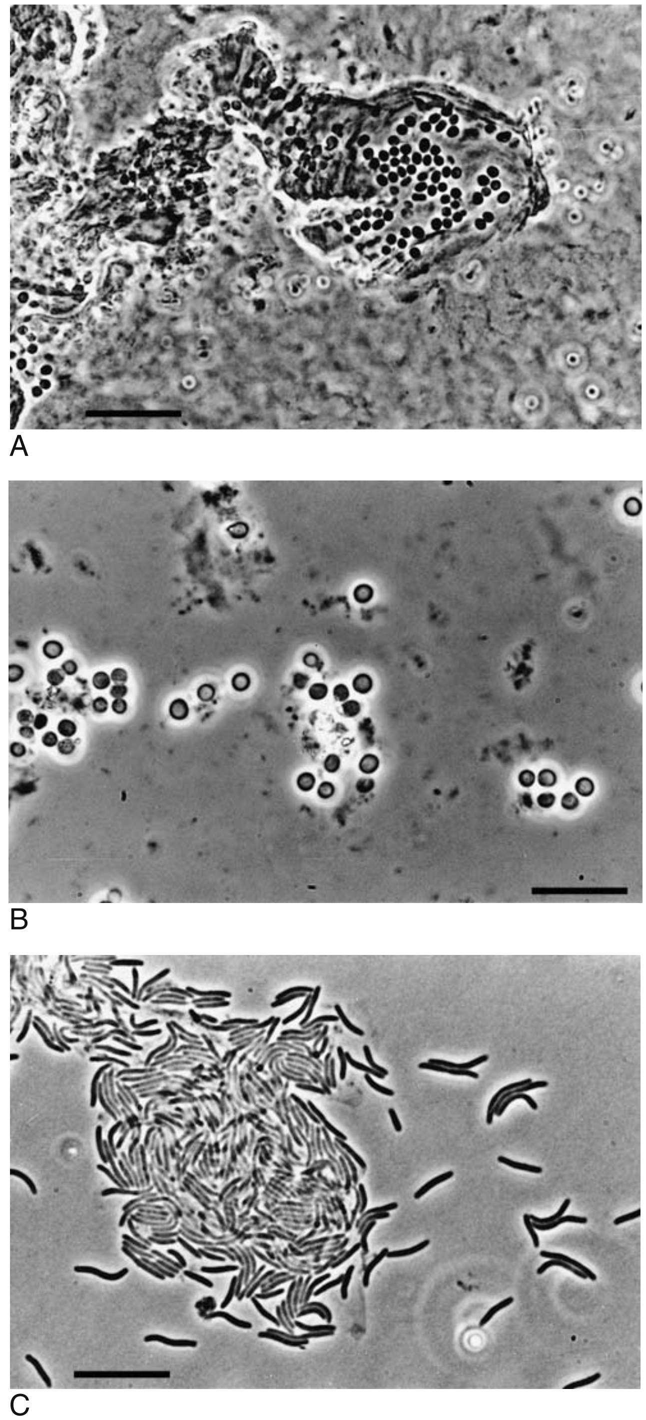

FIGURE BXII.δ.67. *Pyxicoccus fallax*: myxospores from crushed fruiting bodies, and vegetative cells, in phase contrast. In *A*, parts of the sporangiole wall can be seen. *(C)* The vegetative cells of the organism are like those of *Corallococcus* and clearly different from those of *Cystobacter*. Bar = 16 μm (*A*), 10 μm (*B*), 13 μm (*C*).

Family II. **Cystobacteraceae** McCurdy 1970, 286[AL]

HANS REICHENBACH

Cys.to.bac.ter.a′ ce.ae. M.L. masc. n. *Cystobacter* type genus of the family; *-aceae* ending to denote a family; M.L. fem. pl. n. *Cystobacteraceae* the *Cystobacter* family.

Vegetative cells are slender, flexible rods with tapering ends, often long, needle shaped. **The fruiting bodies are either naked masses of slime and myxospores, of cartilaginous consistency,** and of very variable size and irregular shape, or, in most cases, **are made up of pale to deep brown sporangioles** in various arrangements, with or without a slime stalk or pedicle. **Myxospores are short, optically refractile rods to spheroids**, but in the latter case always slightly deformed and accompanied by short rods, **with rounded or tapering ends**.

The swarm colonies produce a firm slime layer with more or less conspicuous, straight, often branched radial veins. The slime sheet may become extremely tough, so that it can hardly be broken with the inoculation loop. Congo red is quickly adsorbed and gives the swarm a purple red color.

Of the proteolytic–bacteriolytic nutritional type. All species utilize mono-, di-, and polysaccharides; some vigorously degrade chitin.

Type genus: **Cystobacter** Schroeter 1886, 170.

Key to the genera of the family Cystobacteraceae

I. Fruiting bodies are naked masses of myxospores embedded in slime of cartilaginous consistency, more or less cushion-like, of very variable shape and size. Vegetative cells long, slender needles. Myxospores short, fat rods with rounded ends.

Genus *Archangium*

II. Fruiting bodies composed of sporangioles with a distinct wall.
   A. Sporangioles sessile.
      1. Sporangioles relatively large, in more or less extended aggregates, often piled up and sometimes surrounded by a translucent slime layer.

         Genus *Cystobacter*

      2. Sporangioles rather small, often glassy, translucent and empty, in chains and sheets.

         Genus *Hyalangium*

   B. Sporangioles borne on (white) slime stalks.
      1. Sporangioles relatively small, spherical, bean- or calotte-shaped, pale brown, solitary on short, delicate stalks, do not degrade chitin.

         Genus *Melittangium*

      2. Sporangioles moderately large, spherical to club shaped, dark red brown, solitary or in clusters on conspicuous stalks. Vegetative cells of moderate length, slender, boat-shaped. Myxospores short, often slightly curved, fat rods with rounded or slightly tapering ends. Degrade chitin very efficiently.

         Genus *Stigmatella*

TAXONOMIC COMMENTS

While it is usually easy to place an isolate in this family, determination of its genus and species is frequently not as unequivocal as it may seem from the key above, because the organisms may not produce typical fruiting bodies. Rather, uncharacteristic structures are seen that are practically indistinguishable from *Archangium* fruiting bodies, i.e., structures that are very variable in shape and size, that have ridges or cushion-like masses, that sometimes pile up and form finger-like projections, and that are often very large due to fusion of adjacent fruiting bodies. For this reason, the family *Archangiaceae* has been omitted in this edition of the *Manual*: the borderline between *Archangium* and the genera with sporangioles is markedly fluid. One may even doubt whether a separate genus *Archangium* is justified. In problematic cases one has to rely on additional characteristics such as the shape and size of vegetative cells and myxospores (both of which appear to be relatively stable features), the swarm structure; or degradation of chitin. But the differences between genera and species with respect to these characteristics are often minimal, and their usefulness is limited by the degree of experience of the investigator. A further source of confusion lies in the fact that apparently not all species and even genera of the family have been isolated and studied, so that organisms that cannot readily be assigned to an existing genus may represent new taxa.

The nomenclature of the genera of the family is somewhat muddled, mainly because the taxonomic relevance of the shape of the vegetative cells was not understood until the 1960s. The type genus of the family, *Cystobacter*, was described by Schroeter (1886) with the two species *Cystobacter fuscus* and *"Cystobacter erectus"* (now *Stigmatella erecta*), although Schroeter did not recognize the peculiar life cycle of the organisms. In 1897 Thaxter described *Cystobacter fuscus* again, now as a myxobacterium. He acknowledged Schroeter's priority and used his name for the organism. However, in 1904, after having discovered the very old description of *Polyangium vitellinum* Link 1809, he renamed it *"Polyangium fuscum"*, being misled by similarities in fruiting body shape and structure. In the following years a series of further species were added to that genus. As is recognized today, they are actually quite different organisms and are separated in two suborders. This sequence of events has to be kept in mind when trying to understand the older literature. Only in 1970 were the real connections finally recognized, and the genus *Cystobacter* was reestablished (McCurdy, 1970).

The genus *Archangium* was established by Jahn (1924) to comprise several previous and two new species with fruiting bodies consisting of convoluted, braided strings of rod-shaped myxo-

spores in hardened slime, without an outer wall. The genus is problematic, as will be discussed below.

The genus *Stigmatella* has a tortuous history as well. *Stigmatella aurantiaca* was first described by Berkeley and Curtis (in Berkeley, 1857) as a mold and was rediscovered by Thaxter in 1892, who named it *"Chondromyces aurantiacus"*, again misled by a superficial similarity of fruiting body structure between *Chondromyces crocatus* and *Stigmatella aurantiaca*. In fact, the organism had in the meantime been described two more times as a mold, *Stilbum rhytidospora* Berkeley and Broome 1873 and *"Polycephalum aurantiacum"* Kalchbrenner and Cooke 1880. In 1969, workers in the field realized that the organism is not directly related to *Chondromyces*, and the genus *Stigmatella* was restored (McCurdy and Khouw, 1969; Reichenbach and Dworkin, 1969). The second of Schroeter's species, *"Cystobacter erectus"*, was also found by Thaxter, who described it in 1897 as *"Chondromyces erectus"*. Jahn (1924) created a new genus, *Podangium*, for it, because he felt that fruiting bodies with one single sporangiole on a stalk were sufficiently different from *Chondromyces* to justify that separation.

The genus *Melittangium* also has a complicated history. The first species was described by Thaxter in 1892 as *"Chondromyces lichenicolus"* (etymologically correct *lichenicola*). Jahn (1924) transferred it to the genus *Podangium*; at the same time he created the genus *Melittangium* for his new species, *Melittangium boletus*. Later the species *"C. lichenicola"* was transferred to the genus *Melittangium* (McCurdy, 1971b).

The new genus *Hyalangium* will be discussed below.

Genus I. **Cystobacter** *Schroeter 1886, 170*[AL]

Hans Reichenbach

Cys.to.bac'ter. Gr. fem. n. *kystis* bladder; M.L. masc. n. *bacter* from Gr. fem. n. *bakteria* rod, stick; M.L. masc. n. *Cystobacter* bladder-forming rod.

The history of the genus *Cystobacter* and the problems associated with its recognition are discussed above in the introduction to the family. The fruiting body shape and structure of *Cystobacter* is similar to fruiting bodies produced by *Polyangium*, *Sorangium*, *Byssophaga*, *Jahnia*, *Pyxicoccus*, and to a certain extent, *Stigmatella hybrida*. The genus as it is presented here still is heterogeneous and probably comprises at least three different genera. One group of species, with *Cystobacter fuscus* as the main representative, has slender, often slightly C- or S-shaped bent, rod-shaped myxospores with more or less tapering ends. Many strains of this group are efficient chitin degraders. The second group, represented by *Cystobacter disciformis*, has myxospores that are stout, short, fat rods, very much like myxospores of *Archangium gephyra*. These organisms rarely attack chitin. A third group, centered around *Cystobacter gracilis*, has delicate vegetative cells with tapering ends, and small myxospores that are straight or slightly bent rods with rounded ends. Analysis of the available 16S rRNA sequences separates at least the first two groups rather neatly (Spröer et al., 1999).

Type species: **Cystobacter fuscus** Schroeter 1886, 170.

Key to the species of the genus *Cystobacter*

I. Sporangioles brown; myxospores relatively slender rods of moderate length and with more or less tapering ends.
   - A. Sporangioles large, spherical, chestnut brown, in sori with a thick, hyaline, and colorless slime capsule, glistening; efficient chitin degraders.
     Cystobacter fuscus
   - B. Sporangioles moderately large to large, of clearly different size within the sorus, spherical to elongated, dark brown and dull, in convoluted chains appressed to the surface, but ends often pointing upward, without a conspicuous slime matrix; efficient chitin degraders.
     Cystobacter ferrugineus
   - C. Sporangioles moderately large to large, spherical to elongated, in long chains that sometimes form three-dimensional networks, but also may be tightly packed and appressed to the surface, solitary sporangioles, usually on a short slime pedicle or stalk, always dark chestnut brown to almost black, dull, sorus without a slime matrix; efficient chitin degraders.
     Cystobacter badius
   - D. Sporangioles large, yellow-brown to red-brown, spherical, often in chains that may form a three-dimensional network, covered by a delicately plicated, thin slime sheet that gives many of the sporangioles a striking lengthwise striation; may or may not attack chitin.
     Cystobacter velatus

II. Sporangioles brown; myxospores very short fat rods to almost spherical; most strains do not attack chitin.
   - A. Sporangioles moderately large, in crude cultures disk-shaped, the disks often standing on edge, in pure cultures in sori appressed to the substrate; myxospores more or less spherical.
     Cystobacter disciformis
   - B. Sporangioles moderately large, spherical, in sori without a slime matrix; myxospores short, fat rods.
     Cystobacter minus

C. Sporangioles large, dark brown, dull, in large sori without a slime matrix; myxospores short rods with rounded ends, often slightly bent; some strains produce a dark violet pigment.
Cystobacter violaceus

D. Sporangioles moderately large, in sori without a slime matrix; vegetative cells delicate, needle-shaped; myxospores small, short, slender rods with rounded ends; some strains degrade chitin.
Cystobacter gracilis

III. Sporangioles apricot colored or red.

A. Sporangioles apricot colored, moderately large to large, in sori without a slime matrix; does not degrade chitin.
Cystobacter armeniaca

B. Sporangioles cinnabar red, large, spherical to slightly elongated, in large sori that are often erect, board-like, with a thin, glassy slime envelope, efficient chitin degrader.
Cystobacter miniatus

List of species of the genus Cystobacter

1. **Cystobacter fuscus** Schroeter 1886, 170[AL]
fus' cus. L. masc. adj. *fuscus* dark brown.

Vegetative cells are long, slender rods with tapering ends, needle-shaped, i.e., with parallel sides and shortly pointed ends, 0.8 × 5–15 μm (Fig. BXII.δ.68). Sporangioles spherical or ellipsoidal, bright chestnut brown, glistening, 50–180 μm in diameter, in groups (sori) of up to 100 in a common gelatinous, hyaline, colorless slime matrix like a capsule (Fig. BXII.δ.69). Myxospores rather slender rods with pointed ends, often slightly C- or S-shaped, optically refractile, 0.8–1.5 × 2.5–5 μm. Swarm colonies produce a tough slime sheet with veins (Fig. BXII.δ.70), tenacious and difficult to break, often with extended fields of oscillating waves, on peptone agar producing a dark red-brown, diffusing pigment. Grows well on the standard media for myxobacteria. Relatively simple defined media have been found for the organism (Reichenbach and Dworkin, 1992).

Cystobacter fuscus is found in soil and on dung of herbivorous animals; it is moderately common.

The mol% G + C of the DNA is: 68 (T_m).

Type strain: M29, ATCC 25194, DSM 2262.

GenBank accession number (16S rRNA): M94726.

Additional Remarks: Reference strains include ATCC 25195, ATCC 25529, ATCC 29623.

The species is relatively easy to recognize. On yeast agar (VY/2-), it produces copious amounts of typical fruiting bodies for some time after isolation. Later, however, the usual degenerate ridges and padded masses arise. The glistening, chestnut brown fruiting bodies with a hyaline slime matrix, the slender myxospores, and efficient chitin degradation are the hallmarks of the species.

Thaxter caused some confusion when he first renamed his *"Myxobacter aureus" "Cystobacter aureus"* (Thaxter 1897, 408) and then, in 1904, equated it with both *Polyangium*

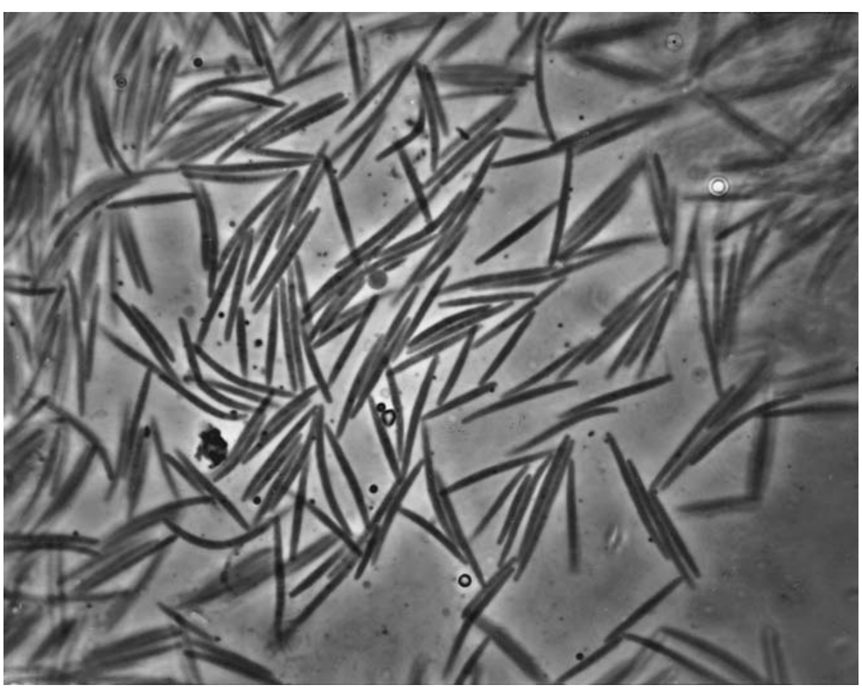

FIGURE BXII.δ.68. *Cystobacter fuscus* vegetative cells. Light micrograph (×1500).

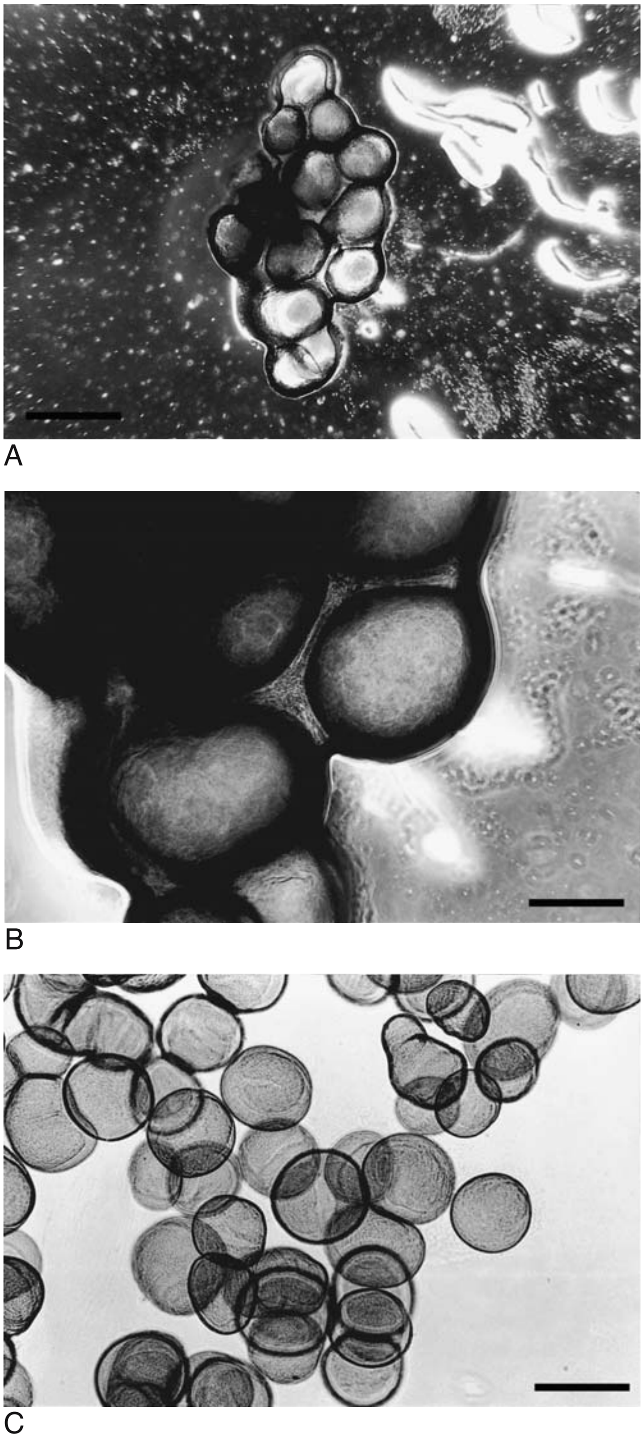

FIGURE BXII.δ.69. *Cystobacter fuscus*: fruiting bodies: (*A* and *B*) on agar surface, (*C*) in embedding medium. The spherical shape, and the rather uniform size of the shining sporangioles and the slime matrix around them are typical. Bar in *A* = 155 μm; bar in *B* = 50 μm; bar in *C* = 100 μm.

vitellinum (Thaxter, 1904), which is most likely correct, and with *Cystobacter fuscus*, which was obviously an error.

2. **Cystobacter armeniaca** *sp. nov.*
ar.me.nia′ ca. Gr. fem. n. *melea armeniaka* apricot tree; M.L. fem. n. *armeniaca* for apricot-colored.

Vegetative cells are rods with tapering ends, of moderate length, 0.8 × 4–8 μm. Swarm colonies with a tough slime sheet and fine radial veins. Fruiting bodies consist of spherical, intensely apricot-colored, orange sporangioles, 60–150 μm in diameter, in sori of variable size, often piled up. Tend to degenerate into ridges and irregular masses of slime and myxospores. Myxospores moderately long and fat rods with rounded or slightly tapered ends, 1–1.2 × 2–4 μm, often C-or S-shaped.

Of the proteolytic–bacteriolytic nutritional type. Individual strains may degrade chitin.

Cystobacter armeniaca somewhat resembles *Cystobacter velatus*, but does not produce looping chains of striated sporangioles and has strikingly apricot-colored fruiting bodies.

Cystobacter armeniaca is found in the usual myxobacterial habitats; it is moderately common. Strain Cb a1 was isolated in 1997 from soil with decaying plant material collected in the Sonoran savanna west of Tucson, AZ, USA. Reference strain Cb a3 comes from a similar sample from the same region.

The mol% G + C of the DNA is: not determined.

Type strain: Cb a1, DSM 14710, JCM 12622.

Additional Remarks: Reference strains include DSM 14711 (Cb a3).

3. **Cystobacter badius** *sp. nov.*
ba′ di.us. L. masc. adj. *badius* chestnut brown.

Vegetative cells are long, slender rods with pointed ends, somewhat shorter than those of *Cystobacter fuscus*, 0.7–0.9 × 6–10 μm. The myxospores, too, are stouter and rod shaped with tapering or blunt ends, often slightly C- or S-shaped, 1.0–1.5 × 3–4 μm. The slime layer of the swarm colony is less tenacious and more frangible. The main distinguishing characteristic is the morphology of the fruiting bodies (Fig. BXII.δ.71). Sporangioles are spherical to elongated, of variable size, 30–180 μm in diameter; in chains that often loop upward but occasionally form three-dimensional networks; ends of sporangioles often point upward; surface of sori therefore rather turbulent; very dark brown to almost black; dull on the plate but glistening at higher magnification; only a trace of a slime matrix around the fruiting bodies, sometimes producing a fine striation; sporangioles often also solitary and then usually on a wrinkled slime cushion or pedicle. Due to the brittle slime sheet of the swarm, the fruiting bodies can easily be removed from the plate.

Growth pattern and nutritional requirements as for *C. fuscus* and *C. ferrugineus*.

Cystobacter badius differs from *Cystobacter ferrugineus* in the looping chains of sporangioles, the single sporangioles on slime cushions, and the stouter vegetative cells and myxospores; *Cystobacter badius* differs from *Cystobacter velatus* in the much darker color of the fruiting bodies, the absence or rare occurrence of three-dimensional networks of sporangioles, and the lack of a delicately plicated slime cover on the sporangioles, also in the occurrence of individual sporangioles on slime cushions. The two species are sometimes very similar. It seems, however, that, in contrast to *Cystobacter badius*, *Cystobacter velatus* normally does not degrade chitin. *Cystobacter badius* differs from *Stigmatella hybrida* in the lack of sporangioles with real stalks, in the production of large sori, in the shape of vegetative cells and myxospores, and in swarm morphology.

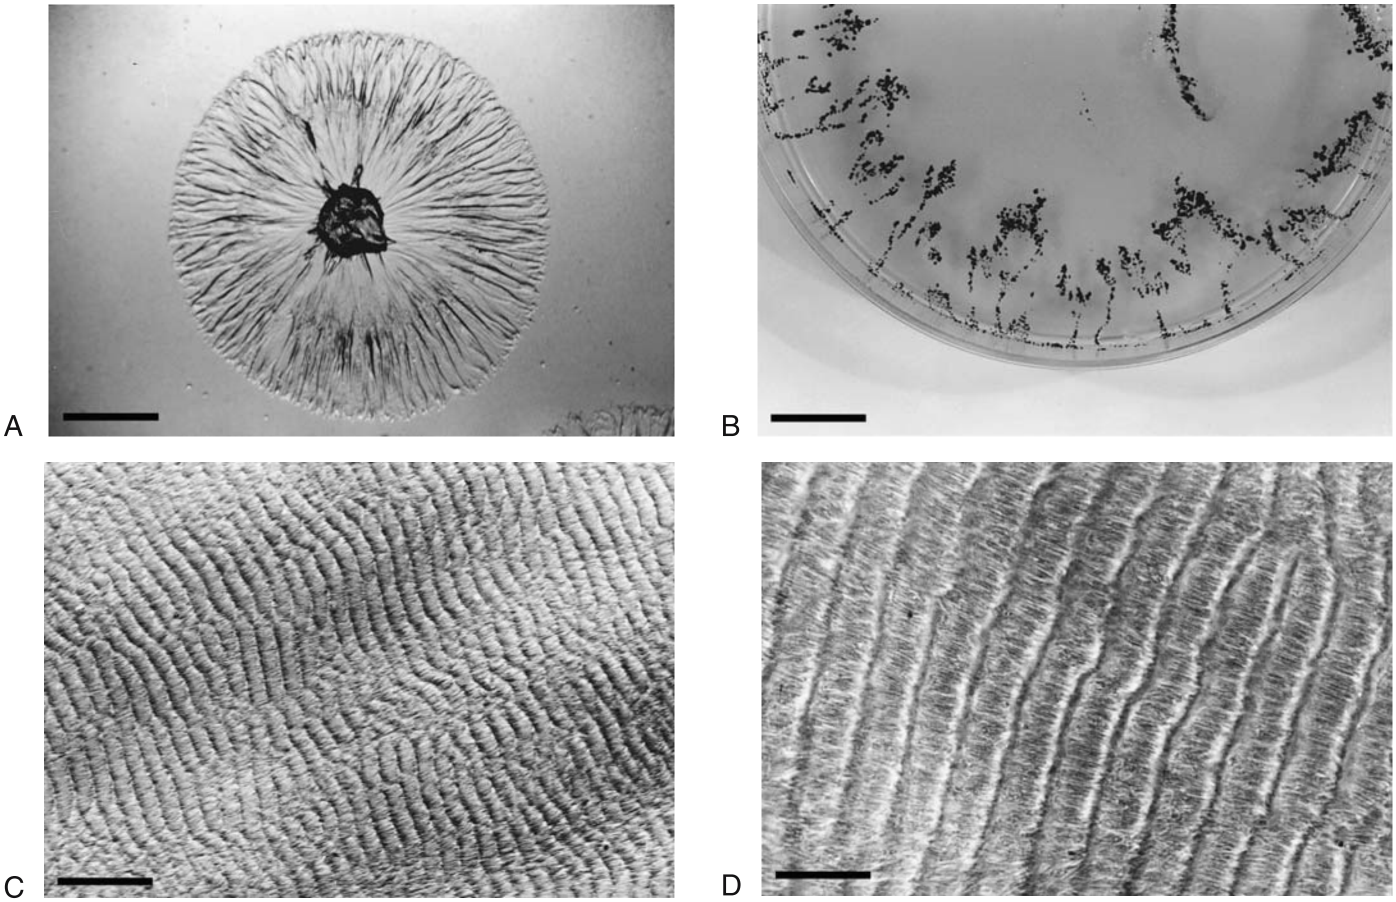

FIGURE BXII.δ.70. *Cystobacter fuscus*: swarm colonies on agar plates. (*A*) Young swarm with straight radial veins as is typical for the family. (*B*) Large swarm with many fruiting bodies. (*C*) The swarms often show extended fields of oscillating waves composed of rows of strictly aligned vegetative cells (*D*). Bar in *A* = 3 mm; bar in *B* = 13.5 mm; bar in *C* = 50 μm; bar in *D* = 20 μm.

Cystobacter badius may be obtained from soil and dung of herbivorous animals; it is moderately common, especially in habitats with a warm, semi-arid climate.

Strain Cb b2 was isolated in 1997 from a soil sample collected in the saguaro savanna west of Tucson, AZ, USA. Reference strain Sg a10 was isolated in 1998 from a similar sample from the island of Malta, and reference strain Cb b11 comes from a soil sample collected in the Dominican Republic and was isolated in 1998.

The mol% G + C of the DNA is: not determined.

Type strain: Cb b2, DSM 14723, JCM 12623.

Additional Remarks: Reference strains include DSM 14738 (Sg h10), DSM 14715 (Cb b11).

4. **Cystobacter disciformis** *comb. nov.* (Thaxter 1904) Brockman and McCurdy *in* McCurdy 1989, 2152 (*Myxococcus disciformis* Thaxter 1904, 89; *Angiococcus disciformis* (ex Jahn 1924, 89) Hook, Larkin and Brockman 1980, 142.)
dis.ci.for' mis. Gr. masc. n. *diskos* disk; L. fem. n. *forma* form, shape; M.L. masc. adj. *disciformis* disk-shaped.

Vegetative cells are slender rods, needle-shaped, 0.7 × 5–10 μm. Fruiting bodies consist of spheroidal, disk-shaped sporangioles, 30–50 μm in diameter and 15 μm thick, in crude cultures often standing on edge, interconnected, forming heaped groups or a three-dimensional network, occasionally on a slime pedicle. In pure culture, the sporangioles tend to lie flat on the surface and are grouped in sori. At first yellowish, then later orange brown. Myxospores ellipsoidal or irregularly spherical, 1–1.5 μm in diameter.

Swarm colonies with a tough slime sheet and radial veins. Of the proteolytic–bacteriolytic nutritional type.

Originally obtained from muskrat and deer dung; appears to be common in slightly acid forest soils and in the fossa region of alkaline peat bogs in Michigan, USA.

The mol% G + C of the DNA is: 68 (Bd).

Deposited strain: ATCC 33172.

The species was placed in the genus *Cystobacter* by McCurdy (1989) in the last edition of this *Manual*. The problems associated with this species, the genus *Angiococcus*, and their relationships to the new genus *Pyxicoccus* are discussed in the Comments on the family *Myxococcaceae*. *Cystobacter disciformis* is clearly different from the above-described group of *Cystobacter* species and perhaps belongs in a genus of its own, which should be named *Angiococcus*. *Cystobacter disciformis* is similar to *Cystobacter minus*, but clearly differs from it in its disk-shaped sporangioles and small myxospores.

Three more species of *Angiococcus* have been described by Singh and Singh (1971), but their status is not clear. Most likely, the organisms are *Cystobacter* species. Type strains are not available. *"Angiococcus brunneus"* has large (90–185 μm), dark brown sporangioles, single or in heaps,

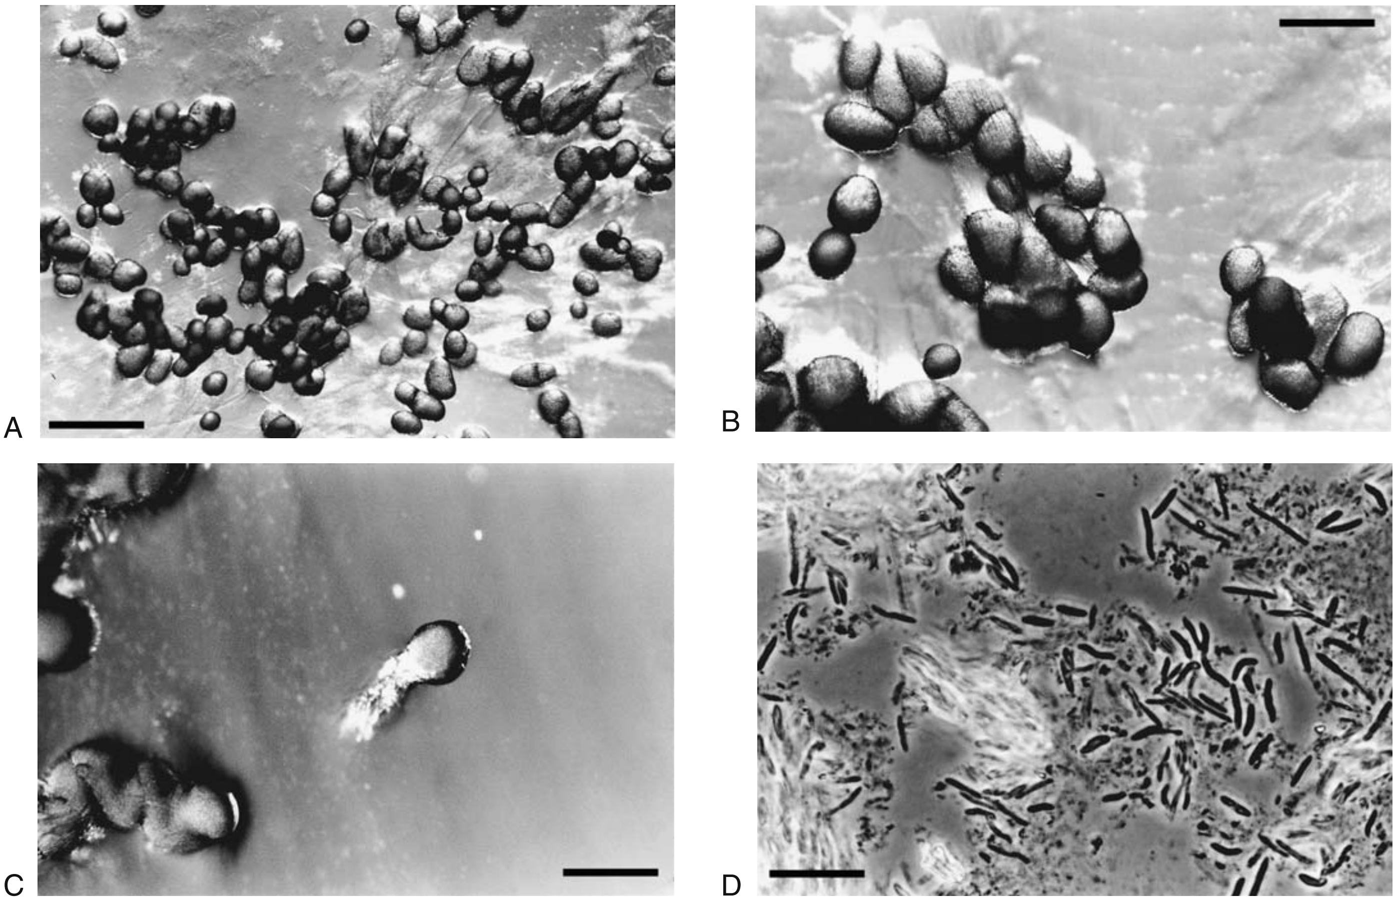

FIGURE BXII.δ.71. *Cystobacter badius*: fruiting bodies on agar plates, and myxospores (*D*) from crushed sporangioles, the latter in phase contrast. The sporangioles are typically either single, often on short slime pedicles (*C*), or in convoluted chains. Bar in $A = 260$ μm; bar in $B = 125$ μm; bar in $C = 155$ μm; bar in $D = 13$ μm.

and large, ellipsoidal to spherical myxospores. *"Angiococcus aureum"* (sic) produces fruiting bodies with very large (50–90 × 140–230 μm), ellipsoidal to elongated, golden colored sporangioles in loose groups. The myxospores are irregularly spherical to ellipsoidal and very large. The sporangioles of *"Angiococcus thaxteri"* are much smaller (30–60 μm) and are densely packed; the myxospores are spherical and medium sized. This species could actually fit *Cystobacter disciformis*. All three species have long, slender vegetative cells with tapering ends; those of *"Angiococcus aureum"* are very fat, measuring 1.0–1.4 μm in width. *"Angiococcus cellulosum"*, described by Mishustin (1938), turned out to be a fungus, *Rhizophlyctis rosea* (Singh and Singh, 1971), while tentatively classified *"Angiococcus moliroseus"* was an actinomycete, *Streptosporangium roseum* (Peterson and McDonald, 1966).

5. **Cystobacter ferrugineus** (Krzemieniewska and Krzemienwski 1927) McCurdy 1970, 288[AL] (*"Polyangium ferrugineum"* Krzemieniewska and Krzemieniewski 1927, 89.)
fer.ru.gi' ne.us. L. masc. adj. *ferrugineus* of the color of iron rust.

Vegetative cells, myxospores, swarm morphology, and growth characteristics as for *Cystobacter fuscus*. The species is distinguished by its fruiting bodies (Fig. BXII.δ.72). The sporangioles are moderately large to large, spherical and often elongated, of variable size even within the same fruiting body, dark chestnut brown, and, in contrast to *Cystobacter fuscus*, dull. They are produced preferentially in long, convoluted chains, the ends of which often are pointing upward. The chains of sporangioles are usually tightly packed, somewhat piled up, and appressed to the substrate, without a prominent slime matrix. The diameter of the sporangioles is 30–180 μm. The usual degenerate fruiting bodies are formed after a strain has been cultivated for some time. The species closely resembles *Cystobacter badius*. It differs in the lighter color of the fruiting bodies and in the lack of solitary sporangioles on slime pedicles.

The organism is found in soil and on dung of herbivores, and is moderately common. Strain Cb fe18 was isolated in 1983 from a soil sample collected on the Chalkidike Peninsula, Greece; the reference strain, Cb fe37, comes from a soil sample with decaying plant material collected in 1996 near Braunschweig, Germany..

The mol% G + C of the DNA is: not determined.

Type strain: Cb fe18, DSM 14716, JCM 12624.

Additional Remarks: Reference strains include DSM 14717 (Cb fe37).

6. **Cystobacter gracilis** *sp. nov.*
gra' ci.lis. L. adj. *gracilis* slim, slight.

Vegetative cells (Fig. BXII.δ.73) are rather short, delicate rods with tapering ends, 0.5–0.6 × 3–5 μm. Swarm colonies

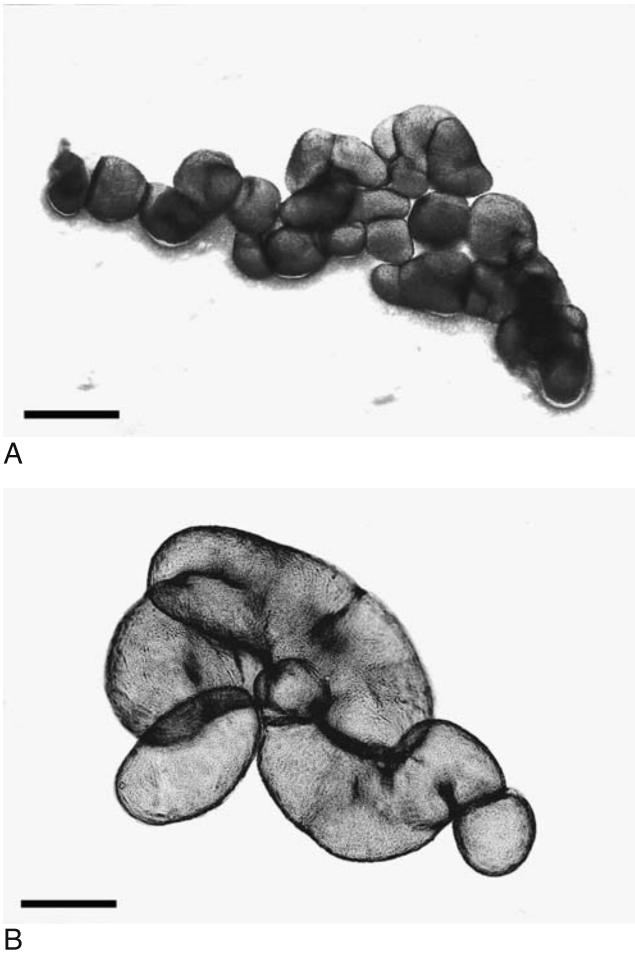

FIGURE BXII.δ.72. *Cystobacter ferrugineus*: fruiting bodies: (*A*) on agar surface, (*B*) in embedding medium. Dull, irregular sporangioles of very different size are typical. Bar in $A = 125$ µm; bar in $B = 55$ µm.

with a thin, tough, locally delicate plicated slime sheet and fine radial veins, more or less red-brown and even violet, sometimes intensely so. On peptone (CY-) agar the swarms spread only reluctantly and produce an intense, red-brown, diffusing pigment. Fruiting bodies (Fig. BXII.δ.74) orange-brown to dark red-brown; sporangioles more or less spherical, 30–80 µm in diameter. However, in cultures, degenerate fruiting bodies in the shape of short to moderately long, thin to somewhat broadened ridges and cushion-like, bulging masses are the rule. Myxospores are short, relatively slender, sometimes comma-shaped rods with rounded ends to almost spherical, small, 0.8–1.4 × 1–3 µm, optically refractile.

Of the proteolytic–bacteriolytic nutritional type. Does not attack chitin and cellulose.

The outstanding characteristics of this species are the short, delicate vegetative cells and rather small myxospores. Also typical is the thin but very tough slime sheet with very fine radial veins. *Cystobacter gracilis* probably represents a genus of its own in a complex of strains that may contain even more species.

Cystobacter gracilis is found in the usual myxobacterial habitats; it is moderately common. Strain Cb g1 was isolated in 1996 from a soil sample with decaying plant material collected in the same year near Beni-Suef, Egypt, by Dr. Mohamed Khalil. The origins of the reference strains are as follows: Cb g2 was isolated in 1996 from a similar sample collected in 1996 near Giza, Egypt; Cb g13 was isolated in 1997 from soil with rabbit dung collected in 1996 near Benson, Arizona, USA; Cb g30 was isolated in 1998 from rotting wood collected in 1998 in the Alsace, France.

The mol% G + C of the DNA is: not determined.

Type strain: Cb g1, DSM 14753, JCM 12625.

Additional Remarks: Reference strains include DSM 14771 (Cb g2), DSM 14754 (Cb g13), DSM 14755 (Cb g30).

7. **Cystobacter miniatus** *sp. nov.*
mi.ni.a′tus. L. masc. adj. *miniatus* cinnabar-red.

Vegetative cells are long, slender, needle-shaped rods, 0.8– 0.9 × 6–10 µm. Swarm colonies with fine radial veins in a brittle slime sheet. Sporangioles spherical to elongated, intensely cinnabar-red, 80–180 µm in diameter, densely packed in large sori with a common, glassy slime envelope, often as a slab strikingly board-like and erect (Fig. BXII.δ.75). Degenerate fruiting bodies in the form of jaggedly branched ridges, bands, knobs, and plaques; also intensely red Fig. BXII.δ.76. Myxospores relatively slender rods with tapering ends, 0.9–1.2 × 2–4 µm, optically refractile.

Of the proteolytic–bacteriolytic nutritional type. Does not attack cellulose but degrades chitin very efficiently.

Cystobacter miniatus is unique and easy to recognize by its cinnabar-red fruiting bodies in large, dense sori that stand in a board-like, upright position. Further, it is a strong chitin degrader, which distinguishes it from *Cystobacter armeniaca*. Its closest relatives are probably among the *Cystobacter fuscus* complex.

Cystobacter miniatus may be found in the usual myxobacterial habitats, but appears to be a rare species. Strain Cb a24 was isolated in 1999 from a sample of rotting sawdust and other decaying plant material collected on the island of Mallorca, Spain, reference strain Cb mi3 was isolated from soil with decaying plant material collected in 1998 in Botswana, South Africa.

The mol% G + C of the DNA is: not determined.

Type strain: Cb a24, DSM 14712, JCM 12626.

Additional Remarks: Reference strains include DSM 14756 (Cb mi3).

8. **Cystobacter minus** (Krzemieniewska and Krzemieniewski 1926) McCurdy 1970, 288[AL] (*Polyangium minus* Krzemieniewska and Krzemieniewski 1926, 33.)*
mi′nus. L. neut. adj. *minus* smaller, less, comparative of *parvus* small.

Vegetative cells are slender, needle-shaped rods with tapered ends, 0.7 × 3–11 µm. Swarm colonies with fine radial veins in a tough slime sheet. Sporangioles spherical or ellipsoidal, relatively small, 20–70 × 20–50 µm, dull grayish to dark yellow-brown and red-brown, with a definite wall, 0.5–1 µm thick, arranged in flat sori up to 500 µm wide within a thin colorless slime layer, often also piled up, sometimes forming branched tree-like structures; when tightly

**Editorial Note:* The neuter form, *minus*, which was correct with *Polyangium*, has been used by mistake for *Cystobacter*, which is a masculine noun; however, according to the Bacteriological Code, the name cannot be corrected.

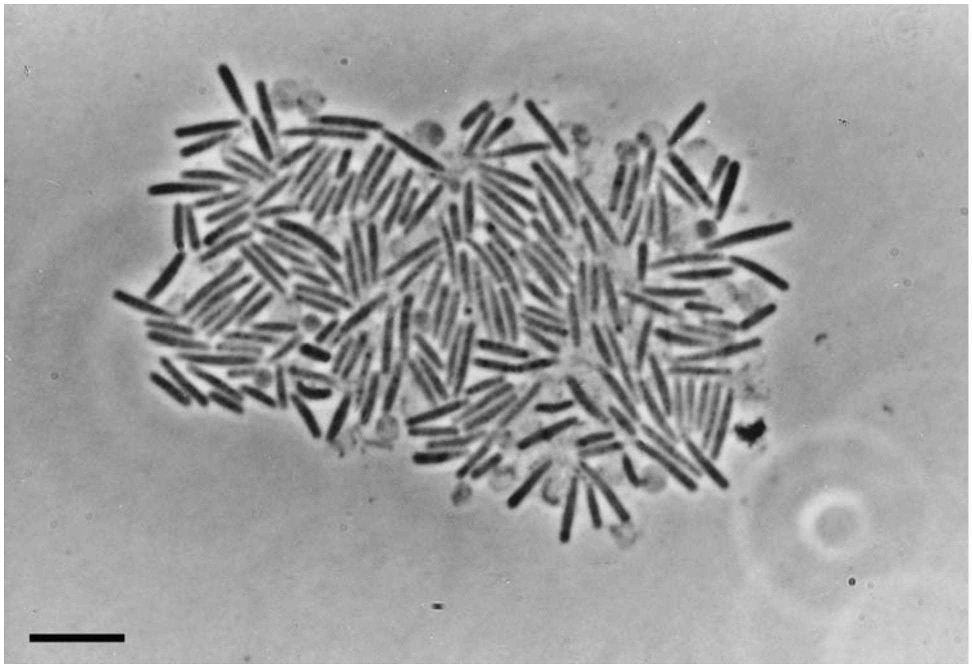

FIGURE BXII.δ.73. *Cystobacter gracilis*: vegetative cells, in phase contrast. Bar = 10 μm.

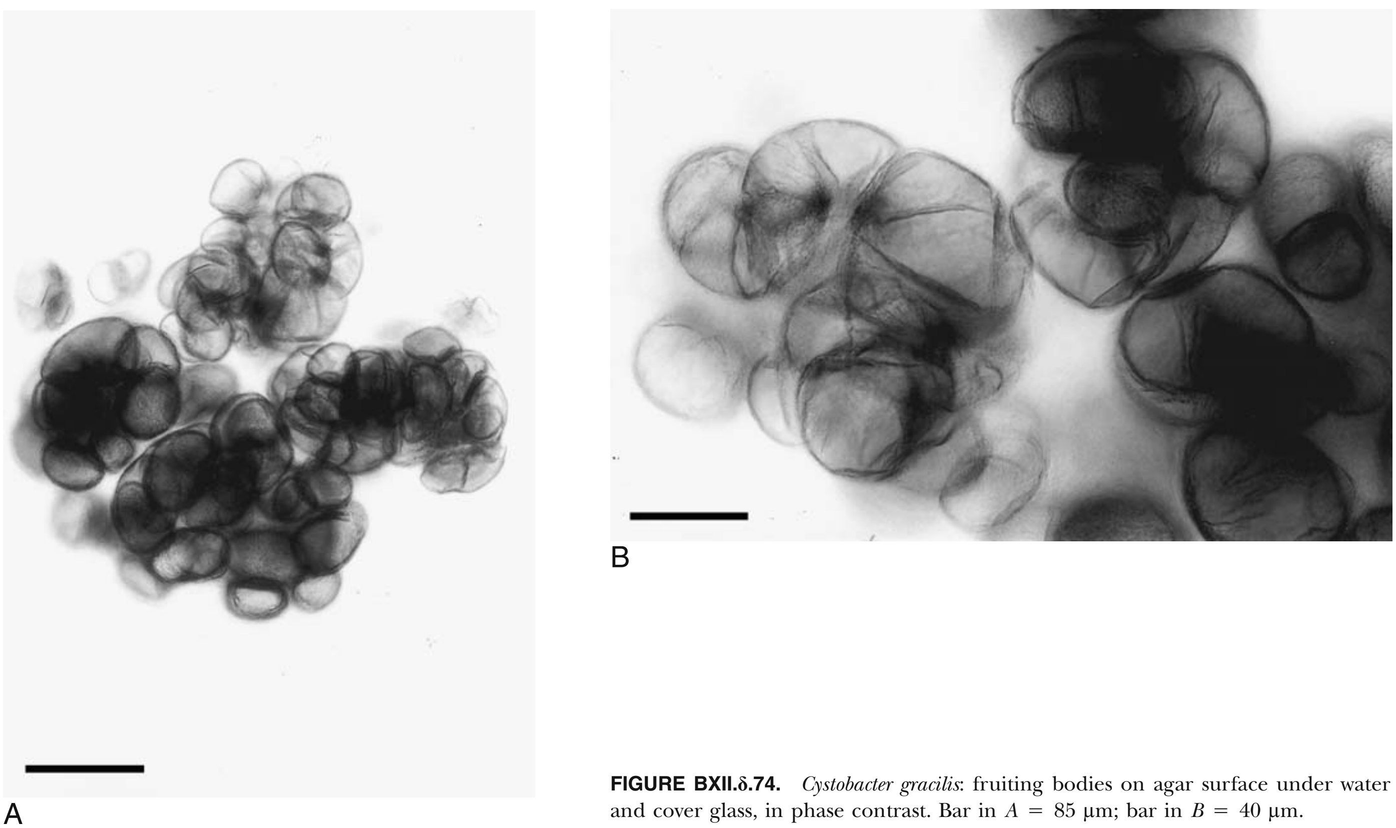

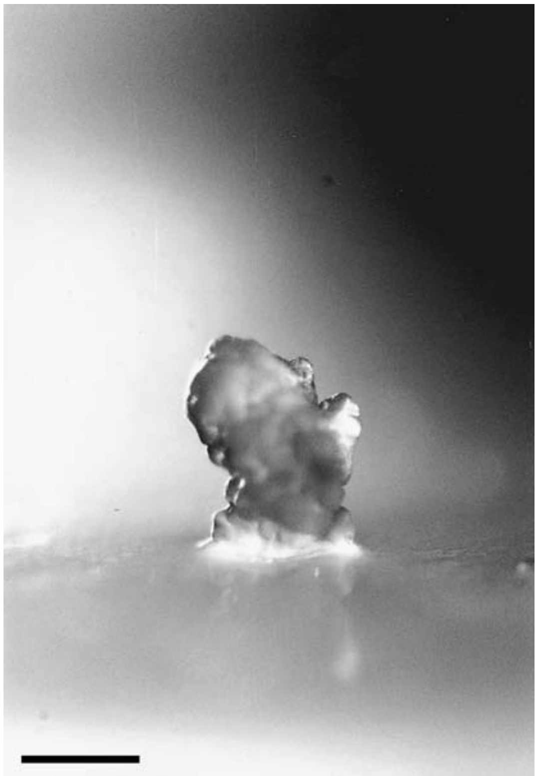

FIGURE BXII.δ.74. *Cystobacter gracilis*: fruiting bodies on agar surface under water and cover glass, in phase contrast. Bar in *A* = 85 μm; bar in *B* = 40 μm.

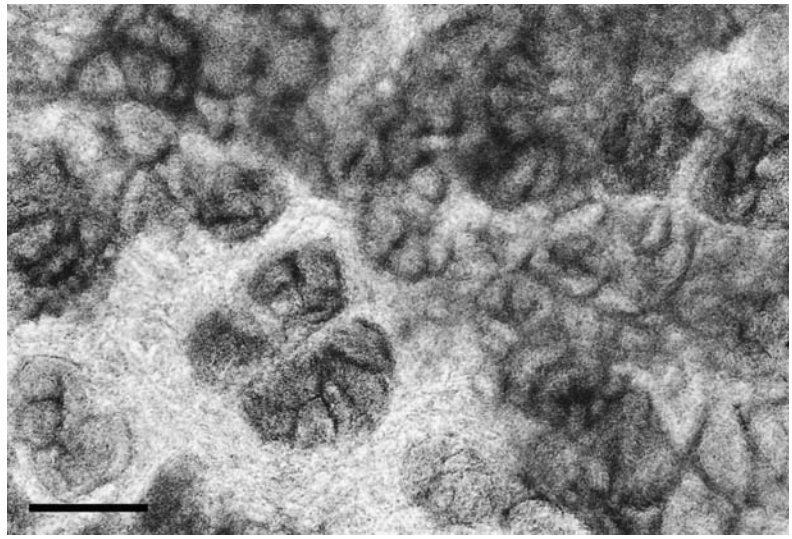

packed, the sporangioles may become polyhedral (Fig. BXII.δ.77). Myxospores stout, short rods with blunt rounded ends to almost spherical; optically refractile; 0.8–1.4 × 1.3–2.7 μm.

Of the proteolytic–bacteriolytic nutritional type. Some strains degrade chitin.

First isolated in Poland from sterilized rabbit dung placed on soil. Found in the usual myxobacterial habitats, moderately common. Strain Cb m2 was isolated in 1983 from soil collected in the same year in Arizona, USA, reference strain Cb m6 was isolated in 1990 from soil with decaying plant material collected near Jaipur, Rajasthan,

A

B

FIGURE BXII.δ.75. *Cystobacter miniatus*: fruiting bodies. (*A*) On agar surfaces the sporangioles often pile up in a peculiar slab-like fashion. (*B*) When squeezed in a slide mount, the sporangioles become distinguishable; in phase contrast. Bar in *A* = 260 μm; bar in *B* = 125 μm.

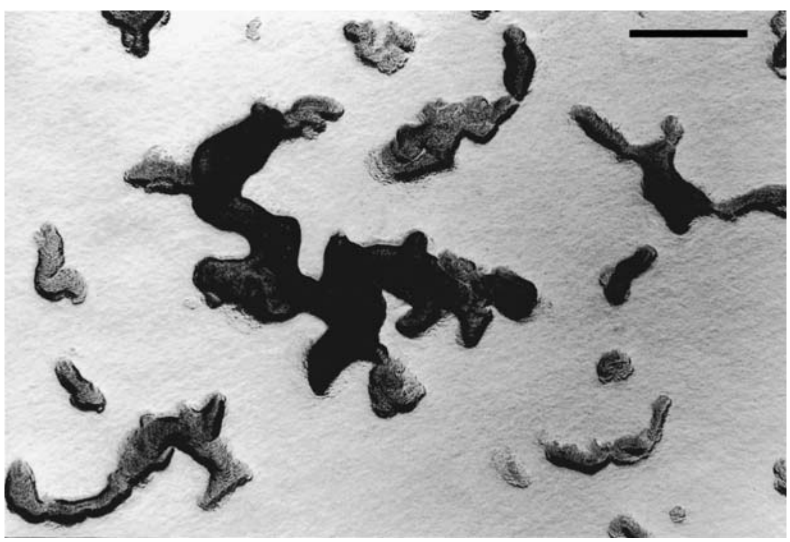

FIGURE BXII.δ.76. *Cystobacter miniatus*: degenerate fruiting bodies. Unlike those of other *Cystobacter* species, these are compact red ridges, often with short branches. Bar = 260 μm.

India, in 1990, and reference strain Cb m28 was isolated in 1998 from a similar sample collected in 1998 in Alsace, France.

The mol% G + C of the DNA is: not determined.

Type strain: Cb m2, DSM 14751, JCM 12627.

Additional Remarks: Reference strains include DSM 14772 (Cb m6), DSM 14752 (Cb m28).

This species is presently difficult to evaluate. It resembles *Cystobacter disciformis* but lacks disk-shaped sporangioles. The 16S rRNA sequences of the two species cluster closely together (Spröer et al., 1999). A comparative study using a number of strains of the two species would be desirable. After its original description, the species was observed only once by Singh and Singh (1971). However, the identity of the organisms of the two earlier descriptions with modern material must remain open. The photographs in the two

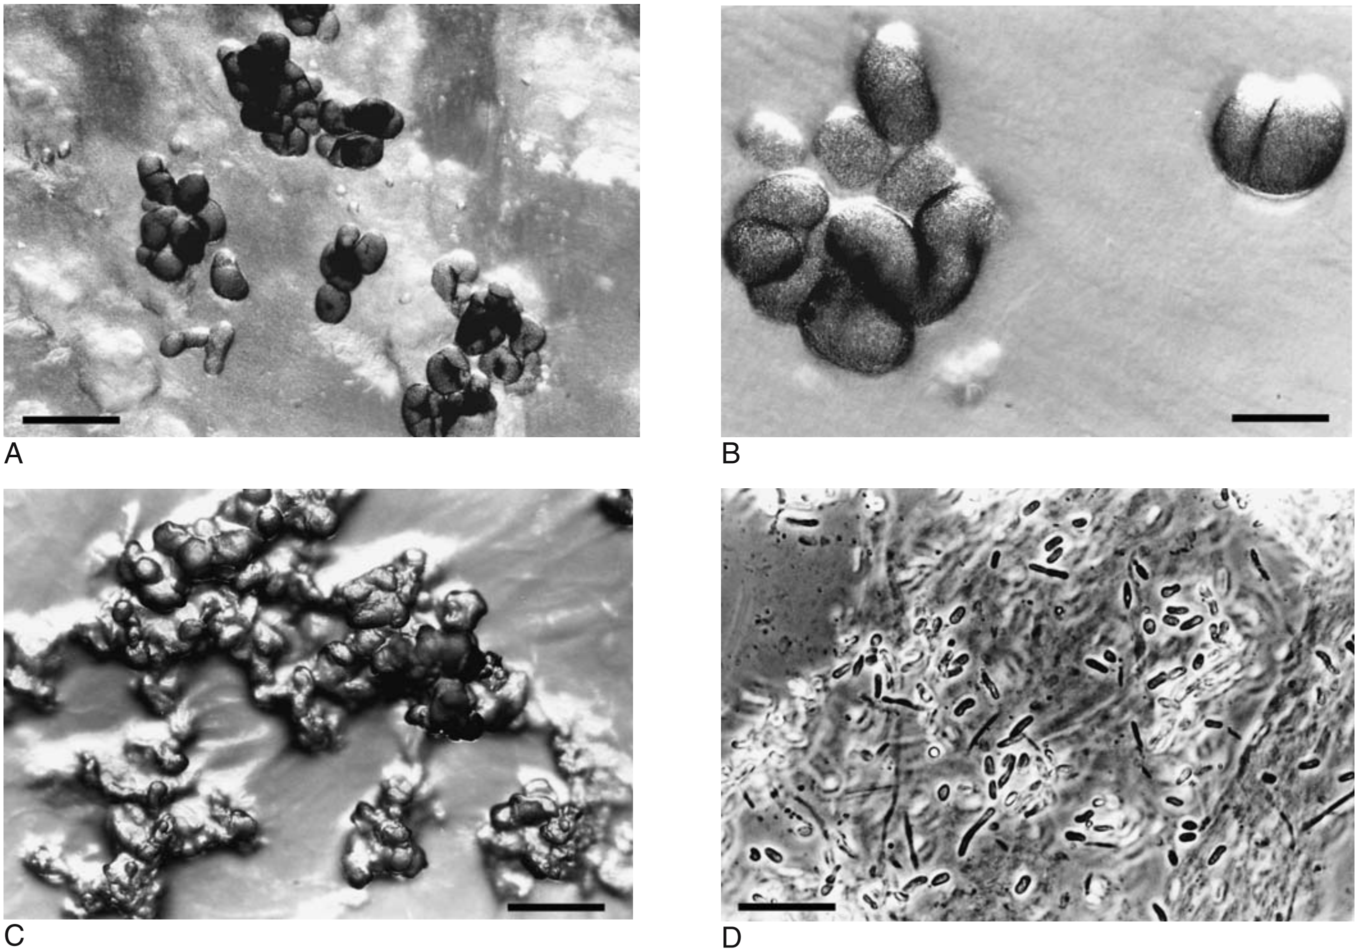

FIGURE BXII.δ.77. *Cystobacter minus*: fruiting bodies on an agar surface, and myxospores from crushed sporangioles (*D*). In *C*, *Archangium*-like degenerate fruiting bodies are seen, as are produced by all *Cystobacter* species. The sporangioles contain many degenerate cells besides typical myxospores (*D*). Bar in $A = 200$ μm; bar in $B = 65$ μm; bar in $C = 260$ μm; bar in $D = 16$ μm.

mentioned articles are not of good enough quality to allow a decision. In fact, some characteristics given in the two articles would even fit the new genus, *Hyalangium*, described below.

9. **Cystobacter velatus** *sp. nov.* (*Polyangium fuscum* biovar velatum Krzemieniewska and Krzemieniewki 1926.)
ve.la'tus. L. v. *velare* to veil, to cover; masc. part. perf. *velatus* veiled, covered.

Cystobacter velatus closely resembles *Cystobacter badius* but differs in the following characteristics: sporangioles golden brown, preferentially in chains that tend to loop upward and to form three-dimensional networks, arise below a thin but tough, colorless, translucent slime layer that is pushed upward by the maturing sporangioles and becomes delicately plicated, giving the sporangioles a strikingly striated appearance (Fig. BXII.δ.78). Single sporangioles on pedicels are absent.

Growth pattern and nutritional requirements as for *C. fuscus*, *C. badius*, and *C. ferrugineus*, with the exception that *Cystobacter velatus* may or may not attack chitin.

Cystobacter velatus is found in the usual myxobacterial habitats and is moderately common.

The species was described by Krzemieniewska and Krzemieniewski (1926), who classified it as a variant of *Cystobacter fuscus* (then *"Polyangium fuscum"*). *Cystobacter velatus* differs substantially from the latter, so that it can be justifiably regarded as a separate species. The differentiation of *Cystobacter velatus* from *Cystobacter badius* can be very difficult, as the two overlap in most characteristics. The darker color of the sporangioles of the former, and the plicated slime cover on the fruiting bodies of the latter are not always prominent. Chitin degradation appears to be a distinguishing characteristic, but it remains to be established how reliable it is. Whether the two species are really separate is an open question at this time.

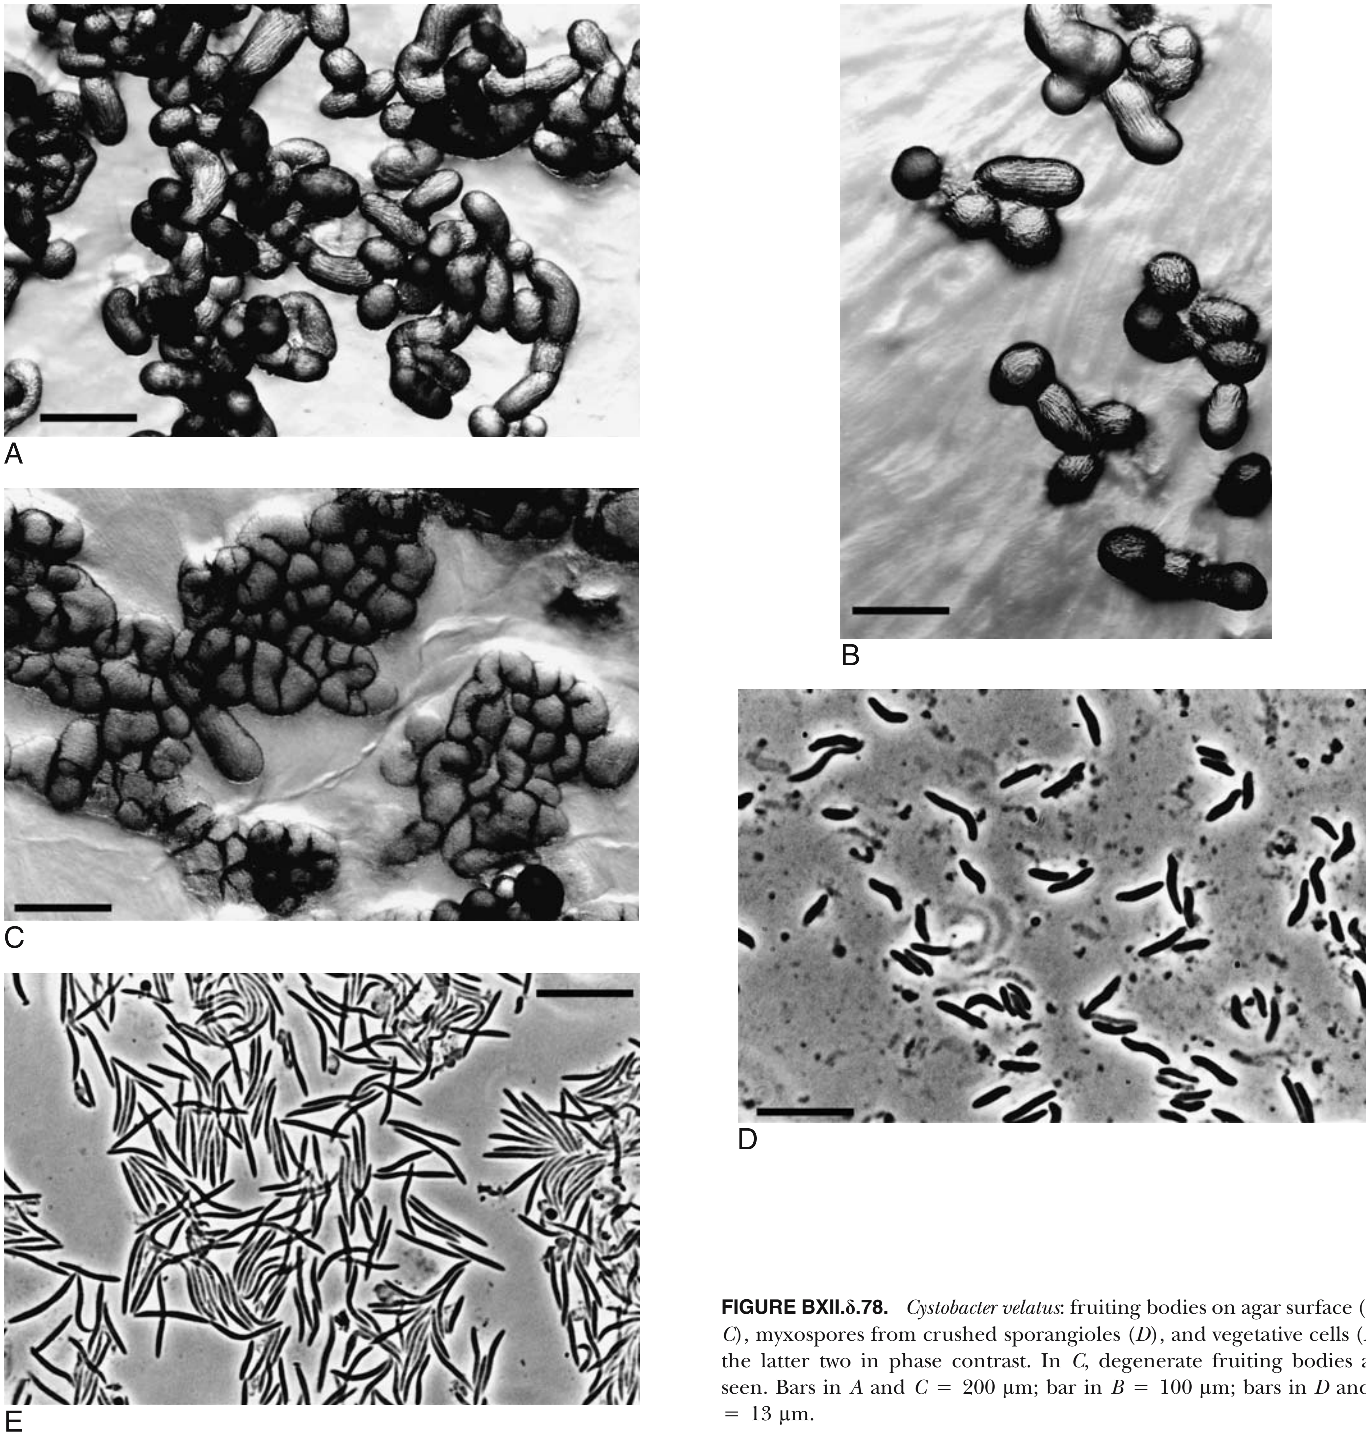
Strain Cb v34 was isolated in 1996 from a soil sample with rotting wood collected near Jaipur, Rajasthan, India, in 1995, reference strain Cb v37 was isolated in the same year from a similar sample from the same site.

The mol% G + C of the DNA is: not determined.

Type strain: Cb v34, DSM 14718, JCM 14718.

Additional Remarks: Reference strains include DSM 14719 (Cb v37).

10. **Cystobacter violaceus** (Kühlwein and Gallwitz 1958) *comb.*



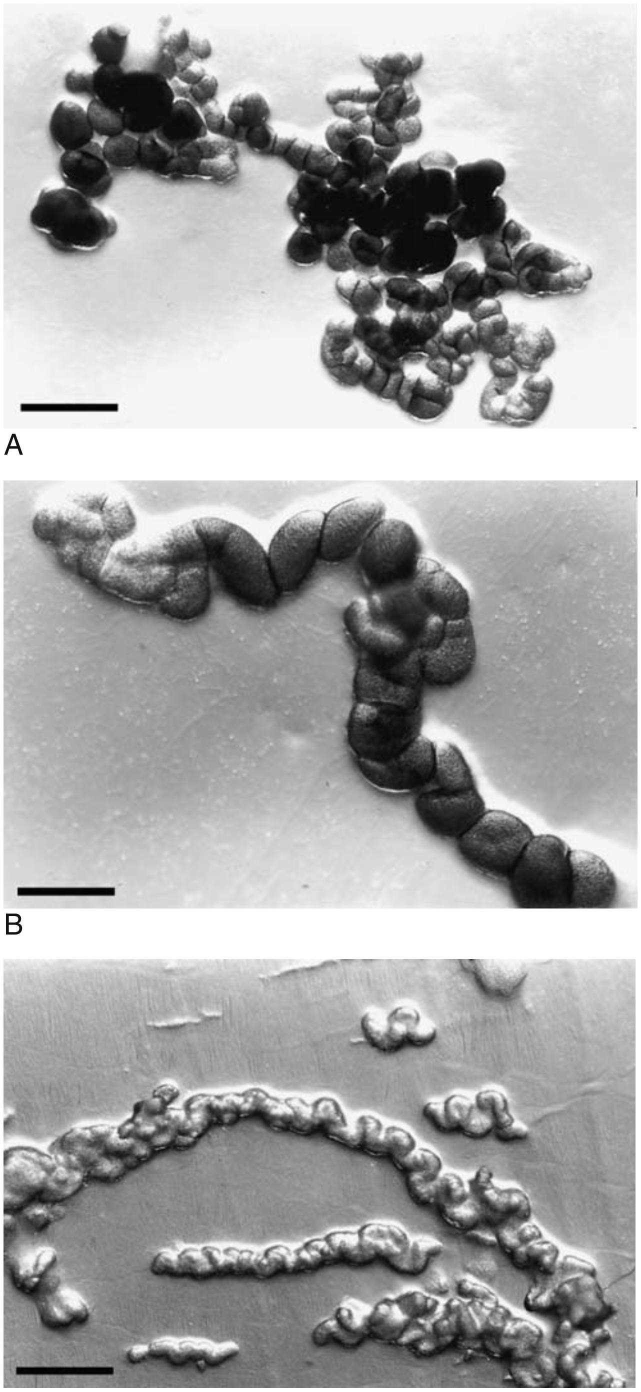


FIGURE BXII.δ.78. *Cystobacter velatus*: fruiting bodies on agar surface (*A*–*C*), myxospores from crushed sporangioles (*D*), and vegetative cells (*E*), the latter two in phase contrast. In *C*, degenerate fruiting bodies are seen. Bars in *A* and *C* = 200 µm; bar in *B* = 100 µm; bars in *D* and *E* = 13 µm.

nov. (*Polyangium violaceum* Kühlwein and Gallwitz 1958, 139; *Archangium violaceum* Kühlwein and Reichenbach 1964, 179.)
vi.o.la' ce.us. L. masc. adj. *violaceus* violet colored.

Vegetative cells are long, slender rods with tapered ends, 0.6–0.7 × 8–12 µm. Swarm colonies produce a tough slime sheet with fine radial veins; the slime apparently consists of a cellulose-like polysaccharide (Reichenbach, 1965c). Fruiting bodies (Fig. BXII.δ.79) consist of large, spherical to ellipsoidal sporangioles, 95–130 × 130–185 µm, single or in groups, dull brown to deep violet. After some time in cultivation only degenerate fruiting bodies are produced in the form of meandering, twisting ridges, which may fuse into extended, dense, irregular masses. The diffusing violet pigment of the original isolate, which was once regarded as typical for the species, is not really a species-distinguishing characteristic. Violet pigments, apparently of a different chemical structure, occasionally occur in individual strains of other myxobacteria, e.g., other *Cystobacter* species and *Sorangium cellulosum*. Myxospores short, stout rods with rounded ends, often bean- or S-shaped, 0.8–1.8 × 1.8–4 µm.

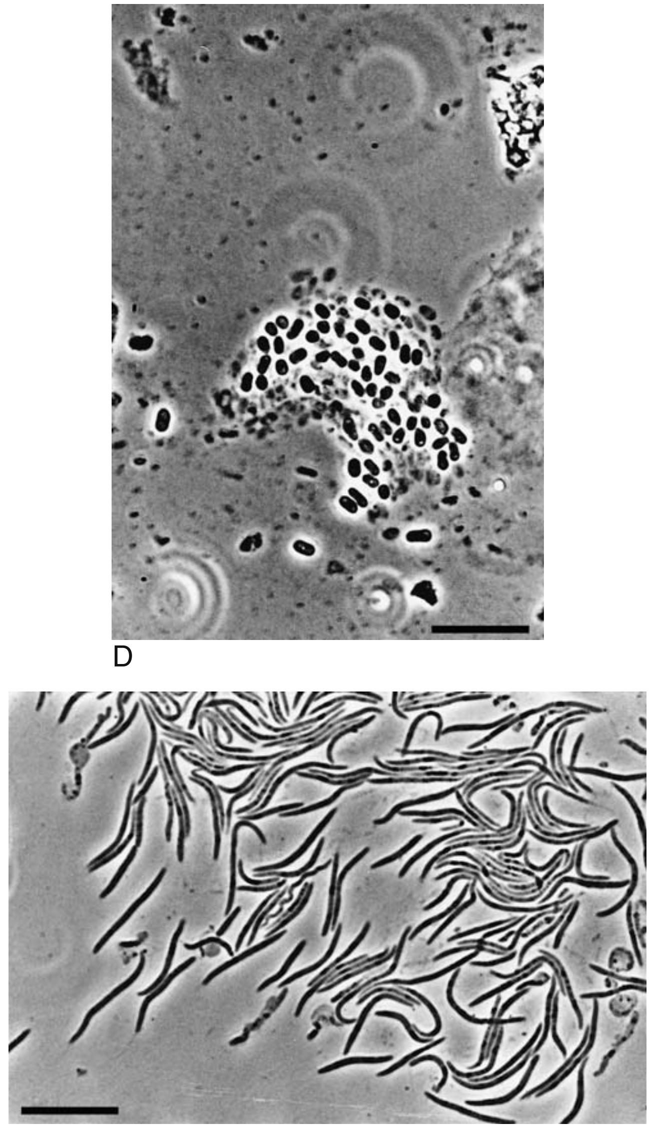

FIGURE BXII.δ.79. *Cystobacter violaceus*: fruiting bodies on agar surface (*A–C*), myxospores from crushed sporangioles (*D*), and vegetative cells (*E*), the latter two in phase contrast. Sporangioles are typically arranged in chains and three-dimensional networks and show a striated surface (*A*, *B*), but they may also occur densely packed in sori with the striation barely visible (*C*). Bar in A = 160 µm; bar in B = 135 µm; bar in C = 200 µm; bar in D = 10 µm; bar in E = 13 µm.

Of the proteolytic–bacteriolytic nutritional type. Efforts to demonstrate cellulose-degradation were negative. Most strains do not attack chitin.

The species bears some resemblance to *Cystobacter ferrugineus*, but has short to very short myxospores with rounded ends. The delineation of the species is presently somewhat blurred. Its history is discussed in the Comments on the genus *Archangium*.

The original isolate came from hare dung collected in Natal, South Africa, but is no longer available. May be found in the usual myxobacterial habitats; rather common. Strain Cb vi61 was isolated in 1996 from goat dung, soil and decaying plant material collected the year before in Rajasthan, India. Reference strain Cb vi59 was isolated in 1996 from soil with rotting plant material collected in 1994 near Giza, Egypt; reference strain Cb vi6 was isolated in 1981 by Dr. Wolfgang Dawid from soil collected in the same year in Ceylon, Sri Lanka.

The mol% G + C of the DNA is: not determined.

Type strain: Cb vi61, DSM 14727, JCM 12629.

Additional Remarks: Reference strains include DSM 14758 (Cb vi6), DSM 14759 (Cb vi59).

Genus II. **Archangium** *Jahn 1924, 66*[AL]

HANS REICHENBACH

Ar.chan' gi.um. Gr. fem. n. *arche* beginning, origin, primitive; Gr. neut. n. *angion* vessel, container; *Archangium* primitive vessel.

Vegetative cells are long, slender, needle-shaped rods with tapering ends. **Fruiting bodies without sporangioles**, contorted strings of myxospores in hardened slime forming cushion-shaped masses, very variable in shape and size, may separate into packets when put under pressure. **Myxospores short, fat rods** with rounded ends to almost spherical, optically refractile. Swarm colonies with branched radial veins in a tough slime sheet. Does not degrade chitin.

Type species: **Archangium gephyra** Jahn 1924, 67.

FURTHER DESCRIPTIVE INFORMATION

The genus *Archangium* is problematic, because its definition rests on a fruiting body morphology that is produced by many other myxobacteria in place of their normal, typical fruiting bodies. However, strains can be isolated from nature that never produce fruiting bodies with sporangioles, with specific types of vegetative cells and myxospores. These may be regarded as representatives of the genus, and they are placed here in just one species, *Archangium gephyra*. It must remain open for the moment whether this is correct and whether more species exist. Three strains that were classified as *Archangium gephyra* based on morphological characteristics, including strain ATCC 25201, possessed very similar 16S rRNA sequences (Spröer et al., 1999). They were also closely related to two strains tentatively identified as *Angiococcus disciformis* (*Cystobacter disciformis*). (The latter are probably *Cystobacter minus* strains.) The *Archangium* 16S rDNA cluster is closely associated with several *Cystobacter* species, which supports the position of the genus in the family *Cystobacteraceae*.

List of species of the genus Archangium

1. **Archangium gephyra** Jahn 1924, 67[AL]
ge' phy.ra. Gr. fem. n. *gephyra* bridge.

Vegetative cells are long, slender, needle-like rods with tapering ends, 0.6–0.8 × 6–15 μm. The fruiting bodies (Fig. BXII.δ.80) are highly variable in size and shape, up to 1000 μm, but usually much smaller. They may be ridges, pads, or often mesenteric masses of contorted and convoluted strings of hardened slime and myxospores, 40–60 μm wide, subdivided by irregular constrictions, without an outer wall, with a knobby or brain-like surface, sometimes with finger-like projections, of firm consistency. When put under pressure, they usually separate into irregular parcels with diameters 15–30 μm and larger. Reddish, brownish, or bluish violet in color. Myxospores (Fig. BXII.δ.81) short, fat rods with rounded ends to almost spherical, often slightly bean-shaped, optically refractile, 1–2 × 1.5–2.8 μm in size. The swarm colonies have a tough slime sheet with radial veins. Of the proteolytic–bacteriolytic nutritional type. Does not degrade chitin. *Archangium gephyra* is found in the usual myxobacterial habitats and is a common organism.

The mol% G + C of the DNA is: 68 (T_m).
Type strain: M18, ATCC 25201, DSM 2261.
GenBank accession number (16S rRNA): M94273.

Other Organisms

Several more *Archangium* species have been described in the past; some may be identical with *Archangium gephyra*, while others are clearly different organisms, and still others cannot be recognized readily due to scanty descriptions. In addition, no reference strains are available. Part of the taxonomic problem arises from the fact that most species were never extensively cultivated or compared with a sufficiently large number of other strains.

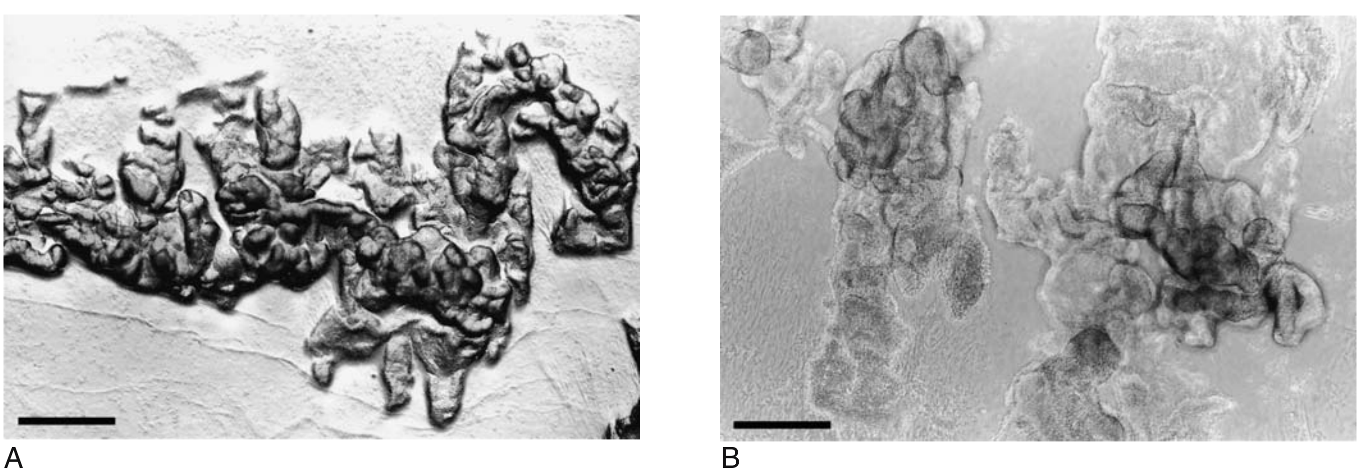

FIGURE BXII.δ.80. *Archangium gephyra*: fruiting bodies. (A) On agar plates: the mass of myxospores and hardened slime usually piles high and often produces horn-like processes. (*B*) Slide mount, phase contrast; the myxospores stick together in irregular parcels. Bar in *A* = 260 μm; bar in *B* = 95 μm.

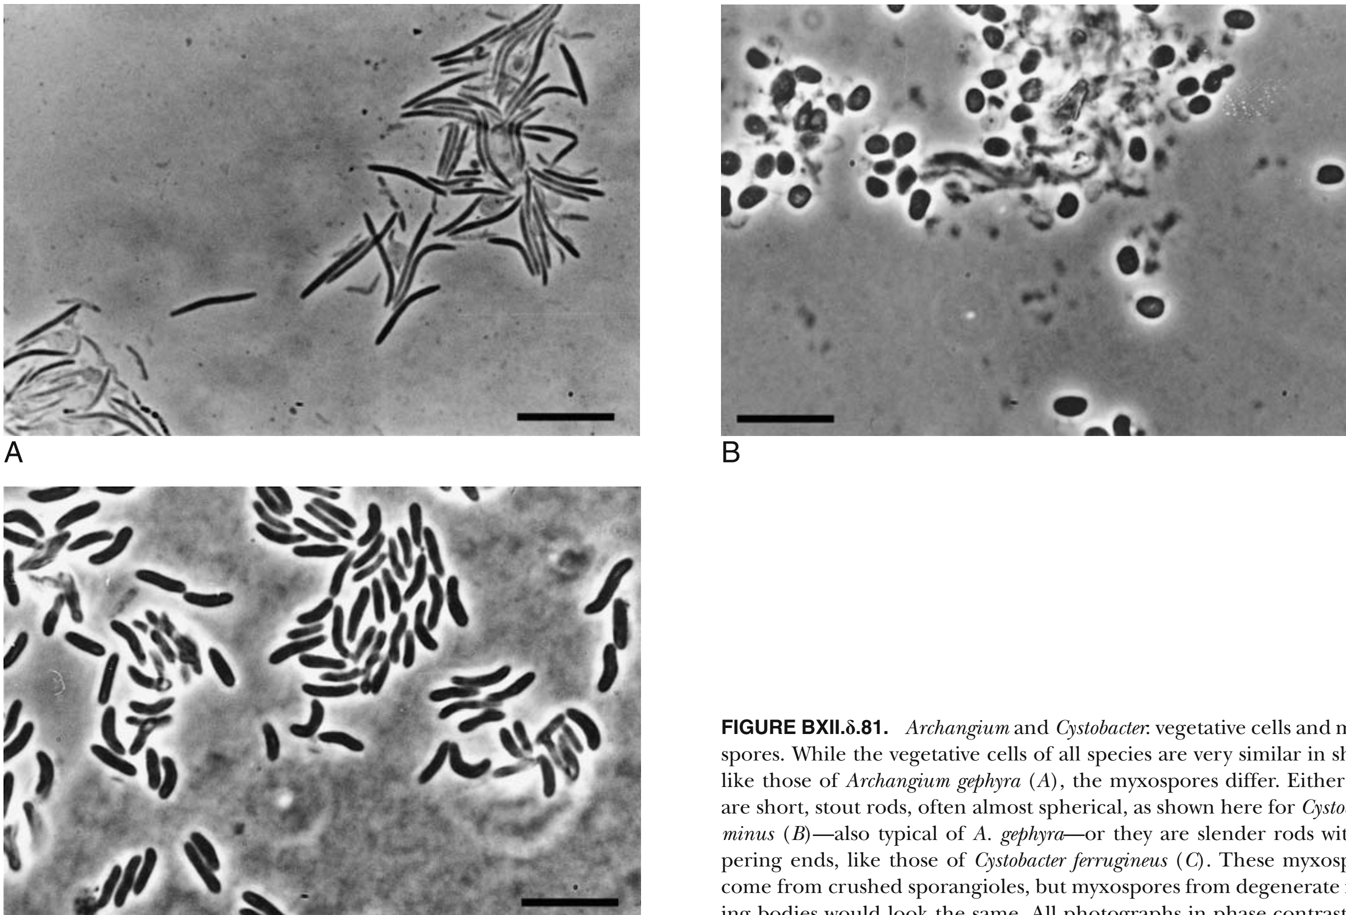

FIGURE BXII.δ.81. *Archangium* and *Cystobacter*: vegetative cells and myxospores. While the vegetative cells of all species are very similar in shape, like those of *Archangium gephyra* (*A*), the myxospores differ. Either they are short, stout rods, often almost spherical, as shown here for *Cystobacter minus* (*B*)—also typical of *A. gephyra*—or they are slender rods with tapering ends, like those of *Cystobacter ferrugineus* (*C*). These myxospores come from crushed sporangioles, but myxospores from degenerate fruiting bodies would look the same. All photographs in phase contrast. Bar in *A* = 10 µm; bars in *B* and *C* = 8 µm.

Archangium gephyra Jahn 1924 may be identical with *"Chondromyces serpens"* Thaxter 1892 (= *"Archangium serpens"* Jahn 1924) and *"Polyangium serpens"* Quehl 1906, as suggested by Krzemieniewska and Krzemieniewski (1926). While Thaxter's description would fit *Archangium gephyra*, his figure of the fruiting body does not; it shows rather loosely piled strings and tubes. In addition, the notion that the organism was found together with *Melittangium lichenicola* makes one suspect that *"Chondromyces serpens"* was an aberrant form of the latter. Therefore, Thaxter's priority is doubtful, and Jahn's name has been approved. Kofler's (1913) *"Myxococcus cerebriformis"* was probably the same organism, although the size of the myxospores was only 1.1–1.6 µm. Jahn's figure of the *Archangium gephyra* fruiting body reminds one of an immature *Cystobacter* fruiting body. *"Archangium primigenium"* Jahn 1924 (= *"Polyangium primigenium"* Quehl 1906) looks very much like *Archangium gephyra*, but Jahn gave the size of the myxospores as 0.8 × 4 µm. Such long, slender myxospores are typical of the *Cystobacter fuscus* complex, so that this organism may actually belong there. Jahn's variant, *assurgens*, is not very convincing, as finger-like, upward pointing projections are quite common with that type of fruiting body. Jahn's description of constrictions that make the tubes occasionally appear like a string of pearls supports the *Cystobacter* hypothesis. Quehl stressed that the fruiting bodies of *"Archangium primigenium"* are entirely homogeneous without tubular structures; this characteristic was also emphasized by Kofler (1913) and by Krzemieniewska and Krzemieniewski (1927) but may not really be a reliable distinguishing characteristic. The latter authors described the myxospores as short rods with rounded ends, and they believed that Jahn's *"Archangium assurgens"* is a separate species. Quehl's observation that his strain produced fruiting bodies only on the glass wall of the dish, and not on the agar surface, suggests that his species is more likely to have been a degenerate *Cystobacter*. The question cannot be decided now, and the species is rightly dismissed. *"Polyangium flavum"* Kofler 1913 was renamed *"Archangium flavum"* by Jahn (1924); he felt that the species might be identical with his *"Archangium thaxteri"*. However, Kofler described the fruiting bodies of *"Polyangium flavum"* as globose or ellipsoidal, with a humpy surface, rather large, 600 × 400 µm, yellow, and easily confused with *Myxococcus virescens*, but containing rods rather than spheres. If such is the case, the organism may be identical with a new bacterium described below as *Kofleria flava* which belongs to the suborder *Nannocystineae*. Jahn gave the size of the rod-shaped cells inside those masses as 2–4 µm. *"Archangium flavum"* has been reported two other times. Krzemieniewska and Krzemieniewski (1930) described rod-shaped cells with rounded ends and fruiting bodies with a tubular structure; one variety had a gelatinous, hyaline slime matrix. Singh and Singh (1971) described fruiting bodies that were lemon yellow with a humped or padded surface; the myxospores were rods 1 × 2.5–5 µm in size. The reports may or may not refer to the same species. Jahn's (1924) *"Archangium thaxteri"* is almost certainly identical to an organism described below as *Jahnia thaxteri* in the *Chondromyces* group: convoluted tubules, 50 µm wide, in a dense mass on a

stout, cushion-like slime stalk, with a yellow slime matrix. Kofler's (1913) *"Myxococcus polycystus"* was perhaps the same organism. *"Archangium violaceum"* Kühlwein and Reichenbach 1964 was an erroneous reclassification of *"Polyangium violaceum"* Kühlwein and Gallwitz 1958 and was in fact a *Cystobacter* species. The authors were misled by the fact that the type strain (which is no longer available) after years of cultivation under many different conditions did not produce fruiting bodies with sporangioles, which it did originally. At that time the degeneration of fruiting bodies of *Cystobacter* and other myxobacteria was not yet understood.

Jahn (1924) added a second new genus, *Stelangium*, to the new family *Archangiaceae*, with *"Stelangium muscorum"* (= *"Chondromyces muscorum"* Thaxter 1904) as the only species. The status of that species is obscure. Thaxter described the organism as similar to *Corallococcus coralloides*: bright yellow-orange, columnar or finger-like fruiting bodies, sometimes furcate, sessile without a stalk, erect, with a bluntly pointed apex, 90–300 × 20–50 μm, apparently without an outer wall. Unfortunately, the myxospores were not described. The organism was reported again by Singh and Singh (1971), with similar fruiting body morphology and rod-shaped myxospores, 1–1.4 × 4–6 μm. In neither case was the organism cultivated. The description of the fruiting body reminds one of *Corallococcus macrosporus* or atypical fruiting bodies of *Myxococcus virescens* (Fig. BXII.δ.62 in the chapter on *Myxococcus*). In both cases, however, the myxospores were spherical. A second species, *"Stelangium vitreum"*, was added by Peterson (1959). It had delicate crystalline orange fruiting bodies, either globose or columnar, 150–200 × 60–70 μm, without an outer wall. The myxospores were rods, 0.7 × 2 μm that occurred in small parcels that were arranged in the fruiting body in a basket-weave fashion. The vegetative cells (shape not mentioned) measured 0.7 × 4 μm. The organism was found on bark, and it, too, was not cultivated. Its identity is unclear.

Genus III. **Hyalangium** *gen. nov.*

HANS REICHENBACH

Hy.al.an' gi.um. Gr. fem. n. *hyalos* glass; Gr. neut. n. *angion* vessel, container; M.L. neut. n. *Hyalangium* glassy vessel.

Vegetative cells are delicate, slender rods with tapering ends. Fruiting bodies consist of small spherical sporangioles that are **often empty** and then look **glassy and transparent**, arranged in extended, dense sheets, or often, in chains. **Myxospores are short rods or irregularly spherical;** optically refractile. Swarm colonies with a thin but tough slime sheet with fine veins, adsorbs Congo red with a purple red color. Of the proteolytic–bacteriolytic nutritional type.

Type species: **Hyalangium minutum** *sp. nov.*

FURTHER DESCRIPTIVE INFORMATION

This organism differs substantially from the *Cystobacter* species discussed above and is therefore classified in a new genus. The distinguishing characteristics are as follows. The vegetative cells are shorter and more delicate than those of *Cystobacter* species. The sporangioles are small and often empty and glassy. They are arranged in monolayer sheets or in short chains and do not pile up, or do so only slightly. The swarm colonies have a delicate slime sheet with very fine veins. The only species known so far somewhat resembles *Cystobacter disciformis*, although the latter has much different fruiting bodies. In addition, some traits are like those of *Polyangium minus* (now *Cystobacter*) in the original description of Krzemieniewska and Krzemieniewski (1926). The identity of *Hyalangium* with that organism cannot be ruled out with certainty, but even if the two organisms should be the same, a reclassification would be required.

List of species of the genus Hyalangium

1. **Hyalangium minutum** *sp. nov.*
mi.nu' tum. L. neut. adj. *minutum* small, tiny.

Vegetative cells are slender, delicate rods with tapering ends, 0.6–0.7 × 3–6 μm (Fig. BXII.δ.82). Fruiting bodies (Fig. BXII.δ.83) consist of spherical to slightly elongated, potato-like sporangioles, sometimes with unilateral constrictions by incomplete cross-walls, grayish brown or brown, but often empty, colorless, glassy, and transparent; sometimes one or two secondary sporangioles are produced within the empty husk. The sporangioles are surrounded by a definite, irregularly indented wall, 1.5–3.5 μm thick. Occasionally a fine, regular striation can be seen on the surface of the sporangioles, with a distance of the striae of 0.6 μm. The sporangioles measure between 20 × 30 and 40 × 80 μm, usually around 35–45 μm in diameter. They are arranged in extended monolayers, only rarely slightly piled up; sori 400–650 μm across, but often much larger. When fruiting starts to degenerate, the sporangioles arise in short chains. Degenerate fruiting bodies are narrow, delicate ridges with tapering ends, but never the cushion-like structures typical of *Cystobacter* spp. Myxospores (Fig. BXII.δ.84) short rods with rounded ends, often slightly bent or bean-shaped, 1.5–1.8 × 2.1–4 μm, or irregularly spherical with a diameter between 1.8 and 2.6 μm, optically refractile.

Swarm colonies with a delicate but tough slime sheet with very fine radial veins, often slightly wrinkled and tinted yellow brown by a diffusing pigment. Of the proteolytic–bacteriolytic nutritional type. Does not attack chitin.

Hyalangium minutum is found in the usual myxobacterial habitats; it is rather common but easily overlooked because of its inconspicuous, translucent fruiting bodies and often complete degeneration of fruiting. The type strain, NOCB-2, was isolated in 1992 from soil with decaying plant material collected by Dr. S. Yamanaka in the mountains of Izu and Manazuru peninsula in Japan. Reference strain NOCB-4 comes from a sample collected in 1992 in Indianapolis, IN, USA, and was isolated in 1993; reference strain Hy m4 was isolated in 1998 from soil with rotting wood collected in 1997 in Iowa City, IA, USA.

The mol% G + C of the DNA is: not determined.

Type strain: NOCB-2, DSM 14724, JCM 12630.

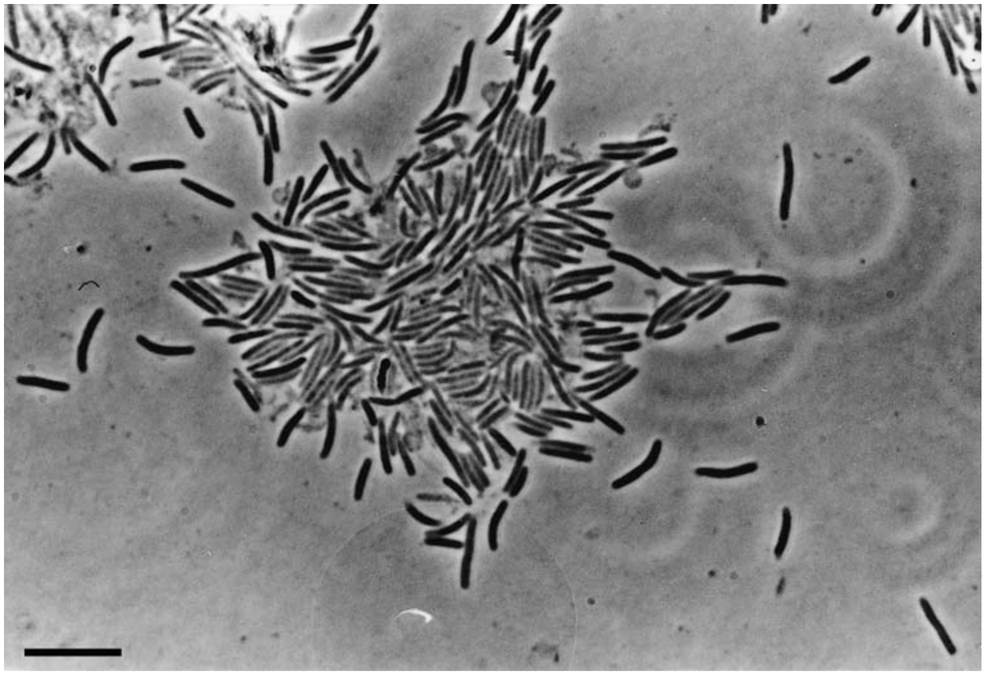

FIGURE BXII.δ.82. *Hyalangium minutum*: vegetative cells, in phase contrast. Bar = 13 μm.

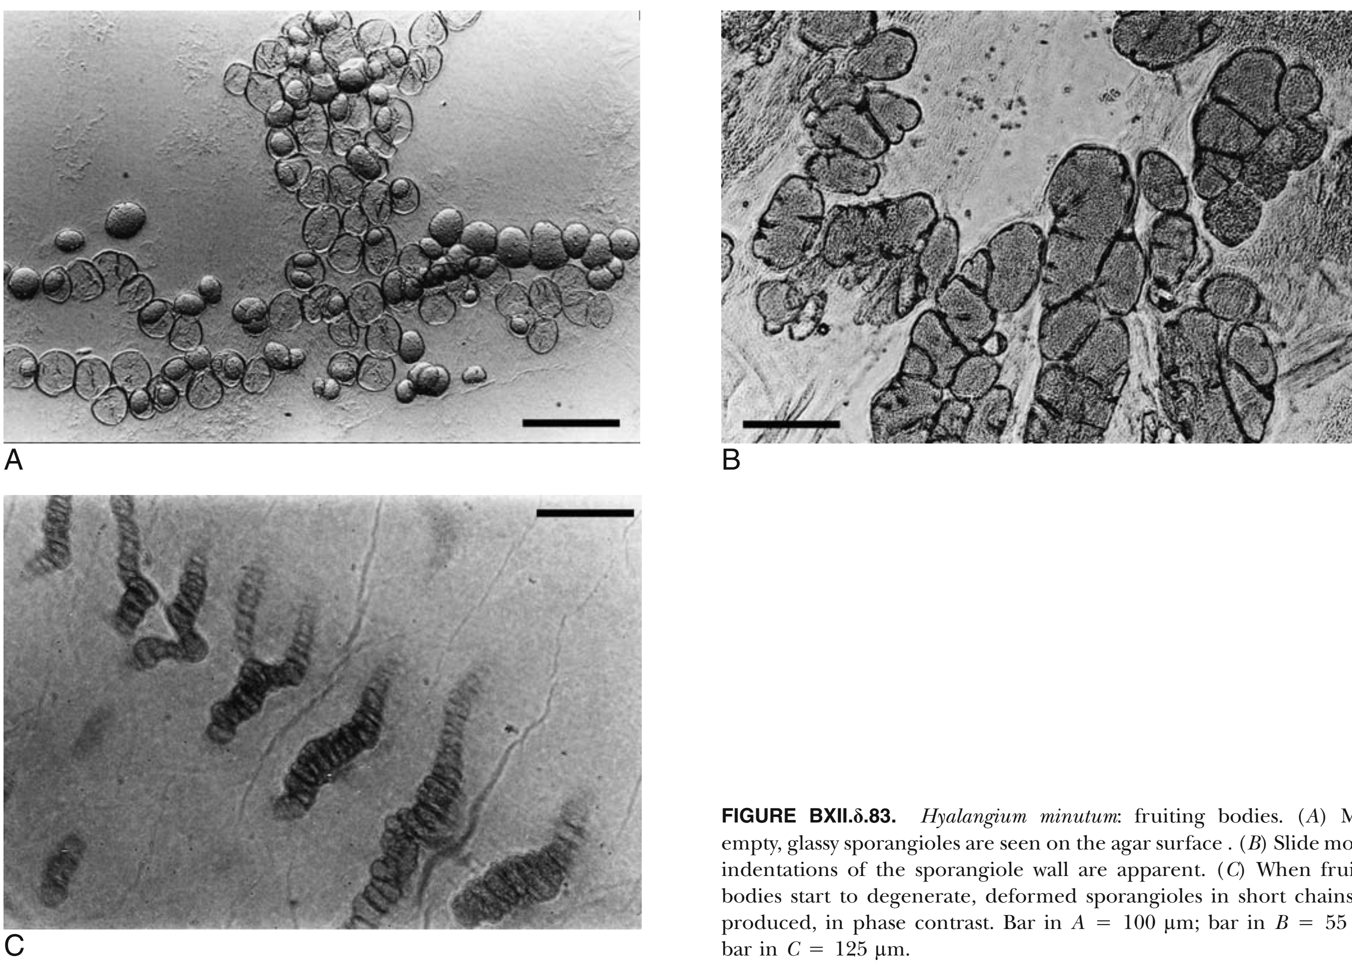

FIGURE BXII.δ.83. *Hyalangium minutum*: fruiting bodies. (*A*) Many empty, glassy sporangioles are seen on the agar surface . (*B*) Slide mount; indentations of the sporangiole wall are apparent. (*C*) When fruiting bodies start to degenerate, deformed sporangioles in short chains are produced, in phase contrast. Bar in *A* = 100 μm; bar in *B* = 55 μm; bar in *C* = 125 μm.

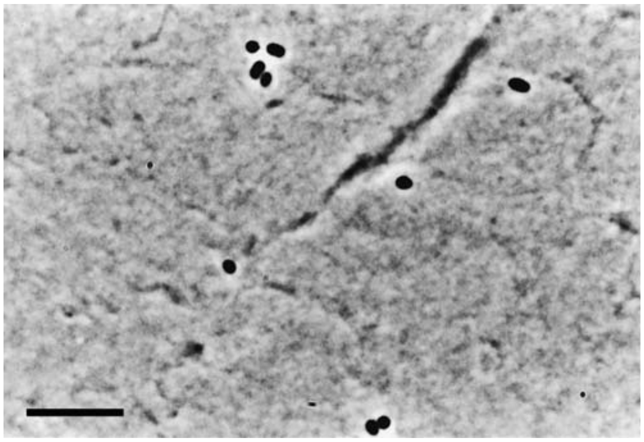

FIGURE BXII.δ.84. *Hyalangium minutum*: myxospores from crushed sporangioles, in phase contrast. Bar = 10 μm.

Additional Remarks: Reference strains include DSM 14725 (NOCB-4), DSM 14721 (Hy m4).

As mentioned above, it cannot be ruled out that the species is identical with *Polyangium minus* (now *Cystobacter*) Krzemieniewska and Krzemieniewski 1926. The 16S rRNA sequences of the type strain and of a second isolate, NOCB-4, cluster closely together and are well separated from *Cystobacter* species. The most closely related sequences are those of *Stigmatella* (Spröer et al., 1999).

Genus IV. **Melittangium** *Jahn 1924, 7[AL]*

HANS REICHENBACH

Me.lit.tan′ gi.um. Gr. fem. n. *melitta* bee; Gr. neut. n. *angion* vessel; M.L. neut. n. *Melittangium* a vessel resembling a honeycomb.

Vegetative cells are slender rods with tapering ends. **Fruiting bodies consist of solitary sporangioles on slime stalks**. **Myxospores rod shaped, optically refractile**. Swarm colonies with a slime sheet and radial veins. Of the proteolytic–bacteriolytic nutritional type.

Type species: **Melittangium boletus** Jahn 1924, 78.

FURTHER DESCRIPTIVE INFORMATION

While the sporangioles of these organisms typically sit on stalks, sporangioles without stalks are also produced, and may be either solitary or arranged in looping chains. Degenerate fruiting bodies are narrow, delicate ridges, pustules, sometimes finger-like, erect, or irregular, gnarled, knobby masses. The fruiting bodies of *Melittangium* are smaller than those of the *Stigmatella* species and lighter in color. The 16S rRNA sequences of *Melittangium boletus* and *Melittangium alboraceum* cluster together and are closely related to those of *Cystobacter fuscus* complex. The sequence of strain ATCC 25946 of *Melittangium lichenicola*, however, is most closely related to those of *Corallococcus* strains (Shimkets and Woese, 1992; Spröer et al., 1999). The GenBank sequence, M94277, does not, however, belong to strain ATCC 25946, as has recently been shown by a new sequence determination at the DSM using a fresh culture from the ATCC (Spröer, personal communication). *Melittangium boletus* and *Melittangium lichenicola* were placed for some time in the genus *Podangium* (Stanier, 1957). However, the type species of that genus, *"Podangium erectum"*, differs substantially from the *Melittangium* species and is now classified as *Stigmatella erecta*.

Key to the species of the genus *Melittangium*

I. Sporangiole like a mushroom cap, brown, on a short stalk; efficient chitin degrader.
Melittangium boletus

II. Sporangioles spherical, ellipsoidal or kidney-shaped, pale orange to light brown.

A. Sporangiole on a short, delicate stalk, does not decompose chitin.
Melittangium lichenicola

B. Sporangiole on a long, often bent stalk.
Melittangium alboraceum

List of species of the genus Melittangium

1. **Melittangium boletus** Jahn 1924, 78[AL]

bo.le′ tus. L. masc. n. *boletus* a kind of mushroom.

Vegetative cells are slender, needle-shaped rods with tapering ends, 0.7 × 4–9 μm. The fruiting body (Fig. BXII.δ.85), when typical, consists of a single, colorless, grayish or yellowish brown to dark red brown semispherical sporangiole with a flat base like a mushroom cap, 50–100 μm wide and 40–50 μm thick. The sporangiole is borne on a delicate, short white stalk, 10–30 μm wide and up to 60 μm long, but usually much shorter. Sometimes a slime knob is seen at the base of the stalk. Fruiting bodies with spherical, club-shaped, or kidney-shaped sporangioles may be found in addition to typical fruiting bodies. In addition, the stalk may be lacking, so that the sporangioles sit directly on the substrate, in which case they may be arranged singly, in chains, or in packets. After some time in culture, only degenerate fruiting bodies are produced. The fruiting bodies of *Melittangium boletus* arise singly or in loose groups. Myxospores short, often rather slender and slightly C- or S-shaped bent rods with rounded or slightly tapered ends, optically refractile, 0.7–1.0 × 1.5–5 μm.

Swarm colonies with radial veins in a tough slime sheet,

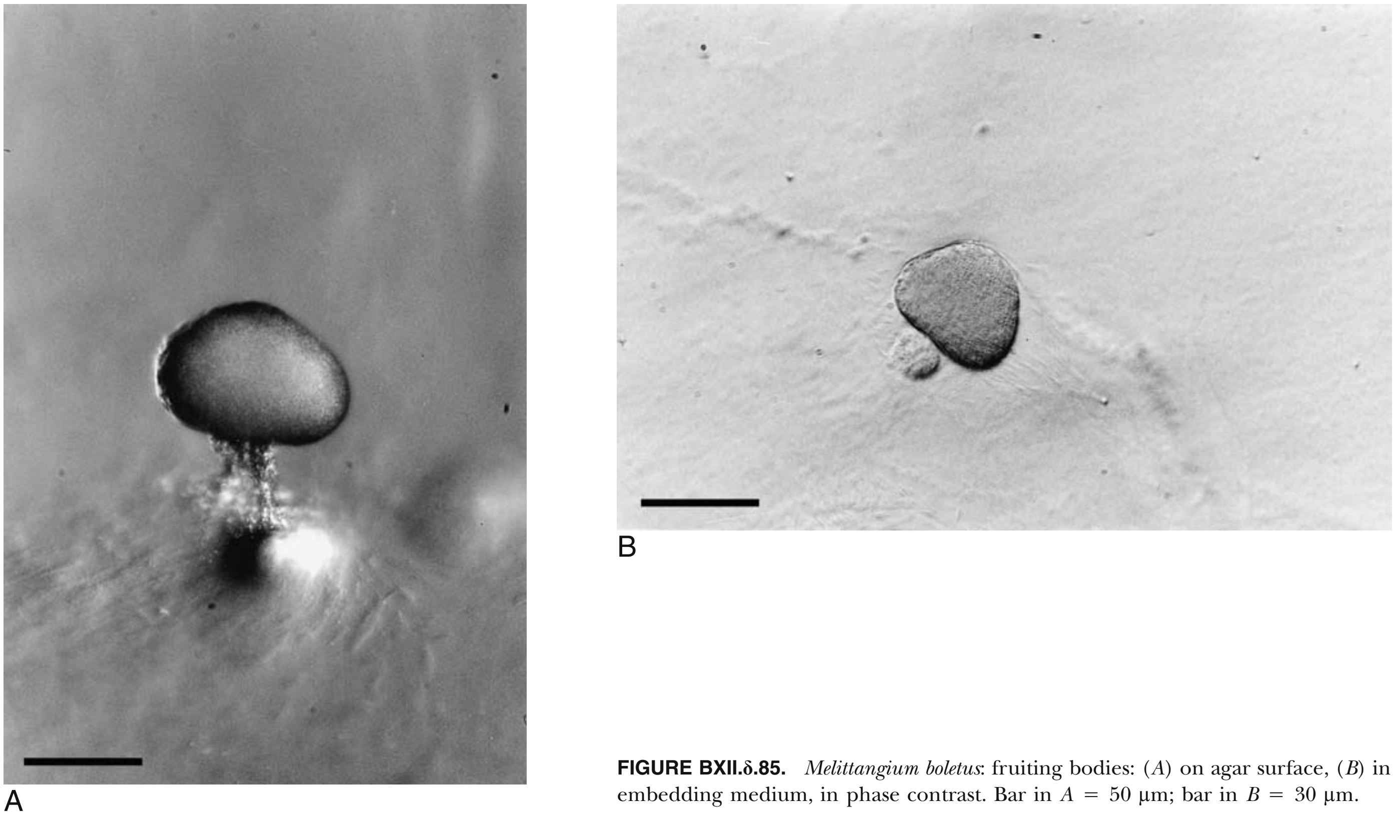

FIGURE BXII.δ.85. *Melittangium boletus*: fruiting bodies: (*A*) on agar surface, (*B*) in embedding medium, in phase contrast. Bar in *A* = 50 µm; bar in *B* = 30 µm.

on many media bright chrome yellow with a greenish tinge. Of the proteolytic-bacteriolytic nutritional type. Degrades starch and chitin very efficiently, but not filter paper cellulose.

The species is found in the usual myxobacterial habitats, but is not particularly common. Strain Me b8 was isolated in 1995 from a soil sample containing rotting wood and bark collected in the Nawalganj Bird Sanctuary southwest of Lucknow, Uttar Pradesh, India.

The mol% G + C of the DNA is: not determined.

Type strain: Me b8, DSM 14713, JCM 12633.

When typical fruiting bodies are lacking, the species resembles *Melittangium lichenicola*. However, it clearly differs in fruiting body shape and color, in the yellow pigmentation of the swarm colonies, and in efficient chitin degradation. Jahn emphasized that the myxospores on the surface of the spore mass stand parallel to one another and perpendicular on the sporangiole wall; the impressions of their tips in the wall generate a honeycomb-like pattern on the inner face (hence the name). This arrangement appeared unique enough to him to justify the creation of a new genus. However, while this pattern can indeed occasionally be observed, it is often absent. As the fruiting bodies of *Melittangium boletus* are so characteristic, the original description of the species was rather brief. It was soon complemented by other investigators (Krzemieniewska and Krzemieniewski, 1926; Solntseva, 1941). The figure of fruiting bodies in the article by Krzemieniewska and Krzemieniewski shows very long and relatively massive stalks, so that one is reminded more of *Melittangium alboraceum*.

2. **Melittangium alboraceum** (Peterson 1959) McCurdy 1971b, 54[AL]*

al.bo.ra'ceum. L. masc. adj. *albus* white L. masc. n. *racemus* bunch of grapes, grape berry: was erroneously assumed to mean stalk; M.L. neut. adj. *alboraceum* with a white stalk.

Vegetative cells slender rods with square rather than tapering ends, 0.8–1.0 × 4.5–5.0 µm. Fruiting bodies consist of solitary, pale orange, crystalline, globose "cysts", around 35 µm in diameter, with an elastic, indiscernible membrane, on long, angular, distorted, corkscrew-like, snow-white stalks, 20 × 100–200 µm. Myxospores slightly curved rods, 0.8 × 2.5 µm. Found on bark of *Ulmus americana*.

The mol% G + C of the DNA is: not determined.

Type strain: none cultivated.

Additional Remarks: Reference material includes microscope slides Peterson 72 in the herbarium of the University of Missouri, Columbia, MO, USA.

The author reluctantly includes this species in the genus *Melittangium*. The square-ended vegetative cells do not even fit the description of the suborder, and the "cysts" are described to have a gelatinous, indiscernible wall and to be deliquescent, which does not resemble a sporangiole. The photographs in the original paper show long, wavy stalks, unlike those of other myxobacteria. The fact that the fruiting bodies disappeared completely and forever when the

**Editorial Note:* The name given to the organism in the original description was *"Podangium alboracemum"*, which was later corrupted to *alboraceum* (McCurdy, 1971b); however, according to the Bacteriological Code, it cannot be corrected.

bark was dried suggests that these structures may have been immature fruiting bodies, perhaps of a *Chondromyces* species, which indeed often inhabit bark. *Chondromyces* fruiting bodies tend to degenerate into long white stalks with the gradual consumption of the bacterial cell mass at the tip. On the other hand, it should be noted that *Melittangium* strains with very long stalks have been described. They may represent a separate species, albeit not *Melittangium alboraceum*.

3. **Melittangium lichenicola** (Thaxter 1892) McCurdy 1971b, 53[AL]

li.che.ni′ co.la. Gr. masc. n. *leichen* lichen; L. masc. n. *cola* inhabitant, dweller; *lichenicola* inhabitant of lichens.

Vegetative cells are slender, fusiform rods with tapering ends, 0.7–0.8 × 5–8 µm (Fig. BXII.δ.86). The fruiting bodies (Fig. BXII.δ.87) are solitary, small, pale yellowish brown to brown orange spherical, ellipsoidal or club- and kidney-shaped sporangioles, 25–40 µm across, on delicate short white stalks, 5–10 × 10–40 µm. Stalks may be lacking, and sporangioles may then arise in chains or clusters. Normally, the fruiting bodies are produced in large numbers in extended fields. In culture, soon only degenerate fruiting bodies arise as orange to orange brown padded masses, appressed convoluted tubules and ridges. Myxospores appear similar to those of *M. boletus* (see Fig. BXII.δ.88) and are

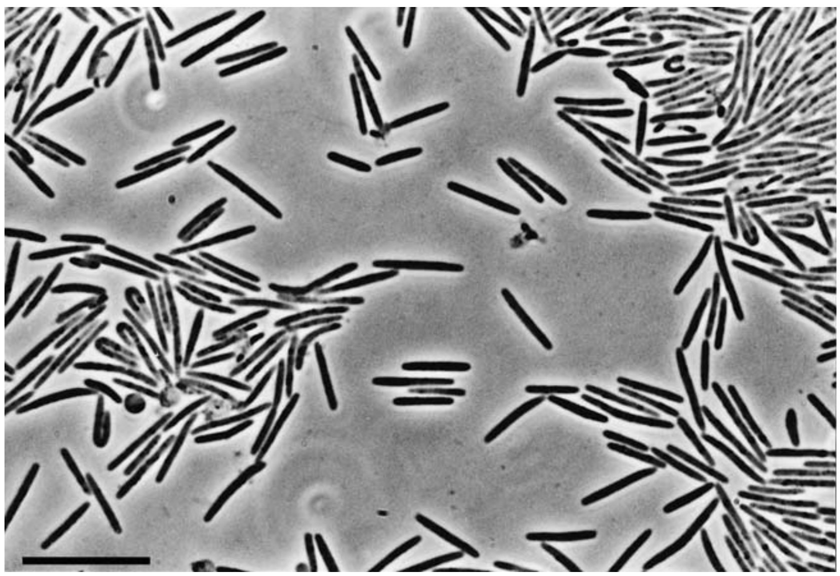

FIGURE BXII.δ.86. *Melittangium lichenicola*: vegetative cells, in phase contrast. Bar = 13 µm.

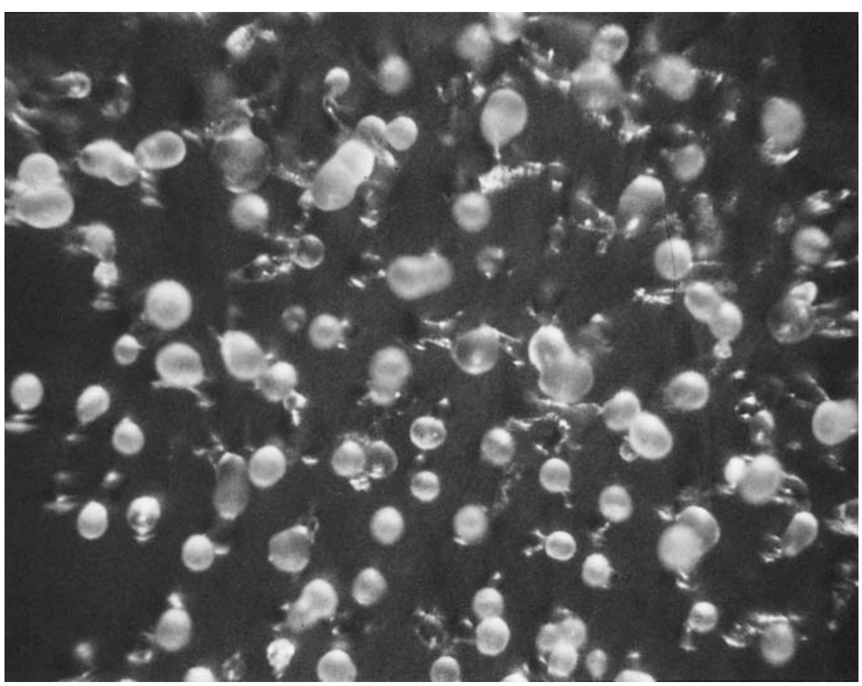

FIGURE BXII.δ.87. *Melittangium lichenicola*: fruiting bodies on agar (× 500).

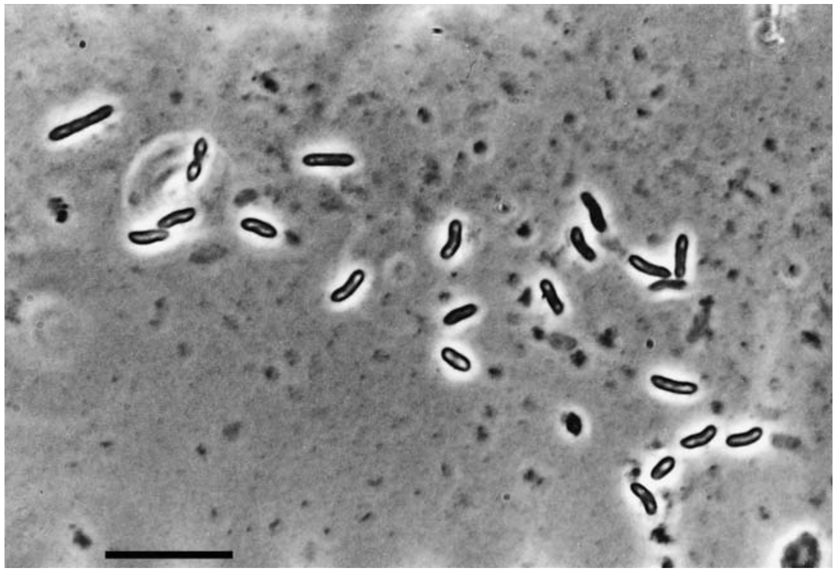

FIGURE BXII.δ.88. *Melittangium boletus*: myxospores from crushed sporangioles, in phase contrast. Bar = 13 μm.

relatively slender rods with rounded or pointed ends, often slightly C- and S-shaped bent and somewhat irregular, 0.8–1.2 × 2.5–4 μm.

Swarm colonies with fine radial veins. Of the proteolytic–bacteriolytic nutritional type. Degrades starch and xylan, but not cellulose, carboxymethyl cellulose, or chitin.

Originally discovered as a purported parasite of lichens, *Melittangium lichenicola* is found in the usual myxobacterial habitats; it is a rather common organism. Reference strain Me l 31 was isolated in 1990 from soil with decaying plant material collected in 1988 in Carinthia, Austria.

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 25946, DSM 2275.

GenBank accession number (16S rRNA): M94277.

Additional Remarks: Reference strains include DSM 14740 (Me l 31).

As mentioned, the GenBank sequence published and used for the type strain of *Melittangium lichenicola* is probably that of a *Corallococcus* and does not belong to strain ATCC 25946.

Melittangium lichenicola can easily be confused with *Melittangium boletus*. The fruiting bodies of the latter, when typical, are somewhat larger, darker brown in color, and the sporangioles are shaped like a mushroom cap; also, the swarm colonies produce a yellow pigment and efficiently degrade chitin. It is not certain, however, whether the latter two traits are reliable distinguishing characteristics. Further, *Cystobacter disciformis* may be a source of error. However, the sporangioles of that organism are intensely orange-brown, disk-shaped, often piled up in opuntia-like clusters, and without stalks. *"Chondromyces gracilipes"* Thaxter 1897 (= *"Podangium lichenicolum"* Jahn 1924) is most likely identical with *Melittangium lichenicola*.

Genus V. **Stigmatella** *Berkeley and Curtis* in *Berkeley 1857, 313*

HANS REICHENBACH

Stig.ma.tel'la. L. neut. n. *stigma* gen. *stigmatis* brand, mark; L. fem. dim. *-ella* ending; M.L. fem. n. *Stigmatella* small dark spot.

Vegetative cells are moderately long, boat-shaped, fusiform cells with tapering ends, 0.7–0.8 × 4–8 μm. **Myxospores short, often bent rods with rounded ends**, optically refractile, 0.9–1.2 × 2–4 μm. **Fruiting bodies** consist of more or less spherical **sporangioles, either solitary or in clusters on stalks**. Swarm colonies with an extremely tough slime sheet with radial veins, often with oscillating waves that typically are arranged in long, narrow tracks rather than in extended fields. Adsorbs Congo red with a purple-red color. Of the proteolytic–bacteriolytic nutritional type. **Degrades chitin efficiently**.

Type species: **Stigmatella aurantiaca** Berkeley and Curtis *in* Berkeley 1857, 313.

FURTHER DESCRIPTIVE INFORMATION

Strains of the genus *Stigmatella* are usually easy to recognize by their relatively large, stalked, dark red brown fruiting bodies. In addition, the swarms with their tracks of oscillating waves are typical. The 16S rRNA sequences of the six strains studied cluster closely together as a group and are clearly separate from *Cystobacter*, *Archangium*, and *Melittangium* strains (Spröer et al., 1999). The differentiation of species is more difficult, because typical fruiting bodies are often not produced, and the degenerate forms are the same in all strains. In the case of *Stigmatella aurantiaca* and *Stigmatella erecta*, ecological observations may often help; while *Stigmatella aurantiaca* is only found on rotting wood,

Stigmatella erecta is obtained from soil and dung of herbivorous animals. *Stigmatella aurantiaca* was classified for many years as *"Chondromyces aurantiacus"*; *Stigmatella erecta* was classified as *"Podangium erectum"* (the genus was actually created for it by Jahn, 1924). The two look and behave very similarly and clearly belong in one genus. The genome sizes differ slightly between the two species (9.2–9.9 Mbp for *Stigmatella aurantiaca*, 9.7–10 Mbp for *Stigmatella erecta*; Neumann et al., 1992), but it is not known whether this is taxonomically relevant. Several more species, classified in the genus *Chondromyces* at the time but obviously belonging to *Stigmatella*, were described by Krzemieniewska and Krzemieniewski. Most have since been assigned to *Stigmatella aurantiaca*, and one to *Stigmatella erecta* (Reichenbach and Dworkin, 1969; McCurdy, 1971a). But the authors reported (Krzemieniewska and Krzemieniewski, 1946) that they could not isolate a real *"Chondromyces aurantiacus"*, i.e., *Stigmatella aurantiaca*, for 15 years; they finally succeeded in obtaining several strains from rotting beech wood and bark in Poland. While this is the proper habitat of *Stigmatella aurantiaca*, all earlier strains on which the various species descriptions were based appear to have been isolated from soil and rabbit dung, which are the typical habitats of *Stigmatella erecta*. Yet at least some of their illustrations appear to show *Stigmatella aurantiaca* fruiting bodies. As strains are no longer available, the question of those "new" species cannot satisfactorily be decided. *"Chondromyces brunneus"* (Krzemieniewska and Krzemieniewski, 1946) was originally described as *"Chondromyces aurantiacus"* biovar frutescens (Krzemieniewska and Krzemieniewski, 1927) and later renamed *"Stigmatella brunneus"* (McCurdy, 1971a) and *"Stigmatella brunnea"* (McCurdy and Khouw, 1969). It may have been *Stigmatella erecta*; Krzemieniewska and Krzemieniewski recognized a similarity with that species. *"Chondromyces cylindricus"* (Krzemieniewska and Krzemieniewski, 1930) (= *"Stigmatella cylindrica"* McCurdy, 1971a), and *"Chondromyces medius"* (Krzemieniewska and Krzemieniewski, 1930) (= *"Stigmatella media"* McCurdy, 1971a) were most likely *Stigmatella aurantiaca*. *"Chondromyces minor"* (Krzemieniewska and Krzemieniewski, 1930) was later reinterpreted by Krzemieniewska and Krzemieniewski (1946) as a composite form of *"Podangium gracilipes"*, now *Melittangium lichenicola*, and withdrawn as a species. However, the organism may in fact have been *Stigmatella aurantiaca*. In this edition only three species of *Stigmatella* are listed; they can readily be distinguished from one another.

Key to the species of the genus *Stigmatella*

I. Clusters of sporangioles on an unbranched, common stalk.
Stigmatella aurantiaca

II. Sporangioles solitary on stalks, fruiting bodies often in tufts.

A. Sporangioles usually stalked.
Stigmatella erecta

B. Besides stalked sporangioles many sporangioles without a stalk, solitary or in chains and piles.
Stigmatella hybrida

List of species of the genus Stigmatella

1. **Stigmatella aurantiaca** Berkeley and Curtis *in* Berkeley 1857, 313[AL]

au.ran.ti' a.ca. M.L. fem. adj. *aurantiaca* orange colored.

Vegetative cells, myxospores, and swarm colony as described for the genus. Fruiting bodies (Fig. BXII.δ.89) consist of spherical to ovoid, bright orange to red brown sporangioles measuring 25–45 × 40–60 µm; 1–20, usually 5–15, sporangioles are borne on a common stalk, 60–140 µm high and 30–100 µm wide. The stalk is white but may become orange-brown near the upper end.

The species is easy to recognize when typical fruiting bodies are present, which is often not the case in culture. Stalks with a single sporangiole and completely degenerate fruiting bodies in the form of narrow ridges may be produced. In contrast to the other two *Stigmatella* species, *Stigmatella aurantiaca* seems to be restricted to rotting wood as a substrate, although it does not attack cellulose. It is a very common species in the Midwest of the United States, where it is found on bark and decaying wood. In Minneapolis, a soft-rotten willow trunk was found with large, bright orange-brown patches consisting of thousands and thousands of *Stigmatella aurantiaca* fruiting bodies. The species seems to be rather rare elsewhere, although it also has been found in other places, e.g., in Poland (Krzemieniewska and Krzemieniewski, 1946) and Germany (Dawid, 1978).

Stigmatella aurantiaca was classified for some time as *"Chondromyces aurantiacus"*. However, its fruiting bodies are much smaller than those of the *Chondromyces* species, which may occur in the same habitat. In addition, they arise in a different way. While the stalk of a *Chondromyces* fruiting body is excreted by a globular mass of cells, which is thus lifted upward and only differentiates into a cluster of bright yellow orange sporangioles when stalk formation is completed, the stalk and sporangioles of *Stigmatella aurantiaca* fruiting bodies emerge concomitantly from the aggregated cell mass, so that the stalk initially contains many cells. Most of those cells later emigrate from the stalk or die and lyse, while those in the sporangiole section convert into myxospores.

The mol% G + C of the DNA is: 67–68 (Bd, T_m).

Type strain: ATCC 25190.

GenBank accession number (16S rRNA): M94281.

Additional Remarks: Reference strains include ATCC 33878, DSM 1035 (Sg a8).

2. **Stigmatella erecta** (Schroeter 1886) McCurdy 1971a, 48[AL]

e.rec' ta. L. fem. adj. *erecta* erect, upright.

Vegetative cells, myxospores, and swarm colonies as described for the genus. Fruiting bodies (Fig. BXII.δ.90) consist of yellow-brown to red-brown spherical to club-shaped sporangioles, often slightly larger than those of *Stigmatella aurantiaca* and, in contrast to the latter, single on white stalks. The stalks often are much longer than those of *Stig-*

A

C

B

FIGURE BXII.δ.89. *Stigmatella aurantiaca*: fruiting bodies. (*A*) On agar surface, with sporangioles on long pedicles. (*B*) Young fruiting body at the edge of a piece of filter paper, under water and cover glass. (*C*) Scanning electron micrograph (× 315). Fruiting body on wood. Both a side and a top view are shown. Bar in A = 135 µm; bar in B= 65 µm.

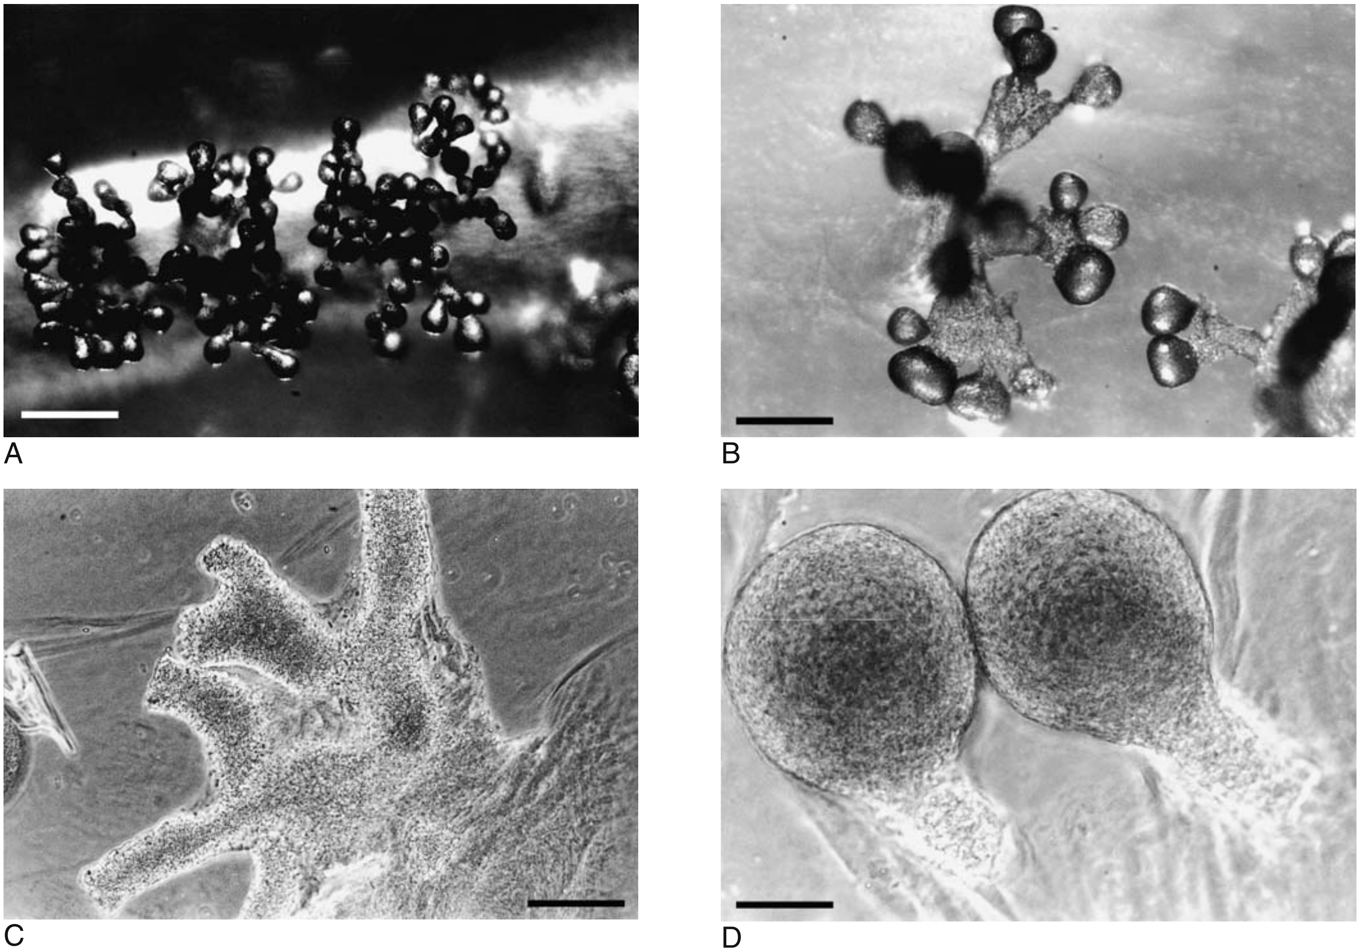

FIGURE BXII.δ.90. *Stigmatella erecta*: fruiting bodies. (*A* and *B*) On agar surface: The fruiting bodies tend to arise in dense clusters (*A*). As the stalks often fuse from the base upward, *S. erecta* fruiting bodies may resemble those of *Stigmatella aurantiaca* (*B*). (*C*) Cluster of stalks, with the sporangioles shed, in phase contrast. (*D*) Sporangioles, slide mount, in phase contrast. Bar in *A* = 160 μm; bar in *B* = 100 μm; bar in *C* = 40 μm; bar in *D* = 20 μm.

matella aurantiaca fruiting bodies, and sometimes are branched, usually near the base, but if the branching is higher up, the fruiting body can be mistaken for a degenerate *Stigmatella aurantiaca* fruiting body. The fruiting bodies of *Stigmatella erecta* often arise in large, dense tufts of 50–100 or more.

Stigmatella erecta can be found in soil and on dung of herbivorous animals and seems to be a more common and more widely distributed organism than *Stigmatella aurantiaca*.

The mol% G + C of the DNA is: 68 (T_m).

Type strain: ATCC 25191.

Additional Remarks: Reference strains include ATCC 25192, ATCC 29622.

3. **Stigmatella hybrida** *sp. nov.*

hy' bri.da. L. masc. fem. n. *hybrida, hibrida* half-breed, bastard.

Vegetative cells (Fig. BXII.δ.91), myxospores (Fig. BXII.δ.92), and swarm colonies as described for the genus. Fruiting bodies (Fig. BXII.δ.93) consist of moderately large to large dark red brown to almost black spherical to elongated sporangioles, 40–100 μm in diameter. The sporangioles can be either solitary on white, sometimes rather delicate, stalks of varying length, or they can be single on a slime pad, or they can be arranged in long, often convoluted and looping chains; these chains sometimes condense into large piles. Stalked fruiting bodies may arise singly or in tufts. Thus, the fruiting bodies of *Stigmatella*

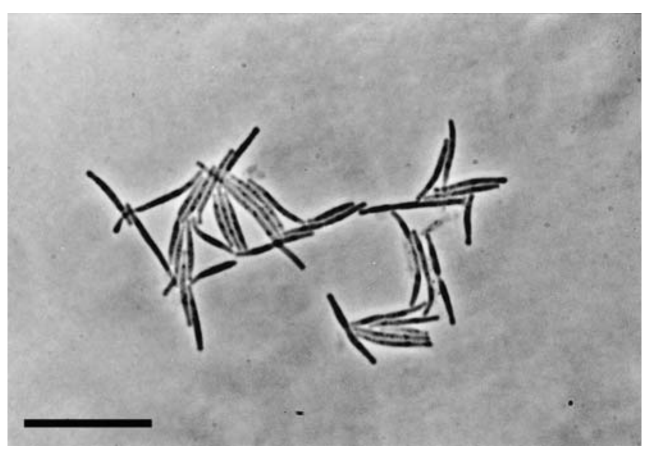

FIGURE BXII.δ.91. *Stigmatella aurantiaca*: vegetative cells from a liquid culture, in phase contrast. The vegetative cells of all *Stigmatella* species are identical in shape and size. Bar = 10 μm.

hybrida resemble those of *Stigmatella erecta*, but are darker in color and often sedentary or in chains. They resemble the fruiting bodies of *Cystobacter badius* and *Cystobacter velatus*, but differ in having their sporangioles on long stalks; further, *Stigmatella hybrida* has shorter, more delicate and fusiform vegetative cells and shorter, often bean-shaped myxospores. This mixture of morphological characteristics suggested the name of the species.

Stigmatella hybrida is relatively common in soil and on dung of herbivores and has a wide distribution. Strain Sg h20 was isolated in 2000 from soil with decaying plant material collected in 1999 on the island of Rhodos, Greece, and reference strain Sg h8 was isolated in 2000 from a similar sample collected in 1997 in the saguaro savanna west of Tucson and Sells, AZ, USA.

The mol% G + C of the DNA is: not determined.

Type strain: Sg h20, DSM 14722, JCM 12640.

Additional Remarks: Reference strains include DSM 14737 (Sg h8).

Additional support for the classification of the organism in the genus *Stigmatella* rather than *Cystobacter* rests on the observation that the pattern of secondary metabolites corresponds to that of the other two *Stigmatella* species and not to that of the cystobacters (Dr. Brigitte Kunze, personal communication).

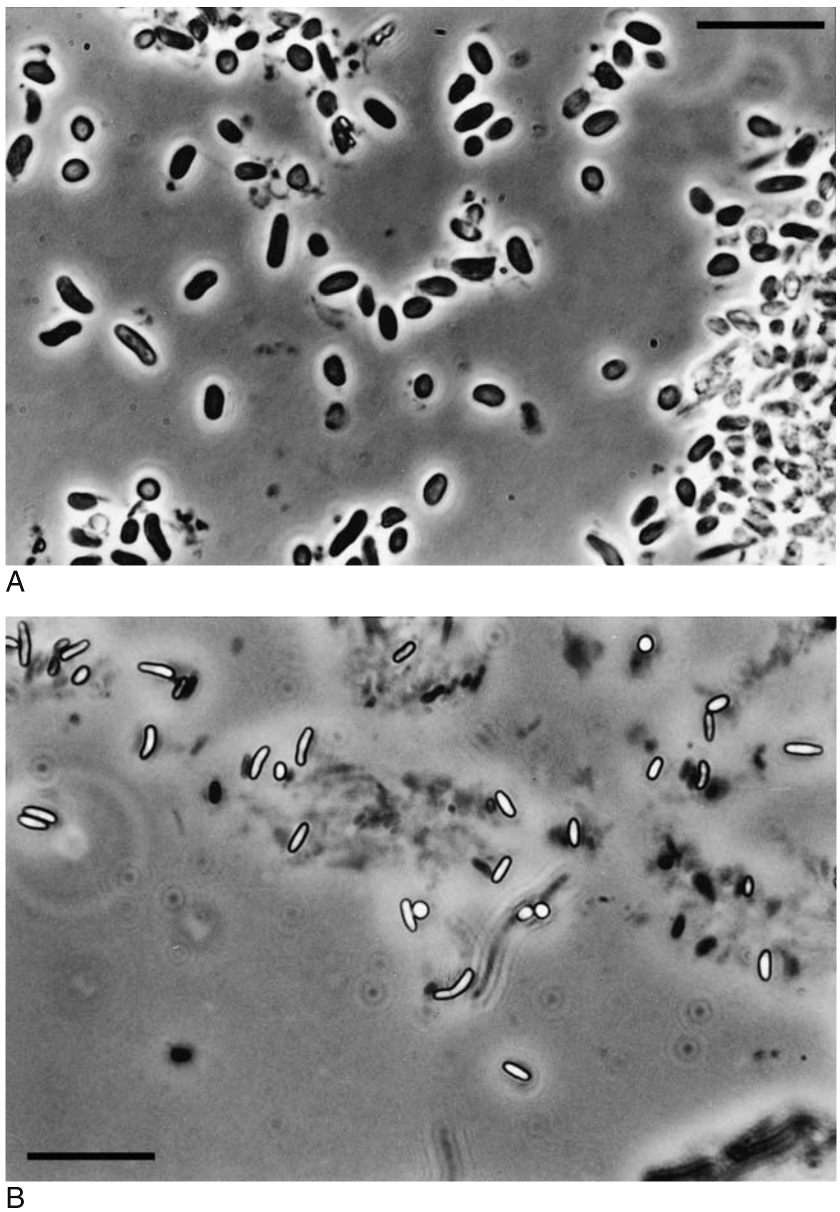

FIGURE BXII.δ.92. *Stigmatella*: myxospores. The myxospores of the *Stigmatella* species are the same in shape and size. (*A*) Myxospores of *Stigmatella erecta* from crushed sporangioles, in phase contrast. (*B*) Myxospores of *S. aurantiaca* produced outside of fruiting bodies on a thin agar layer in a chamber culture. Under such conditions, the optical refractility of the myxospores becomes particularly striking. Bar in *A* = 10 μm; bar in *B* = 25 μm.

Family III. **Polyangiaceae** Jahn 1924, 75[AL]

HANS REICHENBACH

Po.ly.an.gi.a′ ce.ae. M.L. neut. n. *Polyangium* type genus of the family; *-aceae* ending to denote a family; M.L. fem. pl. n. *Polyangiaceae* the *Polyangium* family.

Vegetative cells slender, cylindrical rods with blunt, rounded ends. Often contain optically bright granules of reserve material. **The fruiting bodies always consist of sporangioles**, which may be single or, more often, **clustered in sedentary sori or borne on a slime stalk**. In cultures, strains often refuse to produce fruiting bodies. Yet degenerate fruiting bodies, as are so typical for the *Cystobacteraceae*, are only rarely formed. **The myxospores in the fruiting bodies are morphologically not much different from vegetative cells**, perhaps somewhat shorter and slightly constricted around the middle. However, they are true, optically refractile resting cells, which are as desiccation and heat resistant as the myxospores of the two previous families. **The swarm colonies tend to etch the agar**, producing radial tracks, holes, and pits in the surface of the plate, and often penetrate the substrate deeply. In the genera *Polyangium* and *Byssophaga* discontinuous swarm colonies with scattered cell clusters occur in addition to the more typical coherent swarms with slime sheets and veins. Congo red is not adsorbed to the slime of the swarms. Most species are of the proteolytic–bacteriolytic nutritional type, but some are cellulose degraders and, in contrast to all other myxobacteria, may be cultivated on very simple media with an inorganic nitrogen source and a sugar as the only carbon source.

Type genus: **Polyangium** Link 1809, 42.

Key to the genera of the family Polyangiaceae

I. Fruiting bodies consist of sporangioles without a stalk arranged singly or, more often, in sori, in which they may be so tightly packed as to become polyhedral.
   A. Of the proteolytic-bacteriolytic nutritional type, require an organic nitrogen source.
      1. Sporangioles in clusters (sori).
         Genus *Polyangium*
      2. Sporangioles solitary.
         Genus *Haploangium*
   B. Cellulose degraders; may be cultivated on inorganic nitrogen sources.
      1. Swarm colonies sheet-like, with more or less prominent veins. When grown on filter paper, sporangioles are produced in enormous numbers in the macerated paper; sori are yellow, orange, brown, or black, but never red.
         Genus *Sorangium*
      2. Grows in the form of independently migrating cell companies, or pseudoplasmodia, that finally contract into intensely cinnabar- to carmine-red knob-like masses, resembling *Myxococcus* fruiting bodies. Sporangioles rarely produced; red.
         Genus *Byssophaga*

II. Fruiting bodies consist of sporangioles on a slime stalk or cushion.
   A. Sporangioles bright yellow orange, borne on a long, sometimes branched white stalk.
      Genus *Chondromyces*
   B. Sporangioles orange to red brown, in convoluted, brain-like chains, often on a prominent slime cushion.
      Genus *Jahnia*

FURTHER DESCRIPTIVE INFORMATION

In most cases, it is easy to recognize that a strain belongs to this suborder, because the vegetative cells are so characteristic and clearly different from those of the *Cystobacterineae* and most organisms of the *Nannocystineae*. In addition, the swarm colonies with their pits and etched agar surface are typical. There are two confusing overlaps, however. Strains erroneously classified for some time as *Polyangium vitellinum* (Pl vt1) turned out to have a 16S rRNA sequence that connects them with the *Nannocystis* group (Spröer et al., 1999). Those organisms have the same cell type as *Polyangium*, i.e., slender, cylindrical rods with rounded ends, and fruiting bodies clearly different from those of *Nannocystis*. The swarms do not etch the agar and usually produce a very tough slime sheet. In fact, this bacterium was apparently found long ago by other investigators, e.g., by Kofler (1913), who regarded it as a new species, *"Polyangium flavum"* (*"Archangium flavum"* Jahn 1924). The organism is renamed here *Kofleria flava* in his honor and is transferred to the suborder *Nannocystineae*. The swarm colonies of *Nannocystis* are another possible source of confusion. Those organisms also etch the agar, sometimes transforming the plate into a spongy mass, but tracks and holes produced by *Nannocystis* and the cell clusters in them are usually much smaller than those of *Polyangium*. In addition, the vegetative cells, myxospores, and fruiting bodies of *Nannocystis* are different from those of *Polyangium*.

The type genus of the family, *Polyangium*, is the first myxobacterium ever to be described. Link (1809) did not recognize *Polyangium vitellinum* as a myxobacterium and thought it to be a tiny gasteromycete. But he published very clear drawings of it, so that there can be little doubt that Thaxter's (1892) *"Myxobacter aureus"* was the same organism. For a long time the genera *Polyangium* and *Cystobacter* were not distinguished, because their fruiting bodies look similar, and all those species were classified as *Polyangium*, until the fundamental difference in vegetative cells and myxospores of the two was recognized (McCurdy, 1970). Because of incomplete descriptions of some of those old species, it is impossible today to decide whether they belong to the one or the other genus. In addition, in the early days of myxobacterial

research some species were labeled *Polyangium* even though sporangioles had never been observed. A similar conflation of the genera *Chondromyces* and *Stigmatella* occurred, as has been pointed out above. These cases show clearly that certain basic shapes of fruiting bodies have evolved independently in myxobacteria that are rather distantly related and that fruiting bodies alone are not a sufficient basis for classification.

The genus *Sorangium* was originally created by Jahn (1924) to comprise species with angular sporangioles. He even established a new family for those organisms. Angular sporangioles, however, are not a characteristic to build on, because the shape of the sporangioles depends very much on the culture conditions, which determine whether the sporangioles are densely or loosely packed. Spherical and polyhedral sporangioles may be found in the same culture, and polyhedral sporangioles are seen occasionally in *Cystobacter* and *Pyxicoccus* cultures. It was therefore justified to eliminate a genus based on such a definition (McCurdy, 1970). However, several of the first cellulose-degrading myxobacteria to be described (Krzemieniewska and Krzemieniewski, 1937a, b) were classified as *Sorangium* species, and as cellulose degradation appears to be a very stable and unique characteristic, the genus *Sorangium* is revived here for those organisms. A new genus, *Byssophaga*, is established below for a second, newly discovered, and clearly different cellulose degrader. While *Sorangium* 16S rRNA sequences cluster closely with those of proteolytic *Polyangium*, the two differ in other characteristics besides cellulose degradation, e.g., in the ability to synthesize lanosterol (only *Polyangium*), in swarm morphology, and in sensitivity to certain antibiotics. Some *Sorangium* strains have the largest genomes known for myxobacteria (12 Mbp) (Pradella et al., 2002).

All seven *Chondromyces* strains, for which 16S rRNA sequences have been determined, form one cluster that is strongly separated from the *Polyangium–Sorangium* cluster. This finding could justify creating a separate family for the chondromycetes. For the moment, they are still included in the family *Polyangiaceae* until more information becomes available. *Chondromyces crocatus* is another one of those early myxobacteria that were first described as fungi, in this case a deuteromycete (Berkeley, 1857). The *Chondromyces* group received an unexpected addition through the 16S rRNA sequence of *"Polyangium thaxteri"* (Spröer et al., 1999). A new genus, *Jahnia*, will be created here for this organism.

Genus I. **Polyangium** *Link 1809, 42*[AL]

HANS REICHENBACH

Po.ly.an′gi.um. Gr. adj. *polys, poly* many, much; Gr. neut. n. *angion* vessel, container; M.L. neut. n. *Polyangium* many vessels.

Vegetative cells (Fig. BXII.δ.94) **slender, cylindrical rods with blunt, rounded ends**. **Fruiting bodies consist of spherical or polyhedral sporangioles**, usually in sedentary sori, on agar plates often deep within the substrate, sometimes surrounded by a prominent slime layer, or matrix. **Myxospores morphologically similar to vegetative cells** but optically refractile. **The swarm colonies** (Fig. BXII.δ.95) **often etch the agar** producing deep tracks and tunnels, holes, and pits; often penetrate the agar deeply with a curtain-like swarm edge; swarms often not coherent but broken up into many small, scattered groups of cells that migrate independently, like pseudoplasmodia.

Of the proteolytic–bacteriolytic nutritional type. All strains that have been investigated synthesize lanosterol (Zeggel, 1993).

Type species: **Polyangium vitellinum** Link 1809, 42.

FURTHER DESCRIPTIVE INFORMATION

While it is relatively easy to recognize a strain as a member of the genus *Polyangium*, the differentiation of species is not yet very reliable for several reasons. The first threshold is easy to cross. Beginning with Thaxter (1904) the *Cystobacter* species were lumped into the genus *Polyangium*, because the fruiting bodies looked so similar. The fundamental difference in cell shape be-

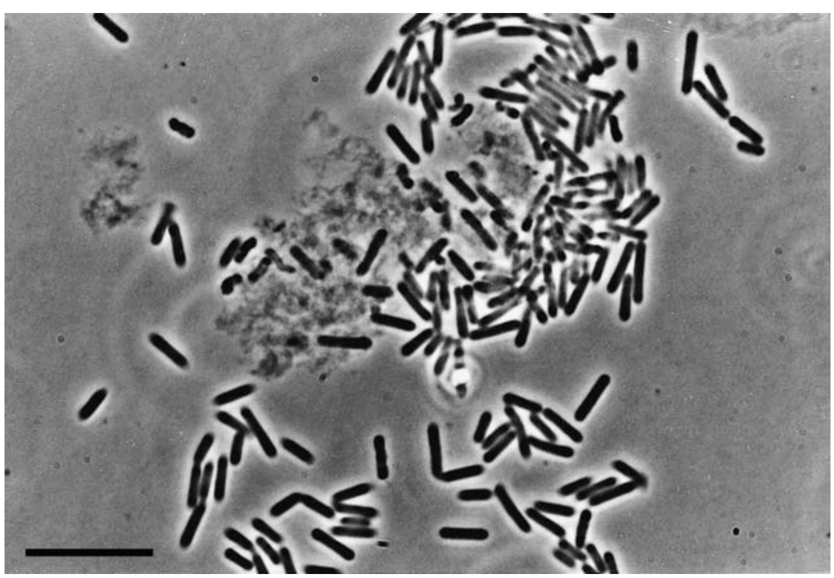

FIGURE BXII.δ.94. *Polyangium spumosum*: vegetative cells from yeast agar, phase contrast. The vegetative cells of all *Polyangium* species are very similar in shape and size. Bar = 13 μm.

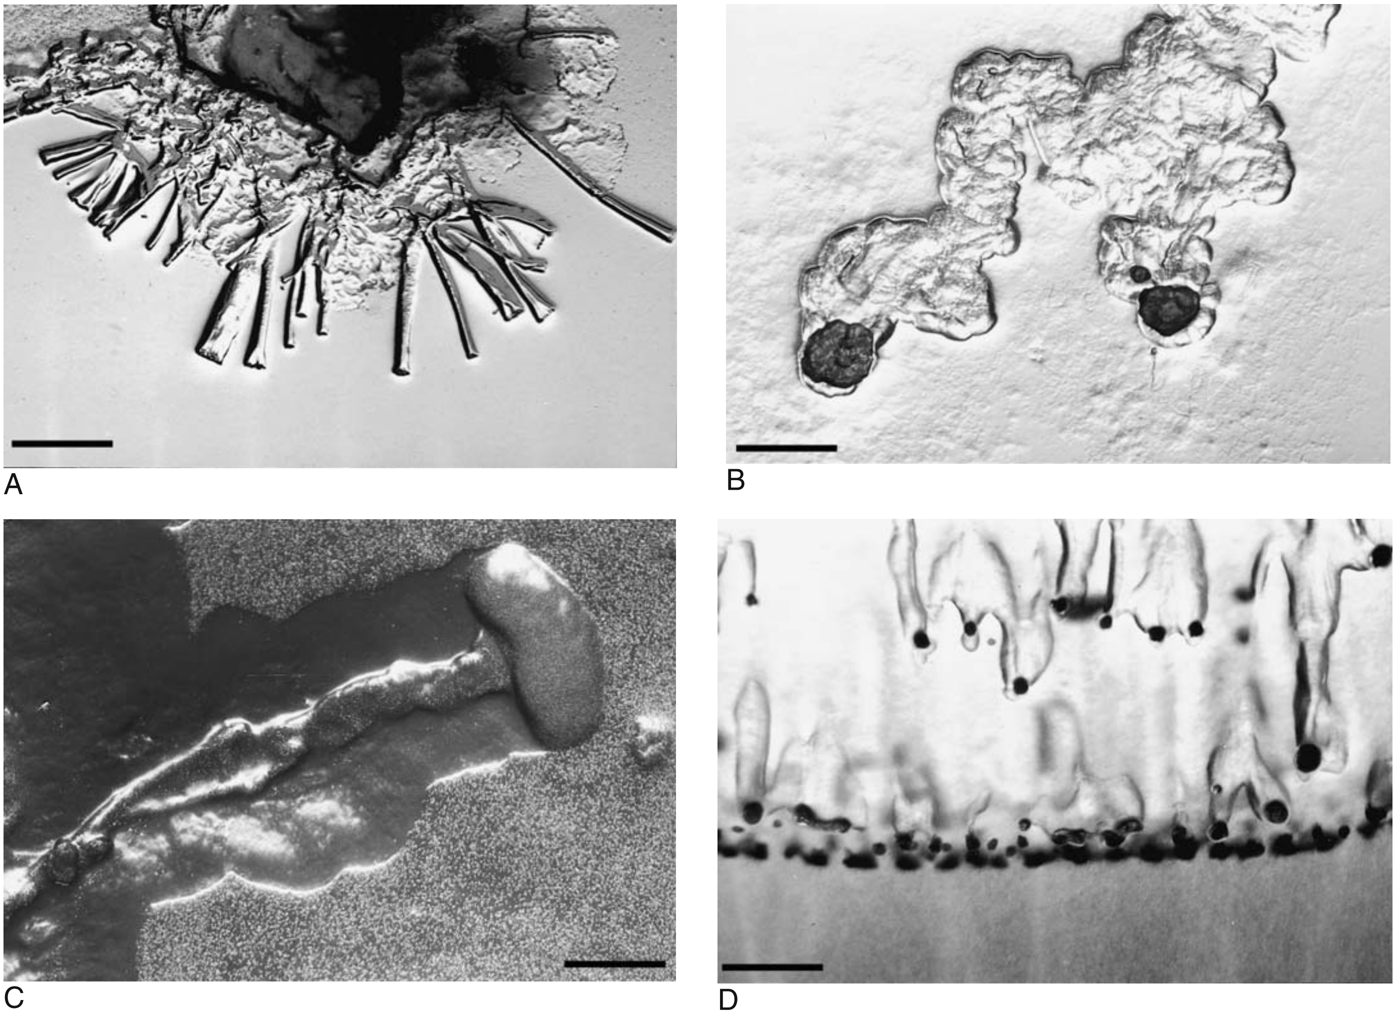

FIGURE BXII.δ.95. *Polyangium* species: swarm colonies on agar plates. (*A*) Growing on a streak of living *E. coli* on water agar, small packs of cells migrate radially away from the inoculum producing deep channels in the agar surface (bar = 1460 μm). (*B*) and (*C*) On streaks of autoclaved *E. coli* (bar in *B* = 960 μm; bar in *C* = 260 μm). (*C*) The cell mass eats a path into the *E. coli* streak and leaves a tail-like slime strand behind. (*D*) *Polyangium fumosum* on yeast agar: the swarm penetrates the agar plate deeply, the swarm edge is a curtain-like sheet of small cell clumps within the agar; note the lytic clearing of the yeast cells inside the swarm (bar = 50 μm).

tween *Polyangium* and *Cystobacter* was observed early (e.g., Krzemieniewska and Krzemieniewski, 1928), but the taxonomic relevance of this observation was not realized until much later (McCurdy, 1970). As mentioned above, the shape change during sporulation and, as a rule, the swarm morphology are clearly different in the two genera. Therefore, the separation of *Cystobacter* (and *Hyalangium*) and *Polyangium* is not problematic. However, over the years many organisms have been described that appear to be real *Polyangium* species, but often are difficult to distinguish and to evaluate based on present data. Most of those species are rare—or at least their preferred habitats have not yet been identified—and most of them have never been cultivated, so that many descriptions are incomplete and imprecise. There is often doubt as to whether later investigators were talking about the same organism when they used a name from the literature. Finally, no type strains are available. Consequently, many *Polyangium* species have been eliminated from the List of Approved Names and from the last edition of the *Manual*. Yet some of the descriptions sound realistic enough to make one suspect that those species may really exist as distinguishable taxa. Several of those organisms are included in the following key to facilitate orientation and to make it easier for future investigators to determine whether a new isolate belongs to a previously described species. On the other hand, the author has isolated several strains that cannot be classified as any of the present species. Apparently, there are even more *Polyangium* species.

Polyangium strains are somewhat difficult to isolate and to handle, but with sufficient effort, all species should be culturable. They all grow on yeast agar (VY/2-), but for unexplained reasons the bacteria sometimes do not grow after a transfer to the same medium on which they grew well before. It seems that the age and perhaps the size of the inoculum is critical. However, fermentations at a relatively large scale (100 l) have successfully been performed with several strains (e.g., Kunze et al., 1993).

As already indicated, a reorganization of the genus is proposed below. The cellulose degraders are removed from the genus *Polyangium* and returned to the genus *Sorangium*. Further, species with solitary sporangioles are collected in the genus *Haploangium* as formerly defined. The remaining genus *Polyangium* may still not be completely homogeneous, as the species with very large sporangioles may not be closely related to the species with small, more or less angular sporangioles. This question can be answered only when more data become available.

Key to the species of the genus *Polyangium*

I. Not parasitic on freshwater algae.
  A. Sporangioles yellow to orange brown.
    1. Sporangioles spherical, bright yellow to orange, large (80–350 μm), only few in the sorus, sorus with a prominent slime envelope.
      a. Sorus in a hyaline, gelatinous, colorless slime matrix.
        Polyangium vitellinum
      b. Slime envelope of the sorus bright yellow.
        Polyangium luteum
    2. Sporangioles spherical or angular, colorless to golden brown, moderately large to small.
      a. Sporangioles golden brown, spherical, of moderate size (around 40 μm); sori with 2–12 sporangioles in a slime matrix that is often yellow.
        Polyangium aureum
      b. Sporangioles colorless to yellow-orange and reddish-brown, angular, small (5–15 μm), in large numbers densely packed, in sheet-like sori without a prominent slime envelope.
        Polyangium sorediatum
  B. Sporangioles brown or gray to almost black.
    1. Sporangioles in the sorus of very variable size, roundish, in three-dimensional translucent packets looking like a drop of foam, brownish.
      Polyangium spumosum
    2. Sporangioles in the sorus more or less of the same size, sorus often sheet-like or in the form of a ring, opaque, smoky-gray to blackish.
      Polyangium fumosum
II. Parasitizes freshwater algae (*Cladophora*).
  Polyangium parasiticum

List of species of the genus Polyangium

1. **Polyangium vitellinum** Link 1809, 42[AL]
vi.tel.li' num. L. masc. n. *vitellus* egg yolk; L. neut. adj. *vitellinum* in the color of egg yolk.

Vegetative cells cylindrical with rounded ends, 0.7–0.9 × 4–10 μm. Sporangioles spherical to ellipsoidal, golden yellow, 75–350 μm in diameter, with a thick, golden yellow wall; occur in groups of 4–6 (1–12 according to different authors) in a common, gelatinous, hyaline, and colorless slime envelope or matrix. Size of sori 0.7–1 mm (up to 4 mm) (the size of a large grain of sand; Link, 1809). Myxospores resemble vegetative cells in shape, but are shorter, 0.9 × 3.5 μm. Older sporangioles contain a yellow, oily material. Observed on decaying wood and bark, particularly under very wet conditions, e.g., in swamps. The organism appears to have never been cultivated.

The mol% G + C of the DNA is: not determined.

Type strain: Acc. no. 4564, Thaxter collection, Farlow Herbarium, Harvard University, Cambridge, MA, USA.

Additional Remarks: Polyangium vitellinum was well known to the botanists who used to roam forests and swamps in search of myxomycetes and fungi. They found the organism normally on wet wood and bark, and in pools, ditches, and swamps, a few sori at a time. Their descriptions of the organism are the most reliable ones (Thaxter, 1893; Zukal, 1897b; Quehl, 1906). There is some uncertainty whether later authors really were always dealing with the same organism when they wrote about *Polyangium vitellinum*, and how much they relied on earlier records for their descriptions. Jahn's description (Jahn, 1911, 1924) was essentially the same as that of Quehl (1906). Krzemieniewska and Krzemieniewski (1930) obtained an organism from forest soil that resembled Thaxter's *Polyangium vitellinum*. In addition their photograph seems to fit the appearance of *Polyangium vitellinum*. The size of the sporangioles is at the lower end of the earlier measurements, and the habitat was perhaps not quite typical. Also McCurdy's description (McCurdy, 1970) may refer to *Polyangium vitellinum*. The color of the sporangioles was more reddish or brownish, the number of sporangioles in the sori (20) exceeded somewhat that given in the older reports, and the photograph does not show the prominent slime envelope (which may, however, have dried up). The organism described and cultivated by Dawid (1977) and illustrated in the former edition of the *Manual* differs from *Polyangium vitellinum* substantially in the size of the sporangioles, at least if the magnification of the photograph is given correctly. In addition, the ease with which it was cultivated is somewhat suspect. The bacterium identified by the author as *Polyangium vitellinum* and used for 16S rRNA sequencing (Spröer et al., 1999) was clearly not *Polyangium vitellinum*, and is now classified in the new genus *Kofleria*. In fact, this author has not yet seen a real *Polyangium vitellinum*. With the exception of Dawid's organism, the bacterium could never be cultivated in pure culture, but it was propagated on the natural substrate, wood, which was kept very wet for a long time in a dish with water (Quehl, 1906).

Polyangium vitellinum was first described by Link (1809) who classified it as a tiny gasteromycete. Incidentally, he also used first the term *sporangiole* for the encasement of the myxospores. The organism was again described and illustrated, this time in color and at its natural size, by Dittmar (1814), who in fact had collected the original sample on which Link's description was based. Zukal (1897b) rec-

ognized the identity of *Polyangium vitellinum* and *"Myxobacter aureus"* Thaxter 1892, which Thaxter (1904) readily accepted. The demise of the genus *Myxobacter* was already announced by Thaxter in 1897, when he recognized the similarity between *Myxobacter* and the older genus *Cystobacter*. *Polyangium vitellinum* became the type genus and species for the whole group of bacteria and even gave its name to the organisms, the polyangides (Die Polyangiden; Jahn, 1924) in the first monograph on myxobacteria.

Thaxter (1893) described the species *'Myxobacter simplex"*, which he later transferred first to *Cystobacter* (1897) and then to *Polyangium* (1904). It had very large, solitary, bright reddish yellow sporangioles, 250–400 μm in diameter. McCurdy (1970) regarded the species as a variant of *Polyangium vitellinum*; this conclusion was supported by his examination of Thaxter's specimens in the Farlow Herbarium at Harvard University. An organism later described as "*Haploangium simplex*" (Singh and Singh, 1971) and regarded as identical with *Polyangium simplex* Thaxter was evidently not the same bacterium but a member of the *Cystobacterineae*.

2. **Polyangium aureum** (ex Krzemieniewska and Krzemieniewski 1930) Brockman 1989b, 495[VP] (Effective publication: Brockman 1989a, 2162.)
au′re.um. L. neut. adj. *aureum* golden.

Vegetative cells cylindrical rods with rounded ends. Sporangioles spherical to oval, light brown to red brown with an orange-yellow wall, 15–50 × 20–60 μm, 32 × 37 μm on average. Older sporangioles may contain a colorless to yellow liquid besides a few myxospores. Sori contain 2–12 sporangioles in a transparent, sometimes yellow slime matrix. Myxospores resemble vegetative cells, 0.7–0.9 × 2.8–5 μm. Obtained from soil.

The mol% G + C of the DNA is: not determined.

Type strain: no culture.

Additional Remarks: The description seems to refer to a definite type, but the status of the species is not yet clear. Krzemieniewska and Krzemieniewski mentioned that their new species resembled *"Polyangium morula"* Jahn in some respects; the latter species differed mainly in the lack of a thick, yellow slime matrix around the sorus. Whether this is relevant is questionable, and the authors admitted that the two species could be identical. However this is of little help, as the status of *"Polyangium morula"* is also unclear.

3. **Polyangium fumosum** Krzemieniewska and Krzmieniewski 1930, 253[AL]
fu.mo′sum. L. neut. adj. *fumosum* smoke or soot colored.

Vegetative cells cylindrical with rounded ends, 0.6–0.9 × 4–7 μm. Sporangioles spherical or somewhat elongated, often slightly polyhedral, colorless to grayish, with transparent walls, 15–25 × 25–40 μm. Sori (Fig. BXII.δ.96) usually flat, sheet-like, roundish to elongated, often ring-shaped, consisting of 2–50 and more sporangioles; at first pale brown, later smoky gray to soot black. The pigment is found mainly in the slime envelope of the sorus, which, in older fruiting bodies, may transform into a wrinkled sac. Myxospores similar to vegetative cells in shape, 0.7–0.9 × 2.5–5.5 μm. In old sporangioles, the myxospores often degenerate and an oily liquid develops. The organism grows well on yeast agar (VY/2-) with strong lysis of the yeast cells, deeply penetrating the agar plate. Obtained from soil. Not uncommon. Strain Pl fu5 was isolated in 1994 from soil with decaying plant material collected in California, USA, the year before. Reference strain Pl fu11 was isolated in 1999 from a similar sample collected in the same year, also in California.

The mol% G + C of the DNA is: not determined.

Type strain: Pl fu5, DSM 14668, JCM 12636.

Additional Remarks: Reference strains include DSM 14669 (Pl fu 11) Windsor M257.

This *Polyangium* species is easy to distinguish. The moderately sized sporangioles in sheet-like, often ring-shaped, smoky gray to black sori are quite typical. The organism has also been reported and cultivated by other investigators (McCurdy, 1970, Dawid, 1977). It is found relatively often in soil with decaying plant material. It does not attack cellulose.

4. **Polyangium luteum** (ex Krzemieniewska and Krzemieniewski 1927) Brockman 1989b, 495[VP] (Effective publication: Brockman 1989a, 2160.)
lu′te.um. L. neut. adj. *luteum* saffron, golden yellow.

Vegetative cells cylindrical with rounded ends, 0.8–1.0 × 6–8 μm. Sori golden yellow with a thick, pale to bright yellow slime matrix containing 1–2, rarely 3–4 spherical or ellipsoidal sporangioles with thin, colorless walls, 40–120 × 40–90 μm in diameter. The yellow color of the sporangioles seems to be due to the cells within. Myxospores 0.7–0.8 × 4–6 μm. An organism described by Kühlwein and Schlicke (1971) as *Polyangium luteum* produced sori 100–180 × 85–170 μm, with a colorless slime matrix. This organism was isolated from rabbit dung and cultivated as a pure strain. Its swarm colony on agar with suspended *E. coli* resembled that of *Cystobacter fuscus*, which is not typical for a *Polyangium*. The organism hydrolyzed starch, but not cellulose or agar, and could be grown in liquid media in suspension culture, which again is unusual for a *Polyangium*. The author doubts whether this organism was really the *Polyangium luteum* of Krzemieniewska and Krzemieniewski; it is remotely similar to *Kofleria*. Found in soil and on rabbit dung, apparently very rare. New isolates for study would be desirable.

The mol% G + C of the DNA is: not determined.

Type strain: no type strain.

5. **Polyangium parasiticum** (ex Geitler 1925) Brockman 1989b, 495[VP] (Effective publication: Brockman 1989a, 2162.)
pa.ra.si′ti.cum. Gr. adj. *parasitikos;* L. neut. adj. *parasiticum* parasitic.

Vegetative cells cylindrical with rounded ends, 0.7 × 4–7 μm. Sporangioles spherical to somewhat elongated, sometimes slightly polygonal, with a sturdy red brown wall, 25–40 μm in diameter. Mature sporangioles may contain a large drop of an oily liquid. Sori contain 2–20 and more sporangioles within a colorless, hyaline slime matrix. Myxospores resemble vegetative cells, shorter by one-quarter of a cell length at the most. Found on the green alga, *Cladophora*, in a pond near Vienna. Cultivated only on the natural substrate. The organism first grew saprophytically on dead cells of the alga, but when the bacterial population became sufficiently large it attacked young, living cells by digesting a hole in the cell wall and entering the algal cells; the protoplasts, including storage granules of starch, were then completely lysed. Sporangioles were produced within

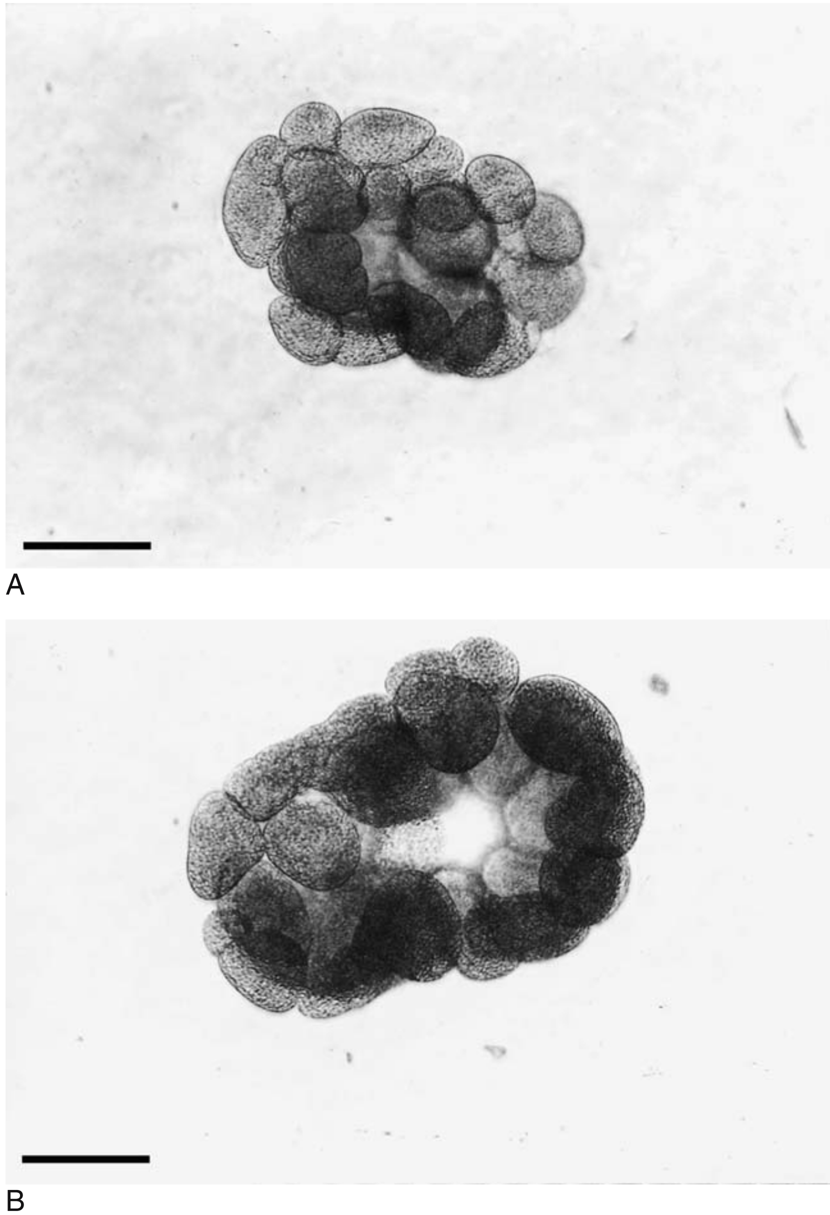

FIGURE BXII.δ.96. *Polyangium fumosum*: fruiting bodies on an agar plate under water and cover glass. The sporangioles are often arranged in rings. Bars = 50 µm.

and outside the *Cladophora* filaments. The myxobacterium did not colonize any other algae in the aquarium.

The mol% G + C of the DNA is: not determined.

Type strain: no type strain.

Additional Remarks: This organism was unquestionably a *Polyangium*. However, the status of the species is undecided. The bacterium also grew also saprophytically, as Geitler himself observed, and it very probably was a soil organism that facultatively parasitized *Cladophora* filaments. A good candidate may be *Polyangium aureum*, which also has red-brown sporangioles of about the same size. The reason why the myxobacterium was found exclusively on *Cladophora* is unknown; perhaps this alga was the only one in the culture with a surface suitable for the myxobacterium. The organism has not been seen since by any other investigator.

A similar case of a parasitic attack, this time on fungi, was reported many years later by Homma (1984). Again, the myxobacterium was a *Polyangium*. It had cylindrical vegetative cells with rounded ends and produced pale to red brown sporangioles that were, however, much smaller (12–22 µm in diameter) than those of *Polyangium parasiticum*. The myxobacterium made many small perforations in the fungal cell wall, entered the cells, and emptied them of their content. Finally, it produced sporangioles within and outside the fungal hyphae and conidia. The author did not give a name to his organism and left its status as a species open. It, too, may have been a facultatively parasitic soil *Polyangium*.

6. **Polyangium sorediatum** (ex Thaxter 1904) Brockman 1989b, 495^{VP} (Effective publication: Brockman 1989a, 2161.)

so.re.di.a′tum. Gr. masc. n. *soros* heap, pile; M.L. neut. adj. *sorediatum* piled up (i.e., the sporangioles).

Vegetative cells cylindrical rods with rounded ends, 0.8 × 3–6 μm. Sori (Fig. BXII.δ.97) colorless to yellow-orange and fox brown, with a very thin matrix, up to 0.5 mm large, flat, sheet-like or cushion-shaped, consisting of numerous roundish to polygonal sporangioles with definite walls, 5–15 μm in diameter, often in delimited clusters within the sorus. Myxospores resemble vegetative cells in shape, 0.8 × 3–4 μm. Readily cultivated on streaks of living or dead *E. coli* on water agar and on yeast agar (VY/2-); often continues to form fruiting bodies long after isolation. Swarm colonies with isolated, shallow tracks, cell clumps at the ends, often with a short slime tail. Does not degrade cellulose. Obtained from rabbit dung, soil, decaying plant material, bark. Moderately common organism, recognizable by its small sporangioles and sheet-like sori. Strain Pl s12 was isolated in 2001 from soil with decaying plant material collected in 2000 in San Diego, CA, USA. Reference strain Pl s4 was isolated in 1995 and came from a similar sample collected near Mumbay, India, in the same year.

The mol% G + C of the DNA is: not determined.

Type strain: Pl s12, DSM 14670, JCM 12637.

Additional Remarks: Reference strains include DSM 14693 (Pl ss4).

Polyangium sorediatum was reported repeatedly after Thaxter's description (Quehl, 1906; Krzemieniewska and Krzemieniewski, 1926, 1927; Dawid, 1977). Jahn (1924) felt that Quehl's strain was *"Polyangium compositum"* rather than *Polyangium sorediatum*, but this was refuted by Krzemieniewska and Krzemieniewski (1926). They also described (Krzemieniewska and Krzemieniewski, 1927) a variant: var. macrocystum, which had sporangioles of 6–10 × 7–16 μm, almost twice the size of Thaxter's organism. Whether this

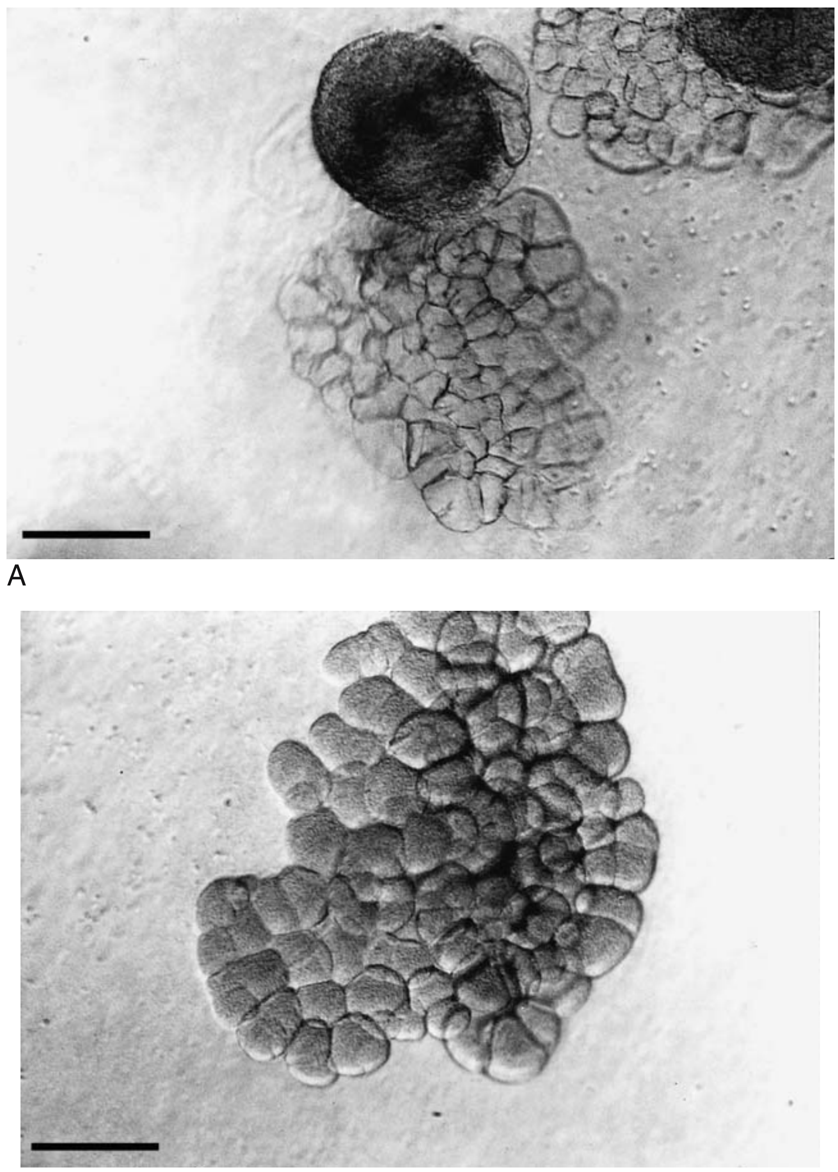

FIGURE BXII.δ.97. *Polyangium sorediatum*: fruiting bodies on agar surface. (*A*) The migrating cell mass has rounded up and is about to produce sporangioles. (*B*) Mature fruiting body. Bar in (*A*) = 65 μm; bar in (*B*) = 35 μm.

difference in size is a reliable characteristic, however, is disputable.

Several more species of *Polyangium* with small, more or less angular sporangioles were described in the early years of myxobacterial research. Jahn (1924) created the genus *Sorangium* for them. The sporangioles of some species were arranged in groups or packets within the sorus, with a well-defined slime envelope of their own. The species differed in the size of the sporangioles and packets and in the color of the sori, all highly variable characteristics that may change considerably even in subsequent cultures of a particular strain. In addition, none of those species has been cultivated, or at least not in pure form, and all were observed only once or rarely. Thus, while there may be fewer species than described by early authors, this author believes that some of them may be true species. Probably none of those species overlaps with *Polyangium sorediatum*, although that cannot be ruled out. For a quick survey, diagnoses of those species are given as far as one can deduce diagnostic characteristics from the old descriptions.

7. **Polyangium spumosum** (ex Krzemieniewska et Krzemieniewski 1930) Brockman 1989b, 495[VP] (Effective publication: Brockman 1989a, 2162.)
spu.mo′sum. L. neut. adj. *spumosum* foamy.

Vegetative cells cylindrical rods with rounded ends, 0.6–0.8 × 4–7 µm. Sporangioles spherical to ellipsoidal or slightly polyhedral with a colorless wall, 20–40 × 20–50 µm, 30 × 35 µm on average, about 20–60 per sorus. Sori (Fig. BXII.δ.98) spherical to somewhat elongated with an inconspicuous, hyaline slime envelope, colorless to light brown, 100–500 µm in size. The sporangioles in the sorus normally are of clearly different size. The sori are relatively transparent and usually three-dimensional resembling a bubble of foam. Myxospores similar to the vegetative cells in shape, only smaller. Older sporangioles may contain only a few myxospores in a granular mass, sometimes in addition to a colorless, oily liquid. Does not degrade cellulose. Grows rather well on yeast agar (VY/2-). Obtained originally from rabbit dung on soil. Not uncommon in soil and decaying plant material. Strain Pl sm5 was isolated in 1995 from soil with decaying plant material collected in 1994 near Braunschweig, Germany; the reference strains, Pl sm9 and Pl sm10, were both isolated in 1996 from similar samples collected at different places in Lucknow, Uttar Pradesh, India, in 1995.

The mol% G + C of the DNA is: not determined.

Type strain: Pl sm5, DSM 14734. JCM 12638.

Additional Remarks: Reference strains include DSM 14735 (Pl sm9), DSM 14736 (Pl sm10).

There is considerable confusion about this species. Krzemieniewska and Krzemieniewski (1927) described a new species, which they named *"Sorangium spumosum"*. This bacterium clearly was not identical with the organism they reported in 1930 as *Polyangium spumosum*. The small size of the sporangioles, 8–26 × 7–20 µm, their colorless to brown walls, and their arrangement in single or double rows suggest that this was instead the bacterium that is listed in this edition as *Hyalangium minutum*. Therefore, the proposal of McCurdy (1970) to rename *Polyangium spumosum* as *"Polyangium paraspumosum"* in order to avoid confusion needs not to be followed; the older name is not valid anyway. Krzemieniewska and Krzemieniewski (1937a) described *"Sorangium spumosum"* again later, this time as a cellulose degrader. However, the vegetative cells were now much fatter, 1.1–1.5 µm wide, which would indeed be typical for *Sorangium cellulosum*. They distinguished two forms, one with smaller and one with somewhat larger sporangioles which, in both cases, were still smaller than those given for *Polyangium spumosum* but which would fit the description of *Sorangium cellulosum*. The author isolated about 20 *Polyangium* strains that correspond quite nicely with the original description of *Polyangium spumosum*. The fruiting bodies strikingly resemble a bubble of foam; this appearance which is caused by the three-dimensional arrangement of rather transparent sporangioles of different sizes. This organism grows very well on yeast agar (VY/2-) under lysis of the yeast cells, penetrating the plate deeply. It does not decompose cellulose. The author has deposited a strain of that organism.

Other Organisms

Apart from the *Cystobacter* species formerly named *Polyangium* and the species now classified as *Haploangium* and *Sorangium*, there are a few more *Polyangium* species in the literature that are now obsolete but may briefly be mentioned.

1. *"Polyangium compositum"* Thaxter 1904, 413. Sporangioles angular, small (former genus *Sorangium* Jahn 1924, 73). Sori completely resolved into sporangioles. Sorus dull yellowish orange; composed of one to six large packets with many sporangioles. Sori 100–170 µm; packets (often called "primary cysts", a confusing terminology now abandoned) 75 × 100 µm on average, sporangioles ("secondary cysts") 10–15 µm. Found on rabbit dung, not cultivated. Probably the same organism that has been reported repeatedly by later authors (Jahn, 1924; Krzemieniewska and Krzemieniewski, 1926, 1927) with slight variations in dimensions and color of the fruiting bodies. Even at that time there was some controversy about identity with Thaxter's species. The slime envelope of the packets was occasionally colored. The organisms were obtained from rabbit and deer dung and from soil, but apparently never cultivated. Jahn (1924) and Krzemieniewska and Krzemieniewski mention that sometimes the development of packets was inconspicuous or absent. Krzemieniewska and Krzemieniewski also described a variant with smaller packets, a further subdivision of the clusters, and sporangioles ("tertiary cysts") of about the size of the type. A similar morphology combined with a much wider variation in color is observed in the *Sorangium cellulosum* complex, so that the question arises whether at least some of the reported *"Polyangium compositum"* strains could have belonged to that species. *Sorangium cellulosum* may indeed be found on substrates like rabbit dung. Krzemieniewska and Krzemieniewski (1937a) reported later that *"Polyangium compositum"* indeed degraded cellulose. Whether or not that organism was identical with the earlier described strains must remain open.
2. *"Polyangium morula"* Jahn 1911, 202. Sporangioles spherical to slightly polygonal, moderately sized, 20–35 µm in diameter, with a thick wall, bright yellow, in mulberry-like sori

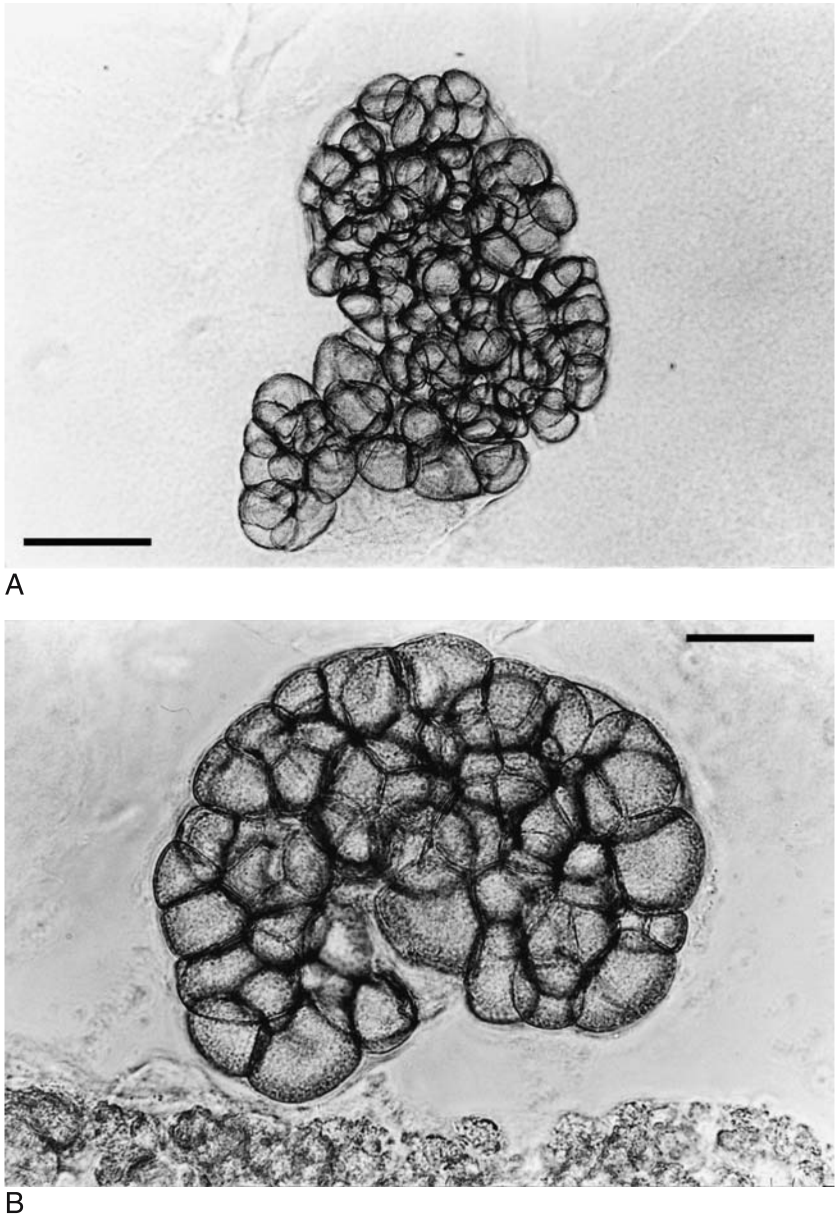

FIGURE BXII.δ.98. *Polyangium spumosum*: fruiting bodies, in slide mounts. Bar in $A = 80$ μm; bar in $B = 40$ μm.

100–200 μm large. Observed only once on rabbit dung and not cultivated. No other report on it seems to exist. Krzemieniewska and Krzemieniewski consider the possible identity of *"Polyangium morula"* and *Polyangium aureum*, but the sporangioles of the latter are said to have a deeper, golden brown color. The author once isolated a strain with striking bright yellow sori, which may correspond to Jahn's description. It was a cellulose decomposer, and thus would now be classified as a *Sorangium*.

3. *"Polyangium schroeteri"* Jahn 1924, 73. Sporangioles angular, small (former genus *Sorangium* Jahn 1924, 73). Sorus incompletely subdivided into sporangioles, orange red. Sporangioles angular, 12–14 μm in diameter. The sori often are kidney-shaped and may show brain-like convolutions. Found on rabbit dung; not cultivated. This "species" was probably an incompletely differentiated form of some other species; Krzemieniewska and Krzemieniewski suggested that it was *"Polyangium compositum"*. The kidney shape of the sori and beginning septation would fit that hypothesis.

4. *"Polyangium septatum"* Thaxter 1904, 412. Sporangioles angular, small (former genus *Sorangium* Jahn 1924, 73). Sori completely resolved into sporangioles. Sorus yellowish-orange to dull orange when dry, 50 to several 100 μm, forming irregular, often confluent masses divided into small, subspherical to subcylindrical packets with a well-defined envelope, containing a few angular sporangioles each. Packets 18–22 × 12–22 μm; sporangioles 10–12 μm in diameter; myxospores 0.8–1 × 3–5 μm. Found in horse dung culture; not cultivated. The organism was seen again by Krzemieniewska and Krzemieniewski (1926, 1927), who obtained it from rabbit dung placed on soil. The packets contained two to seven sporangioles. The dimensions of the packets, sporangioles, and myxospores were essentially those given by Thaxter. In the 1927 paper they also described a variant

with smaller sporangioles (4–10 × 3–8 μm) (var. *microcystum*).

5. *"Polyangium stellatum"* Kofler 1913 had elongated sporangioles with red brown walls, 80–120 × 160–200 μm, arranged in a star-like pattern and sitting on a short, knob-like stalk, sometimes directly on the substrate. The shape of the vegetative cells was not mentioned. As already surmised by Jahn (1924), this may have been an organism belonging to the *Cystobacter–Stigmatella* group. *"Polyangium flavum"* Kofler 1913 (*"Archangium flavum"* Jahn 1924) is now classified as *Kofleria flava*. *"Polyangium indivisum"* Krzemieniewska and Krzemieniewski 1927 was described as similar to *"Polyangium ferrugineum"*; its sporangioles were much smaller and light orange-yellow within a colored slime matrix. It is stated to have had cylindrical cells with rounded ends, "like *Polyangium ferrugineum*". This is contrary to the current concept of *Cystobacter ferrugineus*, and the standing of *"Polyangium indivisum"* is completely obscure. Peterson (1958) described *"Polyangium aurantiacum"* from a herbarium specimen in the Thaxter collection in the Farlow Herbarium at Harvard University and renamed it as *"Sorangium aurantiacum"*, with orange fruiting bodies consisting of angular sporangioles, mostly 7–8 μm wide, with bright yellow walls. The sori were 300–400 μm in diameter and 100 μm high. According to Thaxter the fruiting bodies were found only once on rat dung pellets. The description of the species is not sufficient to allow a reliable identification and evaluation. It may actually have been a *Polyangium sorediatum* strain.

Genus II. **Byssophaga** *gen. nov.*

Hans Reichenbach

Bys.so.pha'ga. Gr. fem. n. *byssos* cotton fabric, fine linen (for cellulose); Gr. v. *phagein* to eat, devour; M.L. fem. n. *Byssophaga* devourer of cellulose.

Vegetative cells cylindrical rods with rounded ends. Swarm colonies consist of independently migrating, pseudoplasmodia-like cell assemblies. Intensely cinnabar- to blood-red. **Fruiting bodies are sori of roundish to polyhedral sporangioles**. **Myxospores resemble vegetative cells in shape but are optically refractile**. Swarm sheet does not adsorb Congo red. Cellulose degrader.

Type species: **Byssophaga cruenta** *sp. nov., nom. rev.* (*Myxococcus cruentus* Thaxter 1897, 409; non *Chondrococcus cruentus* Krzemieniewska et Krzemieniewski 1930, 250/268.)

Further descriptive information

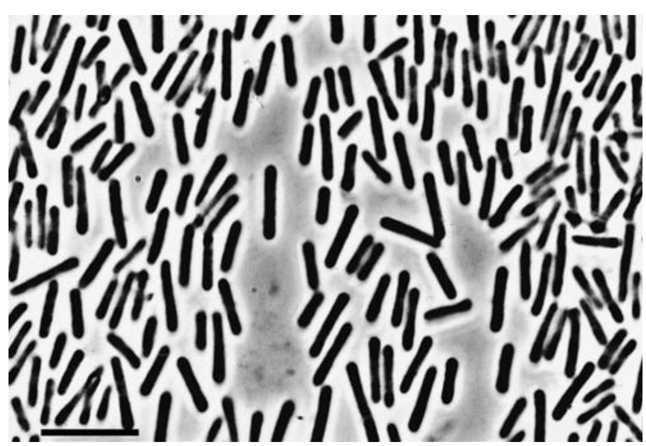
The outstanding characteristic of the genus is the independently migrating flocks of cells. This colony type is unlike that of any other myxobacterium, so that a separate genus seems justified. The only species so far is *B. cruenta*, for which cellulose degradation and an extremely intense red color are typical. The author has occasionally isolated strains with a similar pseudoplasmodia-like pattern of swarm colonies. They were neither red nor cellulose degraders. It still is unclear whether they belong to this genus, and hence cellulose decomposition and color are not listed among the essential characteristics of the genus.

List of species of the genus Byssophaga

1. **Byssophaga cruenta** *sp. nov., nom. rev.* (*Myxococcus cruentus* Thaxter 1897, 409; non *Chondrococcus cruentus* Krzemieniewska et Krzemieniewski 1930, 250/268.)
cru.en'ta. L. fem. adj. *cruenta* blood-red.

Vegetative cells stout, cylindrical rods with rounded ends, 1.2–1.5 × 4–6 μm (Fig. BXII.δ.99). Swarm colonies on agar consist of scattered, independently migrating cell assemblies, in flocks, with a fan-like front and a tapering tail (Fig. BXII.δ.100), intensely cinnabar- to blood-red, becoming carmine-red when aging and dying. The migrating cell masses leave a parchment-like slime track behind, which often has a wrinkled surface. They also may deeply penetrate the agar plate. The pseudoplasmodia finally contract and become spherical knobs, not unlike *Myxococcus* fruiting bodies, 200–500 μm in diameter (Fig. BXII.δ.101). Often form massive rings, with an outer diameter of 330–440 μm and an inner diameter of 80–150 μm, and, rarely, a calyx-like structure with the slime track wrapped around it. Swarms with anastomosing veins, and eventually homogeneous swarms, may be produced upon subcultivation, but the organism may return to the original pattern after transfer to a fresh plate. Fruiting bodies (Fig. BXII.δ.102) are intensely red sori, 220–560 μm and more in diameter, with a thin outer slime envelope. They consist of densely packed roundish to polyhedral sporangioles with a delicate but firm wall, 60–180 μm wide, usually around 80–150 μm. Myxospores resemble vegetative cells in shape and size but are optically refractile.

The organism degrades crystalline cellulose completely and may be cultivated on filter paper as the only carbon source placed on a mineral salts agar with an inorganic nitrogen source, preferentially KNO_3. It grows better if an



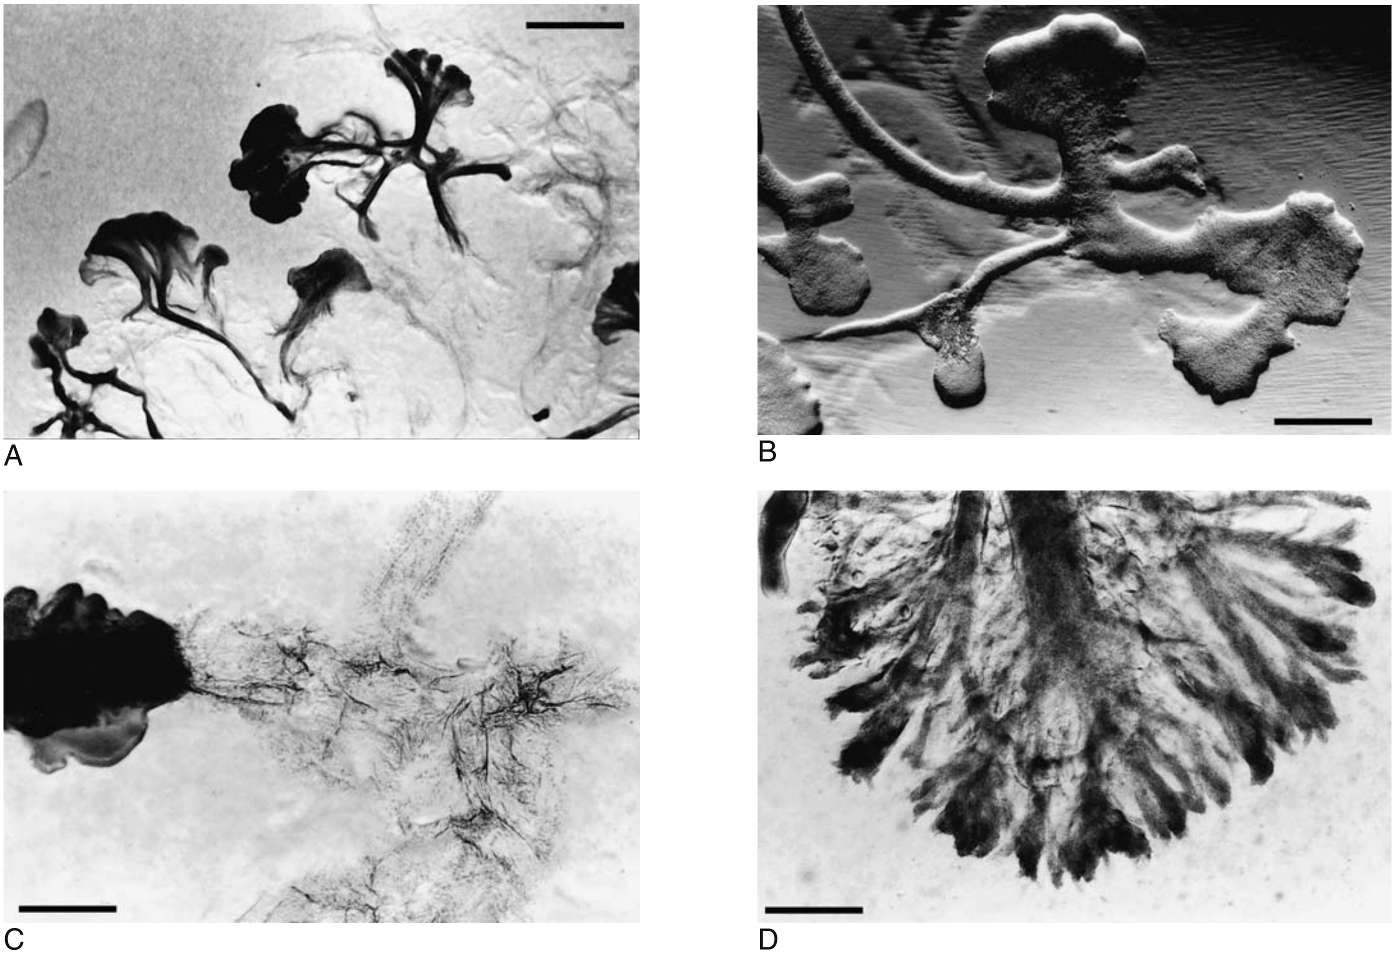


FIGURE BXII.δ.99. *Byssophaga cruenta*: vegetative cells from yeast-maltose agar, phase contrast. Bar = 10 μm.

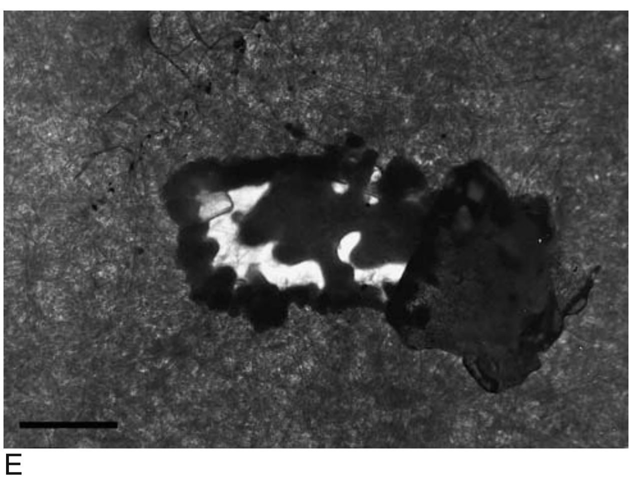

FIGURE BXII.δ.100. *Byssophaga cruenta*: swarm colonies. (*A* and *B*) The swarms of *Byssophaga cruenta* typically consist of independently moving, pseudoplasmodia-like cell packs (bar in *A* = 2100 μm; bar in *B* = 380 μm). (*C*) The migrating cell masses leave a parchment-like slime track behind (bar = 570 μm). (*D*) After many transfers, the organism may begin to grow in more or less coherent swarms (bar = 575 μm). (*E*) Filter paper on mineral salts agar is completely degraded (bar = 1100 μm).

organic nitrogen source is supplied, e.g., casein peptone at low concentrations (0.05–0.1%), but only when combined with a carbohydrate as a carbon source. While glucose is a strong growth repressor (above 0.05%), maltose (up to 4%) stimulates growth. Yeast agar (VY/2-) + 0.2% maltose is a good medium for stock cultures, especially if the inoculum is placed on a piece of filter paper on the agar surface. The yeast cells are degraded.

Starch is hydrolyzed but does not allow good growth, probably because of glucose repression. Growth on chitin agar and decomposition of chitin are slow but are somewhat better if the chitin top layer is on a water agar base (Chit7-agar) and not on a peptone agar base (Chit6-agar; Reichenbach and Dworkin, 1992). The organism has also been cultivated successfully in liquid media. Grows well at 30°C and more slowly at 20°C.

Originally found on cow dung in Tennessee and in woods in the USA, the organism was not cultivated until recently. Strain By c2 was isolated by the author in 2001 from a soil sample with rotting plant material collected in June 1996 in a sagebrush steppe south of Holbrook, Arizona, USA. The sample was air dried and kept at room temperature for 5 years.

The mol% G + C of the DNA is: 69.9 (HPLC).

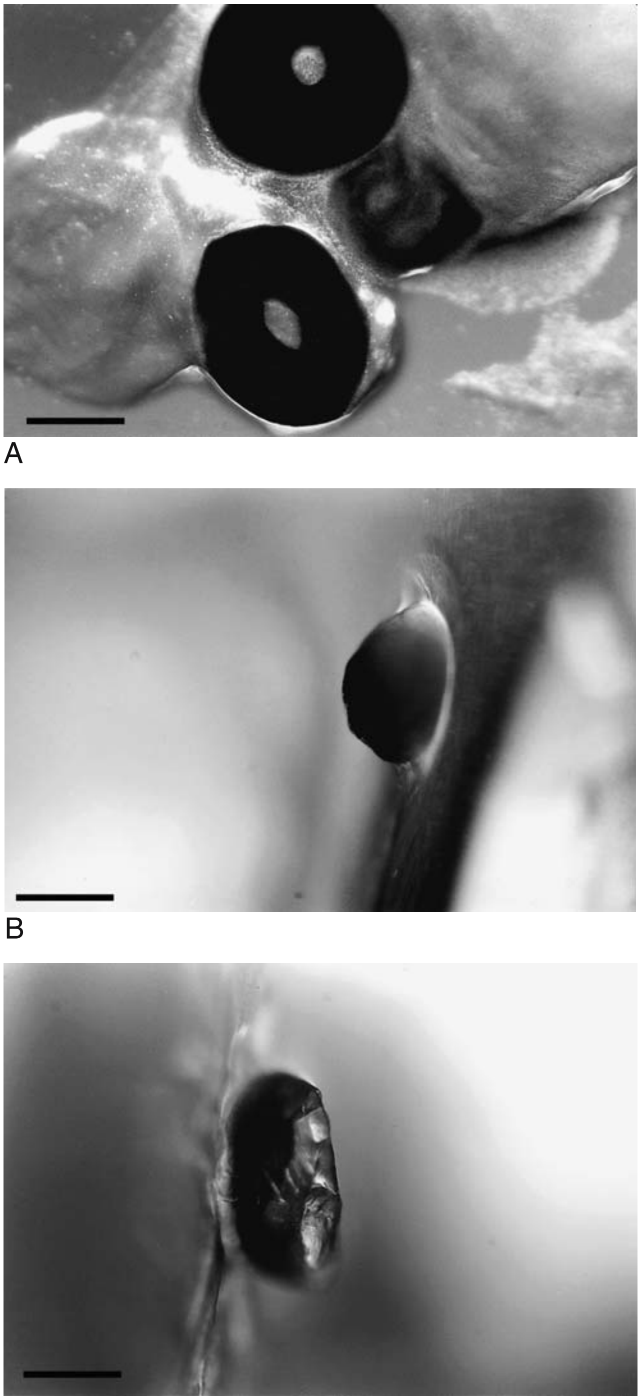

FIGURE BXII.δ.101. *Byssophaga cruenta*: cell aggregates. (*A*) Within the swarm the cells often assemble into massive rings (bar = 200 μm). (*B*) Normally, the pseudoplasmodia finally contract into bright red knobs resembling a *Myxococcus* fruiting body (bar = 260 μm). (*C*) Rarely they produce cup-like structures (bar = 380 μm).

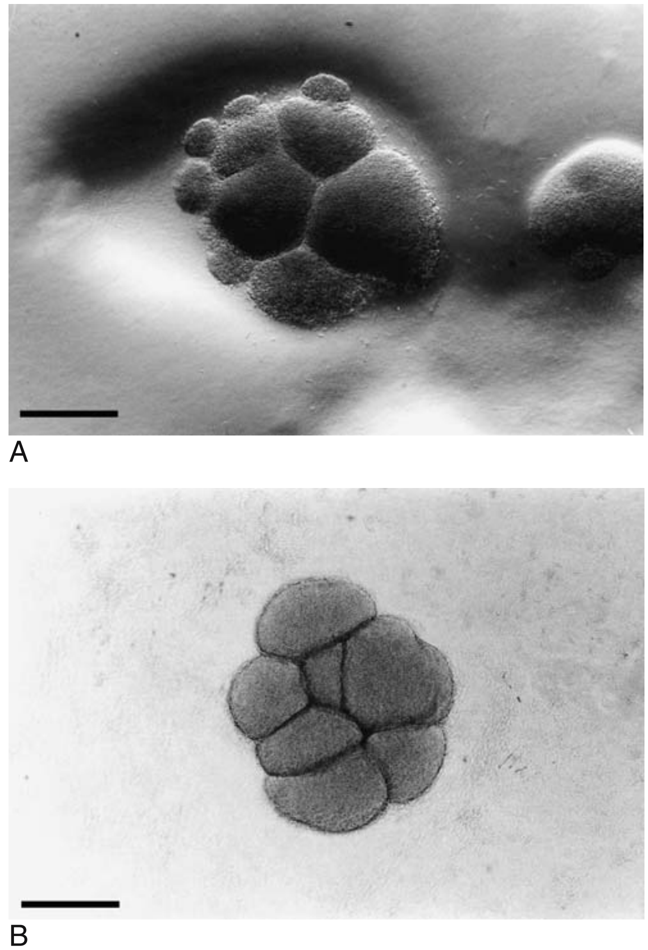

FIGURE BXII.δ.102. *Byssophaga cruenta*: fruiting bodies on surface of agar plates. (*A*) Early stage of fruiting: the developing sorus sits in a depression of the agar surface; sporangioles in the process of differentiation (bar = 80 μm). (*B*) Mature fruiting body, under water and cover glass: the sporangiole walls are clearly distinguishable (bar = 100 μm).

Type strain: DSM 14553, By c2, JCM 12614.

There is little doubt that Thaxter's organism is identical with the one described above. Cell aggregates resembling *Myxococcus* fruiting bodies, incredibly intense red pigmentation, and the structure of the fruiting bodies all are suggestive. The only difference is the shape of the myxospores, which Thaxter describes as oval or irregularly oblong, 0.9–1.0 × 1.2–1.4 μm, i.e., as short rods. But he states that "the spores . . . are not as well developed as in the other species of *Myxococcus*, and seem to suggest a transitional form between *Chondromyces* and *Myxococcus*." As Thaxter could not cultivate the organism—another argument for identity, because cellulose-decomposing myxobacteria were not conceived of at the time—he could not describe the vegetative cells. It seems that no one since has seen, let alone cultivated, the organism. Krzemieniewska and Krzemieniewski (1927) mentioned that they obtained *"Myxococcus cruentus"* abundantly from beech forest soil in Poland, and gave a brief description of their organism (Krzemieniewska and Krzemieniewski, 1930). They curiously renamed it as *"Chondrococcus cruentus"*, although they seem to have seen cysts, i.e., sporangioles that are not produced by *Chondrococcus* (now *Corallococcus*). Their figure of vegetative cells seems to show rods with tapering ends, and the myxospores were essentially spherical. The author is quite sure that this organism was not the same as discussed above; perhaps it really was a red *Corallococcus*.

As a cellulose degrader, *B. cruenta* could qualify to be classified as a *Sorangium* species. There are, however, substantial differences that justify establishing a new genus. In the first place, the swarm pattern with its pseudoplasmodia

is specific to *B. cruenta*. Furthermore, while *S. cellulosum* always produces masses of fruiting bodies, especially on filter paper, *B. cruenta* is a very poor fruiter. In fact, the author has seen fruiting bodies only twice in 5 years. In addition, unlike *S. cellulosum*, *B. cruenta* is completely repressed by low concentrations of glucose and peptone and exhibits a rather low resistance to kanamycin sulfate (up to 10 μg/ml). Finally, the secondary metabolites produced by *Byssophaga* are not those typical of *Sorangium*.

Although this has not yet been proved, the shape of the vegetative cells and the structure of the fruiting bodies suggest that the organism belongs to the *Polyangiaceae*.

Genus III. **Chondromyces** *Berkeley and Curtis* in *Berkeley 1874, 64*[AL]

HANS REICHENBACH

Chon.dro.my' ces. Gr. masc. n. *chondros* cartilage; Gr. masc. n. *mykes* fungus; M.L. masc. n. *Chondromyces* cartilaginous fungus.

Vegetative cells are cylindrical rods with rounded ends. **Swarm colonies produce wide, shallow depressions in the agar surface**, often with an orange band of cells at the edge, agar sometimes slightly etched. Swarms often penetrate the agar deeply. **Clusters of sporangioles borne on long, branched or unbranched white slime stalks**. Myxospores resemble vegetative cells in shape but are optically refractile.

The mol% G + C of the DNA is: 69–70.

Type species: **Chondromyces crocatus** Berkeley and Curtis *in* Berkeley 1874, 64.

FURTHER DESCRIPTIVE INFORMATION

There are several other myxobacterial species with sporangioles on stalks, a fact which has caused some confusion, as already discussed in connection with the genus *Stigmatella*. Most of those species belong to the suborder *Cystobacterineae* and clearly differ from *Chondromyces* in the shape of their vegetative cells and myxospores. *Chondromyces* fruiting bodies are recognizable at once by the bright orange color of the sporangioles, the long, white stalk, and their sheer size. In cultures, older fruiting bodies often degenerate by "growing through", i.e., the bacterial mass on top of the stalk produces another stalk sitting on the original one, usually at an angle, and this process may repeat itself until only a tangle of stalks is left. In addition, species whose fruiting bodies normally have a simple stalk sometimes produce branched fruiting bodies and vice versa. Such aberrant specimens are infrequent and always occur among typical ones; however, a population of fruiting bodies should be available for a reliable diagnosis. In a further deviation from the type, all species sometimes produce stalks with a single sporangiole instead of a cluster.

None of the *Chondromyces* species listed below attacks chitin.

While most *Chondromyces* strains grow in pure culture, many *C. crocatus* strains require a specific symbiont for growth (Jacobi et al., 1996, 1997). There also may be strains of other *Chondromyces* species that need a companion. In pure culture, *Chondromyces* strains produce fruiting bodies only rarely and then under special induction conditions. For example, it was shown that a certain *C. apiculatus* strain requires light for differentiation (Reichenbach et al., 1974). All *Chondromyces* species, however, fruit reliably when grown on filter paper placed on a mineral salts agar, e.g., ST21-agar (Reichenbach and Dworkin, 1992) and inoculated with a mixture of cellulose degrading bacteria derived from nature (other than myxobacteria and cytophagas) and other organisms, such as may be obtained from enrichment cultures for cellulose decomposers. The cultures are kept at room temperature (around 22°C) in daylight.

Key to the species of the genus *Chondromyces*

I. Clusters of sporangioles on branched stalks.
  A. Clusters of tiny sporangioles; stalks normally branched.
    C. crocatus
  B. Clusters of large, spherical, or bowl-shaped sporangioles with many tips, or tails, on the distal surface; stalks unbranched or, often, branched.
    C. lanuginosus

II. Clusters of large sporangioles on simple, usually unbranched, stalks.
  A. Cluster composed of individual sporangioles.
    1. Sporangioles ending in tail-like tips.
      a. Sporangioles turnip-shaped with a single tip, fruiting bodies moderately large, 300–600 μm.
        C. apiculatus
      b. Sporangioles bulbous to spherical, often with 2 or 3 tips, fruiting bodies large, 500–1000 μm.
        C. robustus
    2. Sporangioles bell- or barrel-shaped with a flat end, often hanging down on long, delicate stalklets.
      C. pediculatus
  B. Clusters composed of chains of sporangioles.
    C. catenulatus

List of species of the genus Chondromyces

1. **Chondromyces crocatus** Berkeley and Curtis *in* Berkeley 1874, 64[AL]
cro.ca′ tus. L. masc. adj. *crocatus* saffron-yellow.

Vegetative cells cylindrical rods with blunt, rounded ends, 1.1–1.4 × 3–12 μm (Fig. BXII.δ.103). Fruiting bodies (Fig. BXII.δ.104) are ≥1000 μm high and consist of white or orange branched slime stalks bearing dense, spherical clusters of small sporangioles at the tips of the branches. Often produced in large numbers, like a miniature forest. Sporangioles cylindrical to barrel-shaped with flat or rounded ends, straw-colored to orange, 20–30 × 30–50 μm, borne on very short pedicles or sitting directly on the stalk. Fruiting bodies with simple stalks may be found among those with branched stalks. Myxospores resemble vegetative cells in shape but are optically refractile, 1.0–1.3 × 3–6 μm.

Grows well on yeast agar (VY/2-) with lysis of the yeast cells. Good growth on casein peptone (e.g., CY-) agar. Most strains grow only in the presence of a companion bacterium, which has been found to be always the same regardless of where the *Chondromyces* strain was isolated (Jacobi et al., 1996, 1997). The companion, a *Sphingobacterium*-like organism, does not grow without the *Chondromyces*. However, there are *Chondromyces* strains that do not require a symbiont, e.g., strain Cm c5. *C. crocatus* cultures usually produce a very peculiar odor that is unique among myxobacteria and reminds one of pyridine or raw potatoes, so that new isolates may be identified as *C. crocatus* by this odor alone. Can be cultivated in liquid media together with the companion (Kunze et al., 1994, 1995). Produces at least seven different secondary metabolites, including crocacin, which blocks electron transport in the bc_1-complex of the respiratory chain (Kunze et al., 1994), and the chondramides, which stimulate actin polymerization (Sasse et al., 1998).

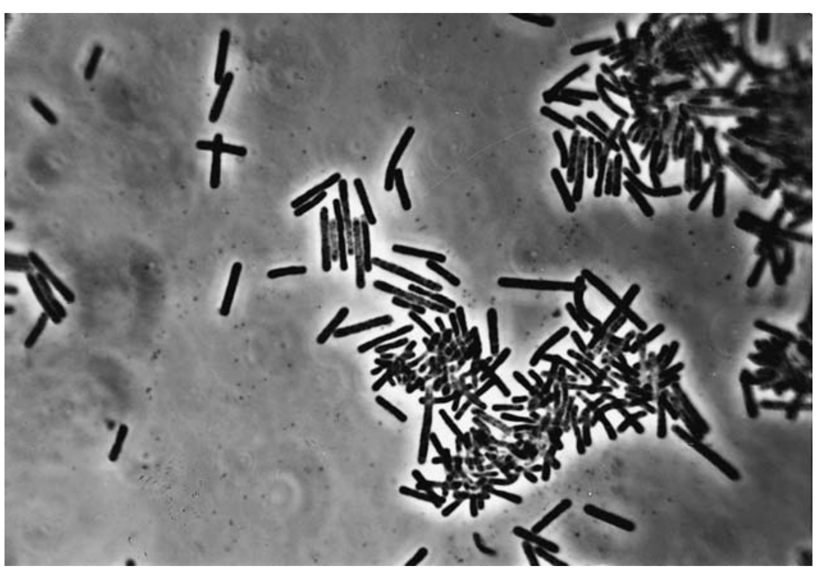
Found on decaying plant material, on bark, in the rhizosphere, and in soil.

The mol% G + C of the DNA is: 70 (T_m).

Type strain: Cm c5, DSM 14714, JCM 12616.

Additional Remarks: Reference strains include DSM 14606 (Cm c2) (Windsor M38) (ATCC 25193).

This is one of the most beautiful myxobacteria. Like *Polyangium vitellinum*, it was first seen by some early mycologists (Ravenel, Curtis, Berkeley) who took it, however, for a fungus. This history shows that the achievements of Roland Thaxter were by no means trivial when, in 1892, after careful and keen observations and experiments, he discovered the bacterial nature and most astonishing life cycle of those peculiar organisms, whereas other well-known and outstanding scientists failed to do so. The first description, essentially a figure, but an unmistakably characteristic one, was provided by Berkeley (1857). The type specimen, fruiting bodies on a decayed gourd or melon from South Carolina, came from the Curtis Herbarium and was probably originally collected by Ravenel. A brief species definition was later supplied (Berkeley, 1874). Thaxter (1892) realized at once the identity of his organism with the specimen in the Curtis collection and retained the name. Thaxter obtained his isolates from old straw in Cambridge, MA, and from Ceylon. A few years later, the same organism was described by Zukal (1896), this time as an unusual myxomycete, *"Myxobotrys variabilis"*. He found the organism on the bark of a willow tree near Vienna. His figures leave no doubt—and he later realized his mistake and admitted (Zukal, 1897b), if reluctantly (Zukal, 1897a)—that *Myxobotrys* was a myxobacterium and identical with *C. crocatus*. It appears that *C. crocatus* has not been found in European samples for more than a hundred years. Only recently, it was isolated again from two samples from sites near Basle, Switzerland. *C. crocatus* has been found, together with other *Chondromyces* species, in the rhizosphere of plants in Assam, India (Agnihothrudu et al., 1959). The symbiont-free strain, Cm c5, was isolated by the author's laboratory in 1988 from a soil sample with decomposing plant material collected in the same year in the tropical rain forest near Iguaçu, Brazil; strain Cm c2, with its symbiont, was isolated in 1982 and comes from a similar sample from the island of Madeira, Portugal.



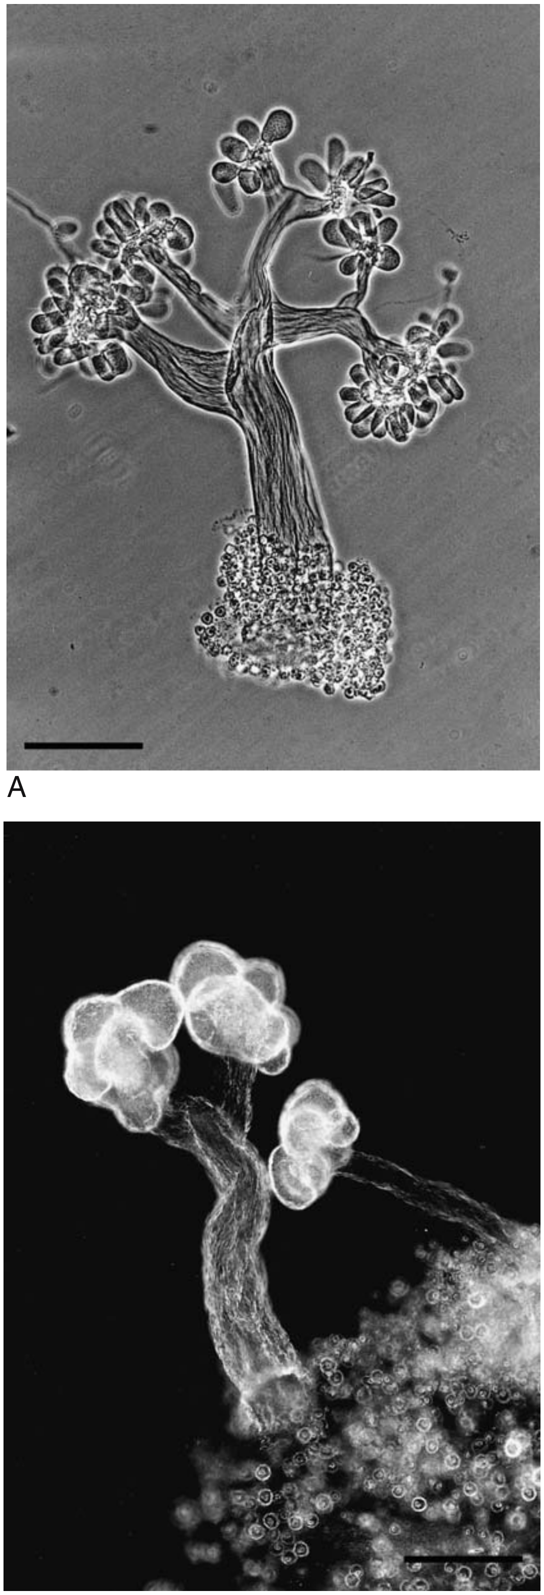


FIGURE BXII.δ.103. *Chondromyces crocatus* vegetative cells. Light micrograph (× 1000).

A

B

FIGURE BXII.δ.104. *Chondromyces crocatus*: fruiting bodies in embedding medium. (*A*) Fully differentiated fruiting body, in phase contrast; (*B*) immature stage, dark field. It should be noted that all photographs of *Chondromyces* fruiting bodies show small specimens, as depth of field is not sufficient for large ones. Bar in *A* = 125 μm; bar in *B* = 105 μm.

2. **Chondromyces apiculatus** Thaxter 1897, 405[AL]
a.pi.cu.la' tus. L. masc. n. *apex* genitive *apicis* tip, point; M.L. masc. adj. *apiculatus* pointed, with a tip or tail.

Vegetative cells cylindrical with rounded ends, 1.1–1.4 × 3–14 μm. Sporangioles bright orange, turnip-shaped when typical, but may also be either more bulbous or more slender; cylindrical, 25–40 × 35–50 μm; always with a conspicuous white tip or tail, up to 35 μm long. The sporangioles sit with or without a pedicle on an unbranched white stalk (Fig. BXII.δ.105). Stalks up to 700 μm long and 15–40 μm wide. Branched stalks are rarely seen. Shape and size of the fruiting bodies very variable and overlapping with those of the following species (see comments on *C. robustus*). Myxospores resemble vegetative cells in shape but are optically refractile, 1.0–1.3 × 3–6 μm.

Originally isolated from antelope dung from Liberia. The organism is very common on rotting wood and bark in the Midwest of the USA, but is also found in soil and similar habitats in other places. Strain Cm a14 was isolated in 1988 from rotting plant material collected in 1981 in Costa Rica, reference strain Cm a2 was isolated in 1966 from the surface of a rotting tree trunk collected in Minnesota, USA. The latter is the only *Chondromyces* strain of which the author is aware that can be induced to produce fruiting bodies under fully defined conditions (Reichenbach et al., 1974).

The mol% G + C of the DNA is: 69–70 (Bd, T_m).

Type strain: DSM 14605, Cm a14, JCM 12615.

Additional Remarks: Reference strains include DSM 14612 (Cm a2) (Windsor M6).

3. **Chondromyces catenulatus** Thaxter 1904, 410[AL]
ca.te.nu.la' tus. L. fem. n. *catena* chain; L. diminutive fem. n. *catenula* a small chain; M.L. masc. adj. *catenulatus* with small chains (of sporangioles).

Vegetative cells (in an earlier stage of fruiting) cylindrical rods with rounded ends, 1.0–1.3 × 4–6 μm. Sporangioles pale yellow to yellow orange, fusiform to elongated and ellipsoidal, 18 × 20–50 μm; 10 or 12 of them in sparingly (once or twice) branched chains; longer ones around 300 μm. The sporangioles are separated in the chains by shriveled, membranous links. The chains arise in dense clusters from the tips of unbranched, stout stalks, 180–360 μm high (Fig. BXII.δ.106).

Found on a rotten poplar log near Hanover, New Hampshire, USA, obtained only once by Thaxter. The organism could be kept on its natural substrate for some time, but was never cultivated in pure culture. There appears to be only one further report of *C. catenulatus*, from southeast Queensland, Australia, with scanning electron microscope images but without any details (McNeil and Skerman, 1972). Thus, the organism seems to be very rare. There are, however, beautiful specimens of Thaxter's in the Farlow Herbarium.

The mol% G + C of the DNA is: not determined.

Type specimen: Acc. no. 4517, Thaxter Collection, Farlow Herbarium, Harvard University, Cambridge, MA, USA.

4. **Chondromyces lanuginosus** Kofler 1913, 861[AL]
la.nu.gi.no' sus. L. fem. n. *lanugo* down, wool; M.L. masc. adj. *lanuginosus* downy, wooly.

Vegetative cells cylindrical rods with rounded ends, 0.9–1.0 × 3–8 μm. Fruiting bodies (Fig. BXII.δ.107) consist of

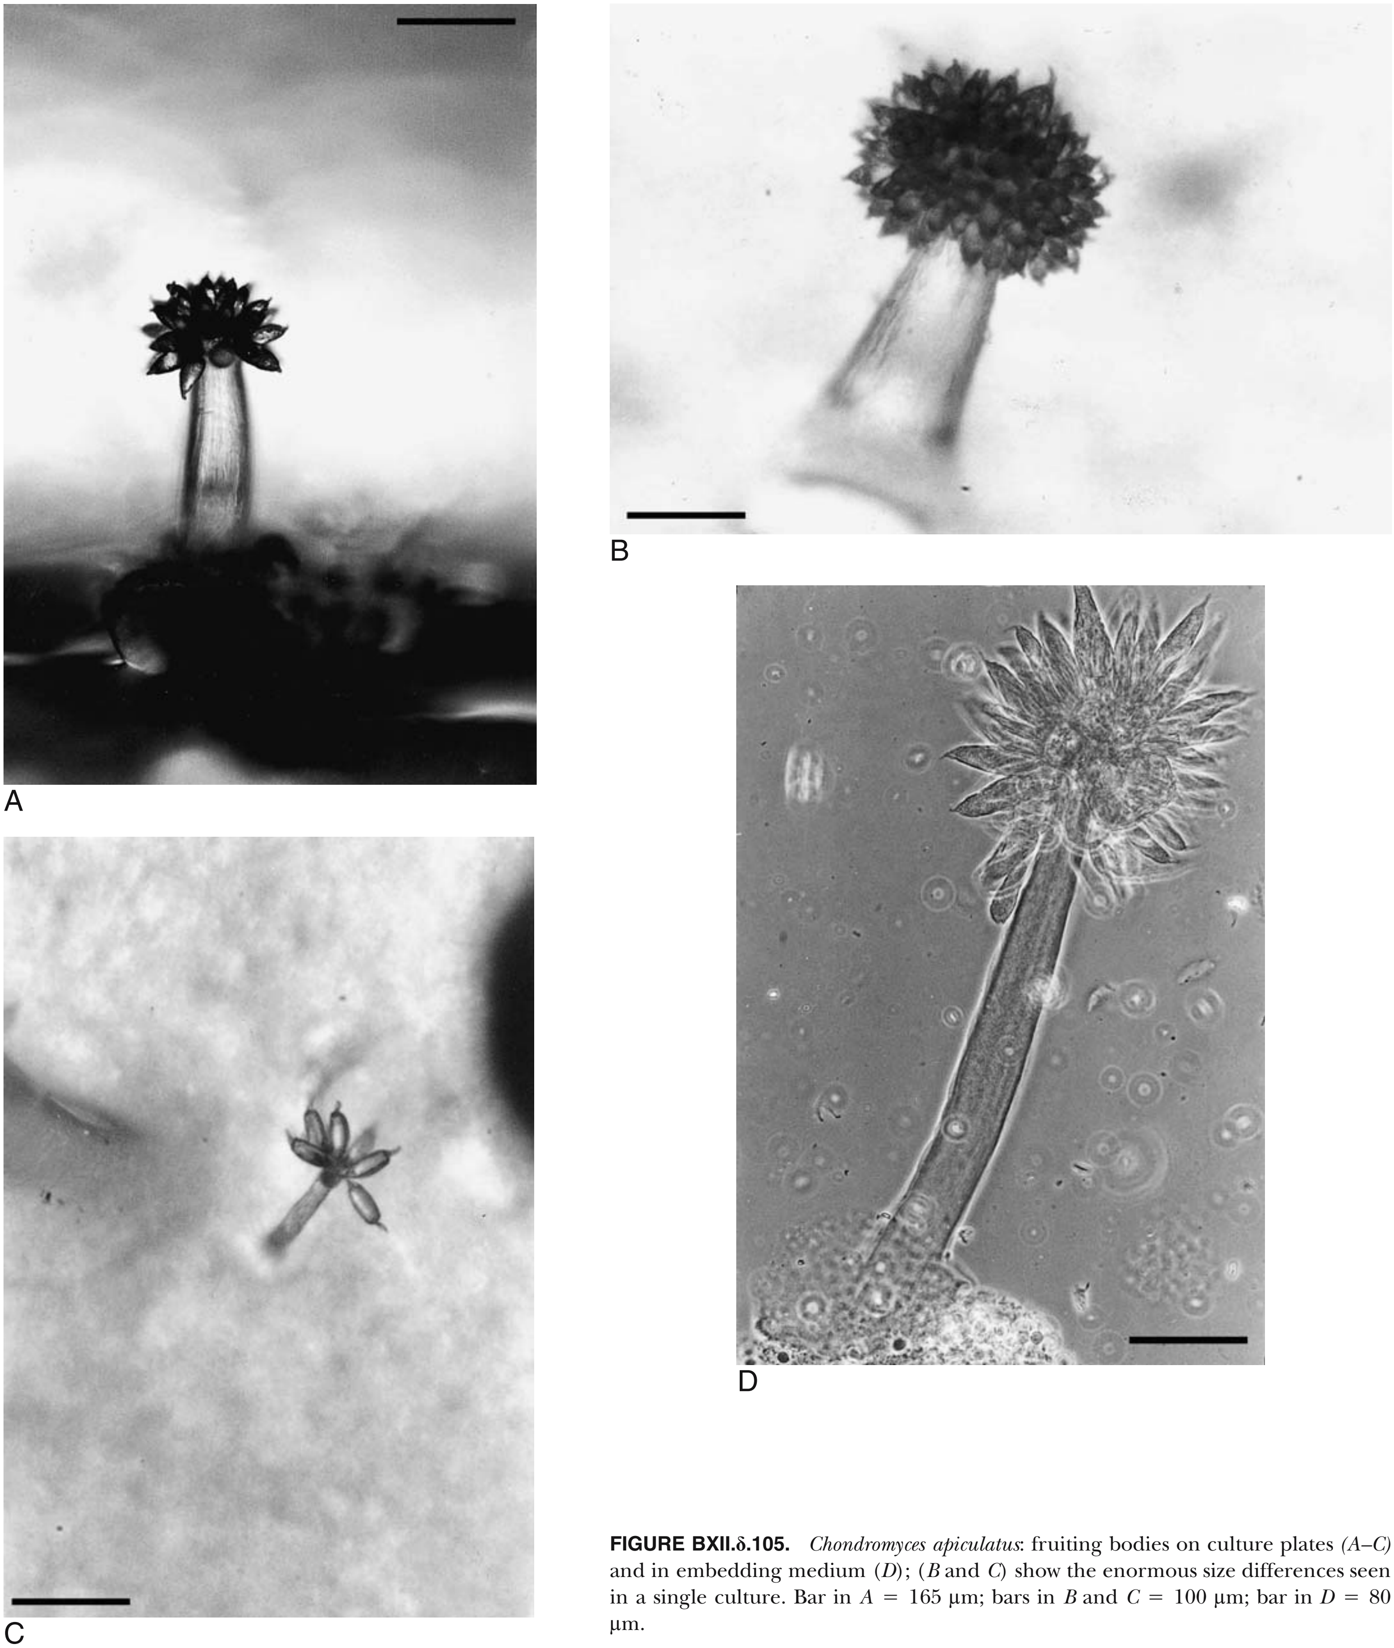

FIGURE BXII.δ.105. *Chondromyces apiculatus*: fruiting bodies on culture plates *(A–C)* and in embedding medium (*D*); (*B* and *C*) show the enormous size differences seen in a single culture. Bar in *A* = 165 μm; bars in *B* and *C* = 100 μm; bar in *D* = 80 μm.

long, white or yellowish slime stalks, 700–1000 μm or more long, often rather slender, width 40–130 μm or more at the base, narrowing down to 20 μm at the tips; unbranched or, branched; sometimes repeatedly branched. At the tips of the stalks are clusters of 2–7, but sometimes as many as 20–30 large straw-colored to orange sporangioles, 65–110 μm

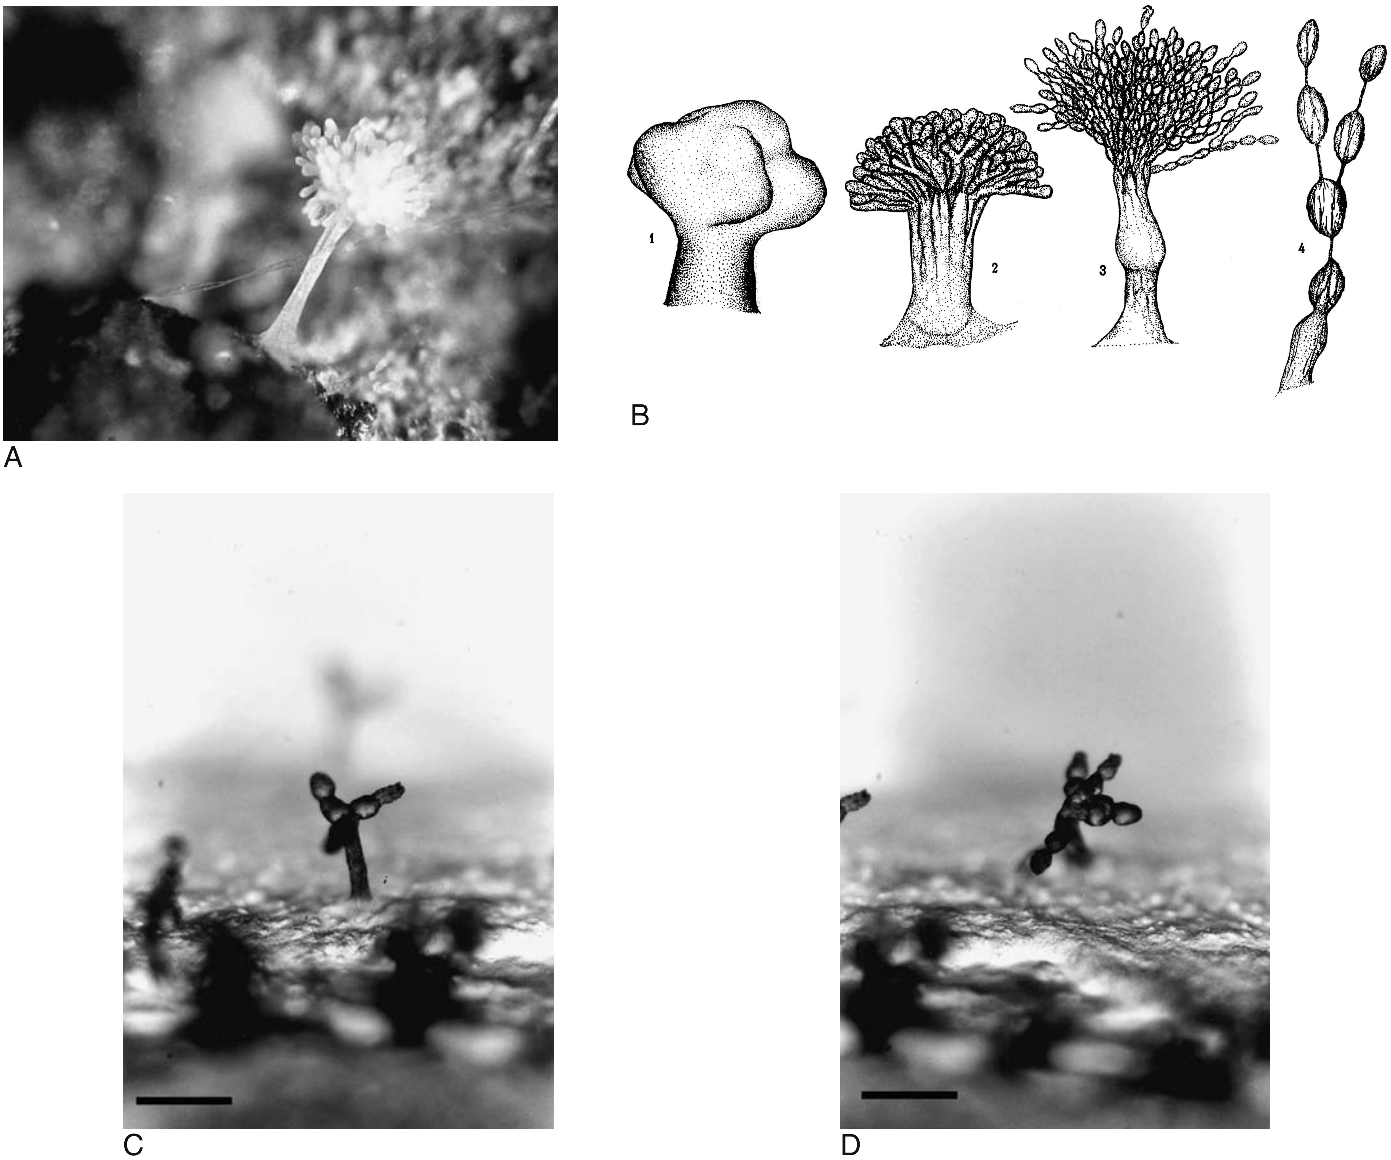

FIGURE BXII.δ.106. *Chondromyces catenulatus*: fruiting bodies. (*A*) Light micrograph (× 120). (*B*) Figures 1–4 from the original description by Roland Thaxter (1904). (*C* and *D*) Small, atypical fruiting bodies of *Chondromyces crocatus* with chains of sporangioles resembling *C. catenulatus*. Bar in *C* and $D = 200$ μm.

(range: 45–265 or more) wide. The sporangioles are spherical or cup-shaped, depressed spheres and bear many fine, white hair-like tails 10–50 μm long, giving the head a downy appearance. Myxospores resemble vegetative cells in shape but are slightly smaller, 0.7–1.1 × 2.5–3.5 μm, and optically refractile.

The organism grows well in pure culture, e.g., on yeast (VY/2-) and casein peptone (CY-) agar. Yeast cells are decomposed; chitin and cellulose are not degraded.

Originally obtained from hare dung found near Vienna and from deer dung in Canada; it also has been found in soil with decaying plant material and on bark. Appears to be a rare species. Strain Sy t2 was isolated in 1987 from soil with decaying plant material collected in 1986 in Upper Franconia, Germany; reference strain Sy t1 is a parallel isolate. Reference strain Sy t7 was isolated in 2000 from the bark collected from a diseased Ficus tree in Karnataka, India, in 1999.

The mol% G + C of the DNA is: not determined.

Type strain: Sy t2, DSM 14631, JCM 12617.

Additional Remarks: Reference strains include DSM 14630 (Sy t1) and DSM 14632 (Sy t7).

Additional Remarks: The fruiting bodies of *C. lanuginosus* are so characteristic and unique that the species cannot be mistaken. It was discovered at almost the same time in two laboratories and given two different names, as the authors did not know of one another, probably due to the disruption caused by World War I. Jahn (1924) later created a genus *Synangium* for those organisms. In addition, he listed *"Synangium lanuginosus"* and *"Synangium thaxteri"* as different species, but this seems not to be justified, as previously observed by Krzemieniewska and Krzemieniewski (1946),

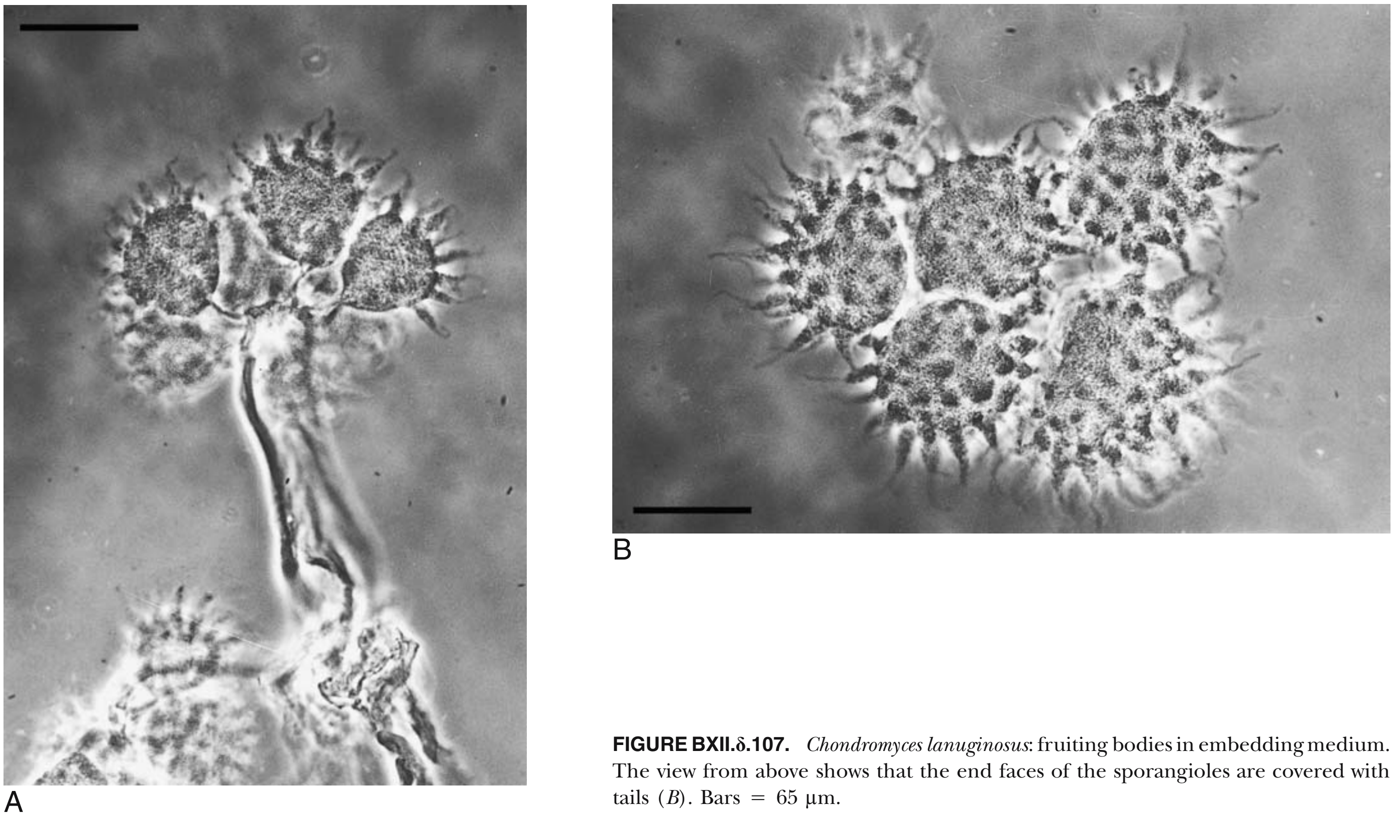

FIGURE BXII.δ.107. *Chondromyces lanuginosus*: fruiting bodies in embedding medium. The view from above shows that the end faces of the sporangioles are covered with tails (*B*). Bars = 65 μm.

for the two descriptions overlap virtually completely except for minor differences in dimensions. *C. lanuginosus* is in all respects comparable to other *Chondromyces* species, so that a genus of its own seems not to be meaningful. 16S rRNA sequence analysis positions *C. lanuginosus* strain Sy t2 close to one of the *C. apiculatus* strains, Cm a2, among the other *Chondromyces* species (Spröer et al., 1999).

This appears to be a less common *Chondromyces* species. Over a period of 25 years, the author's laboratory isolated seven strains from samples from Germany, Ceylon, India, and California. After duplicates were removed, the actual number was reduced to four. Three more strains have been reported in the literature—from Japan (Watanabe and Tanaka, 1929), Poland (Krzemieniewska and Krzemieniewski, 1946), and Tanzania (Dawid, 1980). Krzemieniewska and Krzemieniewski cultivated their strain on soaked hay.

Jahn (1924) added *"Chondromyces sessilis"* to his new genus *Synangium* Thaxter 1904. Krzemieniewska and Krzemieniewski (1946) later argued that Thaxter's description may have been founded on stalkless specimens of *C. lanuginosus* fruiting bodies, which may be correct, especially as Thaxter mentioned that "occasionally . . . there seems to have been an attempt to differentiate an irregular cystophore". The organism looks indeed like a degenerate *Chondromyces*—similar forms may occasionally be seen in cultures—but it more closely resembles *C. apiculatus*. At the moment the species cannot be regarded as valid.

5. **Chondromyces pediculatus** Thaxter 1904, 410[AL]
pe.di.cu.la'tus. L. masc. n. *pediculus* diminutive of *pes* foot, small foot; M.L. masc. adj. *pediculatus* with a small foot.

Vegetative cells cylindrical rods with rounded ends, 0.9–1.2 × 3–6 μm. Sporangioles pale yellow to orange, cylindrical, barrel, or bell shaped, with a flat or slightly curved end face that sometimes has a very short tip; 25–40 × 35–60 μm. Clusters of a few to up to 60 sporangioles on long, slender, white slime stalks; often hanging down in an umbel on 20–40 μm long, fine, white pedicles (Fig. BXII.δ.108). A disk-shaped foot may be present at the base of the stalk (as is seen also with other *Chondromyces* species). The whole fruiting body can be up to 1000–1200 μm high. In culture, stouter fruiting bodies with sessile spherical sporangioles may also appear.

Obtained originally from goose dung from South Carolina, USA; the bacterium can also be isolated from soil containing decaying plant material, dung of herbivores, and similar substrates. Contrary to statements in the literature (Krzemieniewska and Krzemieniewski, 1946), the author finds that *C. pediculatus* is perhaps the most common of all *Chondromyces* species. Fifty-five strains were isolated over the years. Strain Cm p51 was isolated in 2000 from soil containing decaying plant material collected in Karnataka, India. In 1999; reference strain Cm p31 came from a similar sample from the island of Majorca, Spain, and was isolated in 1999.

The mol% G + C of the DNA is: not determined.

Type strain: Cm p51, DSM 14607, JCM 12618.

Additional Remarks: Reference strains include DSM 14660 (Cm p31).

C. pediculatus cannot be mistaken when typical fruiting bodies are produced as is usually the case in enrichment cultures, e.g., for cellulose degraders on filter paper over mineral salts agar. The umbels of hanging, bell-shaped sporangioles are quite typical. In addition, the stalks of *C. pedi-*

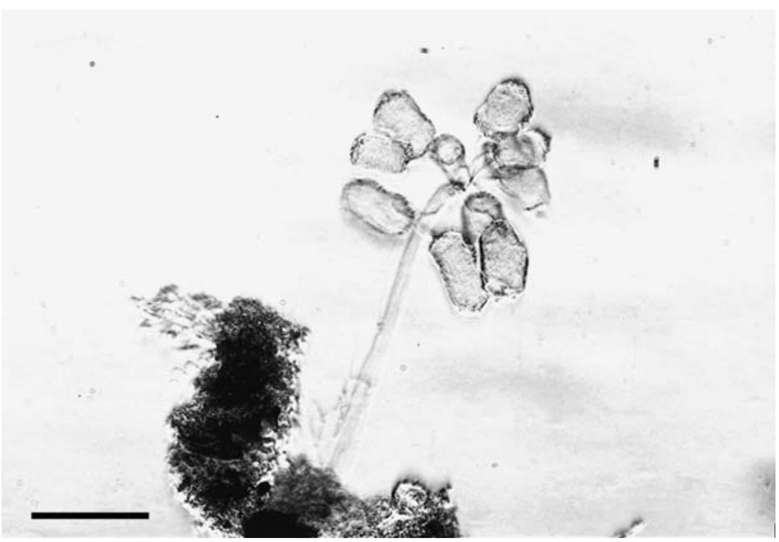

FIGURE BXII.δ.108. *Chondromyces pediculatus*: fruiting bodies. (*A*) In crude culture, sitting on a crumb of soil. (*B* and *C*) In embedding medium; (*C*) especially in cultures, the fruiting bodies do not always develop the characteristic overhanging, bell-shaped sporangioles. Bar in *A* = 100 µm; bar in *B* = 105 µm; bar in *C* = 125 µm.

culatus are normally more slender than those of most other *Chondromyces* species.

6. **Chondromyces robustus** *sp. nov.*
ro.bus′tus. L. masc. adj. *robustus* made of oak wood, strong.

Vegetative cells cylindrical rods with rounded ends, 1.0–1.2 × 4–8 µm. Sporangioles bright orange, almost spherical to turnip-shaped, 70–120 µm long and 30–100 µm wide, with one to three 15–25 µm long, conspicuous white tips, or tails. The sporangioles are arranged in a cluster of a few to 50 or more at the tip of a long, white, unbranched stalk, 200–1100 µm long and 50–400 µm wide (Fig. BXII.δ.109). The whole fruiting body may be up to 1300 µm high. Myxospores resemble vegetative cells in shape but are slightly smaller and optically refractile. Grows well in pure culture on yeast (VY/2-) and casein peptone (CY-) agar.

Obtained from decaying plant material, bark, and soil; moderately common and of worldwide distribution. Strain Cm a13 was isolated in 1980 from soil collected on Isla Mujeres, Yucatan, Mexico; reference strain Cm r9 was iso-

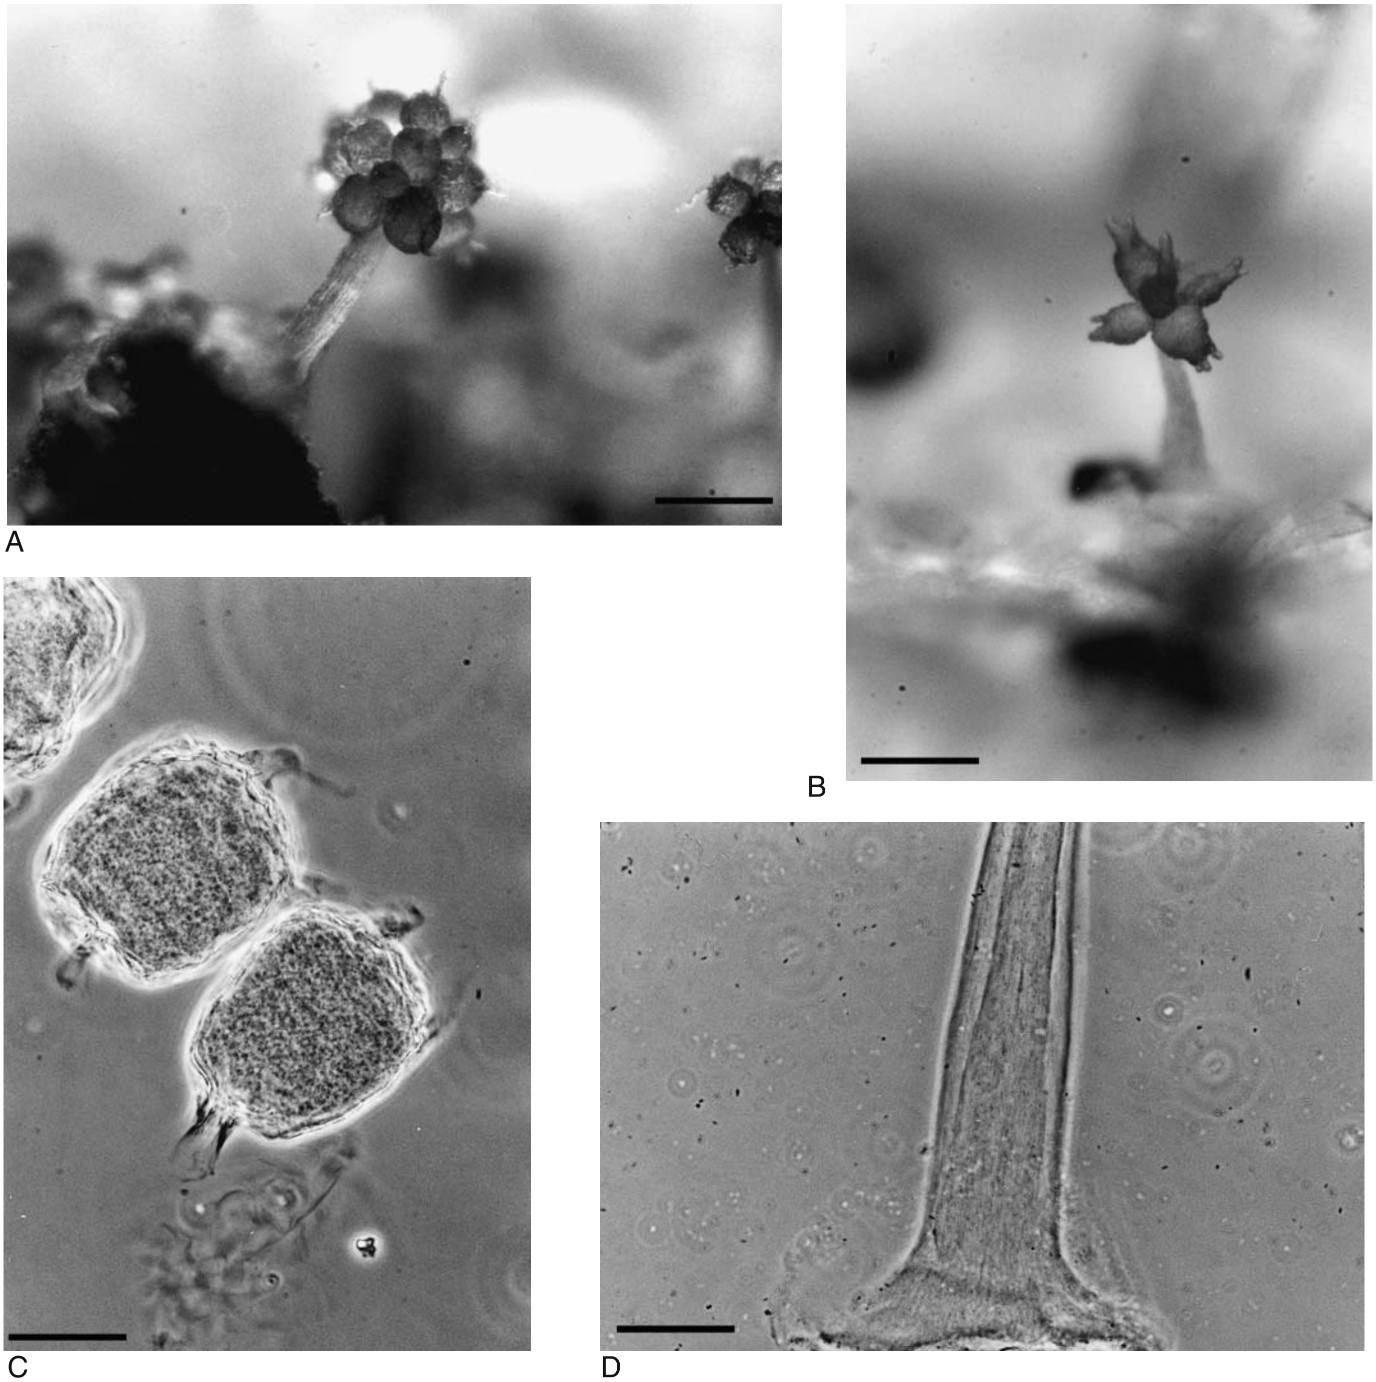

FIGURE BXII.δ.109. *Chondromyces robustus*: fruiting bodies. (*A* and *B*) On culture plates; the young, small fruiting body in *B*, still in the process of differentiation, shows sporangioles with several tips, which are characteristic for the species. (*C* and *D*) In embedding medium; (*C*) sporangioles, one with two tips; (*D*) base of a stalk with base plate. Bar in *A* = 130 µm; bar in *B* = 100 µm; bar in *C* = 30 µm; bar in *D* = 65 µm.

lated in 1996 from soil with decaying plant material collected in Karnataka, India, in 1995.

The mol% G + C of the DNA is: not determined.

Type strain: Cm a13, DSM 14608, JCM 12619.

Additional Remarks: Reference strains include DSM 14739 (Cm r9).

As observed by Thaxter (1897) when he described *C. apiculatus*, the fruiting bodies of that organism are highly variable. This is also the case with *C. robustus*, which displays considerable overlap with *C. apiculatus*. Hence, it is somewhat difficult to distinguish the two, and one should always have a population of fruiting bodies available for diagnosis. In fact, it is not certain whether Thaxter's organism was not what the author is now calling *C. robustus*. However, there is no question that two separate *Chondromyces* species with tailed sporangioles exist. The convincing evidence that Thaxter described a different organism from *C. apiculatus* was the small size of the sporangioles, which he gave as 35 × 28 µm, so that the whole cluster was only 200 µm in diameter on average. Strains with such characteristics are

very common in the Midwest of the USA, although Thaxter's strain came from Liberia. The distinguishing characteristics of *C. robustus* are as follows: (1) sporangioles tend to be bulbous to spherical; (2) in most clusters there are sporangioles with two or three tips; (3) those sporangioles are not divided, so that the tails sit on branched sporangioles, as described by Thaxter for *C. apiculatus*; (4) the tails rise from one point; and (5) *C. robustus* fruiting bodies are much stouter and larger than those of *C. apiculatus*. When the author co-cultivated the type strains of the two species on mineral salts agar with filter paper inoculated with a mixture of cellulose degrading and other soil bacteria—a reliable method to induce fruiting of *Chondromyces* strains—he obtained large fruiting bodies intermingled with ones about one-half to two-thirds the size of the large ones. 16S rRNA sequence analysis showed a certain separation of *C. robustus* and *C. apiculatus*, but the 16S rRNA sequences of all *Chondromyces* strains are rather similar, and the resolution of the method may not allow distinction of species (Spröer et al., 1999). It appears that *C. robustus* is the more common species of the two.

Genus IV. **Haploangium** *(ex Peterson 1959) gen.nov., nom. rev.**

Hans Reichenbach

Ha.plo.an' gi.um. Gr. adj. *haplos* simple; Gr. neut. n. *angeion* vessel; M.L. neut. n. *Haploangium* simple vessel.

Vegetative cells cylindrical rods with rounded ends. Fruiting body consists of a single sporangiole. Myxospores similar to vegetative cells in shape.

Type species: **Haploangium rugiseptum** (ex McCurdy 1970) *comb. nov.* (*Haploangium rugiseptum* Peterson 1959, 5; *Polyangium rugiseptum* McCurdy 1970, 295.)

Further descriptive information

The genus *Haploangium* was established by Peterson (1959) to comprise species with *Polyangium*-type vegetative cells and isolated, solitary sporangioles. The name was not included on the Approved Lists. Peterson (1959) listed four species, two of which were new. *H. simplex* (= *Myxobacter simplex* Thaxter 1893 = *Polyangium simplex* Thaxter 1904) later turned out to be identical with *Polyangium vitellinum* (McCurdy, 1970). The position of *"Haploangium ochraceum"* (= *Polyangium ochraceum* Krzemieniewska and Krzemieniewski 1926) is obscure. The organism had spherical to ellipsoidal sporangioles that were orange to bright red, 30–60 × 50–130 μm, single, in a thick, yellow-brown slime envelope Krzemieniewska and Krzemieniewski usually found myxobacteria on rabbit dung pellets; the often-mentioned color of the slime envelopes may in fact have originated from diffusing brown pigments coming from the rabbit dung. The wall was occasionally seen to fold somewhat into the sporangiole, which, when observed from the side, gave the impression of a subdivision of the sporangiole. Myxospores 0.5 × 4–8 μm. Obtained from rabbit dung on soil. The organism was not cultivated. There is only one later report of *"H. ochraceum"* (Singh and Singh, 1971). The vegetative rods of that organism were thin with pointed ends, 0.5–0.7 × 7–12 μm, the myxospores were shortened rods, 1.4 × 2–3.5 μm, and the sporangioles were pale yellow to light orange. Therefore, this bacterium clearly does not belong to the genus *Haploangium* but to the *Cystobacterineae* and was most likely not the same bacterium as the one described by Krzemieniewska and Krzemieniewski. The Indian scientists also described another new *Haploangium* species, *"Haploangium krzemieniewskae"*. This organism also does not fit the definition of *Haploangium*, as it had long, thin vegetative rods with somewhat tapering ends, 0.5–0.7 × 7–12 μm, and short myxospores, 0.5 × 2–3 μm. The solitary sporangioles were dull pink to gray, 15–35 × 15–50 μm. Found on bark. This species clearly also belongs to the *Cystobacterineae*.

The two new species listed below remain. None of the *Haploangium* species has ever been cultivated, so that all descriptions are incomplete. In the last edition of the *Manual*, following an earlier suggestion (McCurdy, 1970), these *Haploangium* species were included in the genus *Polyangium*. At least *H. rugiseptum* appears so unique in the structure of its fruiting bodies that a genus of its own seems justified. This species is also used as the type species, because Thaxter's *Polyangium simplex* formerly suggested as the type species belongs to a different genus.

While the genus is classified here in the family *Polyangiaceae*, this has still to be proved, e.g., by 16S rRNA sequence data.

Key to the species of the genus *Haploangium*

I. Sporangioles glistening orange-red with a flaky outer surface, heavily winkled when dry.
H. rugiseptum

II. Sporangioles brown to orange brown with a smooth surface.
H. minus

List of species of the genus Haploangium

1. **Haploangium rugiseptum** (ex McCurdy 1970) *comb. nov.* (*Haploangium rugiseptum* Peterson 1959, 5; *Polyangium rugiseptum* McCurdy 1970, 295.)

ru.gi.sep' tum. L. fem. n. *ruga* wrinkle; L. neut. n. *septum, saeptum* enclosure, fencing; M.L. neut. adj. *rugiseptum* with a wrinkled enclosure.

Vegetative cells not described. Sporangioles solitary, globose or oval; sessile or on a short stalk (Hu et al., 1985), up to 200 μm, 85 μm on average. Sporangiole wall with two indistinct layers: the inner one smooth and yellow, the outer one irregular, flaky and dark orange; heavily wrinkled when dry. The sporangiole sometimes contains fatty globules and amorphous material in addition to myxospores. Myxospores

**Editorial Note:* Readers are advised that the type material of *Polyangium rugiseptum* and *Polyangium minor* (sic) are not available as cited. As such, the proposals for new combinations presented here may result in illegitimate names.

cylindrical with blunt ends, 0.8 × 4–6 μm. Found on bark of various trees in Missouri, USA. Could not be cultivated.

The mol% G + C of the DNA is: not determined.

Deposited strain: Peterson 51, University of Missouri Herbarium, Columbia, MO, USA (type specimen).

The author found fruiting bodies that were identified as *H. rugiseptum* quite regularly on rotting wood and old stumps in the Black Forest in Germany, but also could not cultivate the organism. The sporangiole wall has a surface structure unlike that of any other myxobacterium. The species may be the only representative of the genus *Haploangium.*

2. **Haploangium minus** (ex McCurdy 1970) *comb. nov.* (*Haploangium minor* Peterson 1959, 4; *Polyangium minor* (sic) McCurdy 1970, 294.)
mi'nus. L. neut. adj. comparative of *parvus* small; *minus* smaller, less.

Vegetative cells cylindrical with squarish ends, 0.7 × 3.5–4.5 μm. Sporangioles solitary but often in groups of 4–10, globose, oval or bean-shaped, turgid, 60–140 μm, dull orange-brown when fresh, the wall becomes bright yellow-orange, collapses, and becomes wrinkled when drying. Myxospores cylindrical with blunt ends, 0.7 × 2.5–3.5 μm. Obtained on bark collected from various trees in Missouri. Could not be cultivated.

The mol% G + C of the DNA is: not determined.

Deposited strain: Peterson 41, University of Missouri Herbarium, Columbia, MO, USA (type specimen).

The description is reminiscent of *Melittangium lichenicola*, which, although living in the same habitat, has cells with tapering ends. *"H. minus"* was also reported from soil and bark in India by Singh and Singh (1971). Here, the vegetative cells were indeed described as having somewhat tapering ends, and the myxospores were described as being shortened rods. It is still possible that the Indian colleagues were not really describing the same organism. One always has to keep in mind that there are many examples of fruiting bodies of very similar shape and structure occurring in separate genera, families, and suborders of the myxobacteria.

Genus V. **Jahnia** *gen. nov.*

HANS REICHENBACH

Jah'nia. named in honor of Eduard Adolf Wilhelm Jahn (1871–1942), who, in 1911, wrote the first synopsis, and, in 1924, the first monograph on myxobacteria (Claussen, 1942).

Vegetative cells are cylindrical rods with rounded ends. Fruiting bodies consist of coils of sporangioles sitting on a slime cushion or soft slime stalk. Myxospores are like vegetative cells in shape but are optically refractile.

Type species: **Jahnia thaxteri** (ex Jahn 1924) *sp. nov., nom. rev.* (*Archangium thaxteri* Jahn 1924, 71.)

List of species of the genus Jahnia

1. **Jahnia thaxteri** (ex Jahn 1924) *comb. nov., nom. rev.* (*Archangium thaxteri* Jahn 1924, 71.)
thax'te.ri. M.L. gen. masc. n. *thaxteri* of Thaxter, in honor of Roland Thaxter (1858–1932), discoverer of myxobacteria (Pfister, 1993).

Vegetative cells are cylindrical rods with rounded ends, 0.7–0.9 × 3–8 μm. Sporangioles (Fig. BXII.δ.110) bright yellow orange to yellowish red brown, spherical to elongated, often incompletely separated, and rather large (60–90 × 80–120 μm). They usually form long, convoluted strings, but also occur in dense packages and then are sometimes slightly polygonal. They may be piled high, and arise either on the surface or within the agar layer. When typical, the sporangioles are positioned on a slime cushion or on a short yellowish to white stalk (Fig. BXII.δ.111). The whole fruiting body measures about 500–600 μm in height and about the same in width. At least in culture, stalks are usually absent. The first stage of fruiting often is a large, yellow, globular bacterial mass, like the initial stage of a *Chondromyces* fruiting body. Myxospores resemble vegetative cells in shape but are slightly smaller and optically refractile when mature.

Swarm colonies often etch the agar surface, and produce broad trails and wide depressions. A dense, orange band of vegetative cells is often seen along the edge of the swarm. Of the proteolytic–bacteriolytic nutritional type. May be isolated on streaks of living or dead *E. coli* on water agar. Grows well in pure culture on yeast agar (VY/2-) with lysis of the yeast cells as well as on casein peptone (CY-) and skim milk agar. Casein, starch, and xylan are hydrolyzed, chitin is vigorously degraded, and cellulose is not attacked.

May be obtained from soil, dung of herbivores, and decaying plant material. Strains have been isolated from samples from Germany, Cyprus, Senegal, Arizona, and South Africa. Rather uncommon. Strain Pl t4 was isolated in 1988 from soil from South Africa. The reference strain, Pl t3, was originally isolated by W. Dawid from a soil sample from Arizona, USA.

The mol% G + C of the DNA is: not determined.

Type strain: Pl t4, DSM 14626, JCM 12631.

GenBank accession number (16S rRNA): DSM 14625 (Pl t3).

Additional Remarks: J. thaxteri is easy to recognize because of its large, bright orange brown, sporangioles in long strings. Stalks and slime cushions are often not produced, but when they are, the resulting fruiting body is unlike that of any other myxobacterium. (A good color photograph is found in the first edition of *The Prokaryotes* (Reichenbach and Dworkin, 1981). The cultures in the author's laboratory that have been deposited are most probably identical with *Archangium thaxteri* Jahn 1924. The main difference is that Jahn never observed sporangioles but only convoluted strands of tightly compacted cells, as in an *Archangium* fruiting body. In spite of this, he originally identified the organism as a *Polyangium* (Jahn, 1911), but this should not

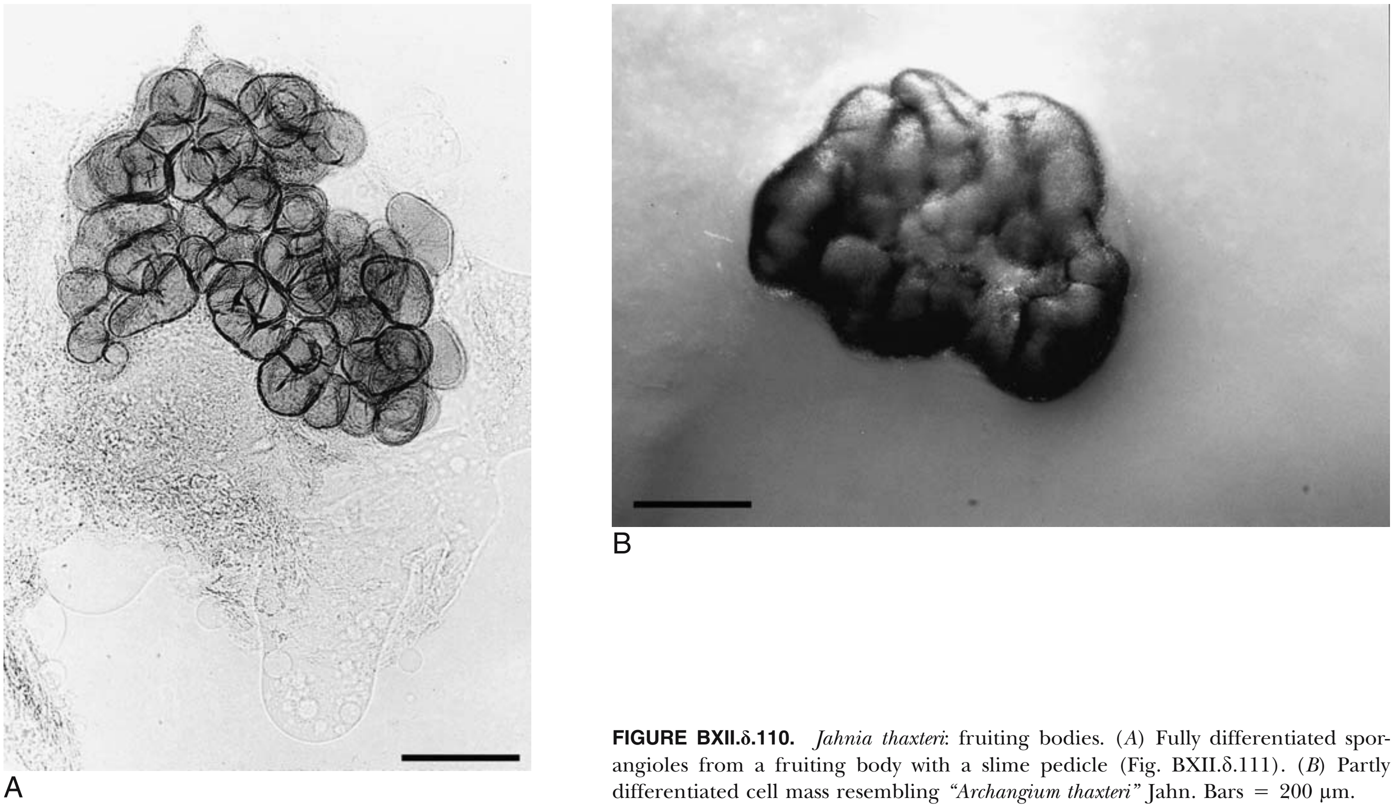

FIGURE BXII.δ.110. *Jahnia thaxteri*: fruiting bodies. (*A*) Fully differentiated sporangioles from a fruiting body with a slime pedicle (Fig. BXII.δ.111). (*B*) Partly differentiated cell mass resembling *"Archangium thaxteri"* Jahn. Bars = 200 μm.

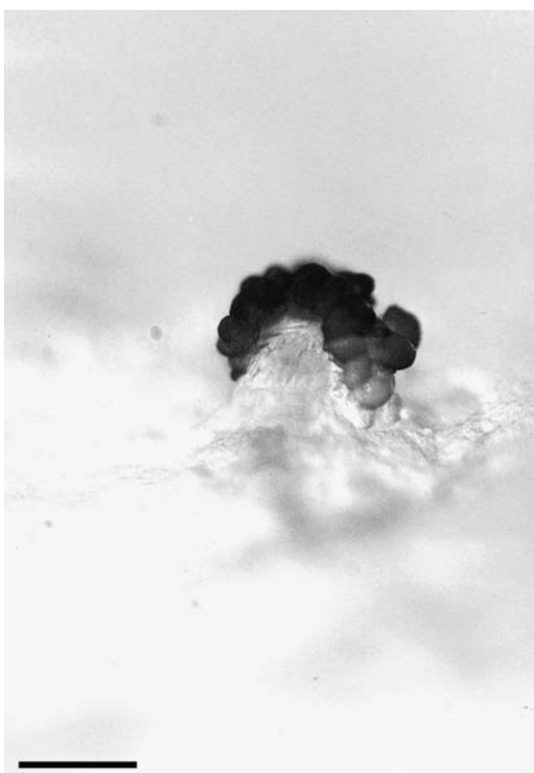

FIGURE BXII.δ.111. *Jahnia thaxteri*: fruiting body with slime pedicle, on agar surface. Bar = 320 μm.

be taken too seriously because the definitions of genera were still rather hazy at that time. Jahn also mentioned that stalks were often lacking and that the bacterium was rare. He found it only four times, always on rabbit dung from the Berlin area, Germany. In the author's opinion, Jahn also observed immature fruiting bodies. The strings of sporangioles arise from convoluted strands of cells that initially look somewhat brain-like; this stage exactly corresponds with Jahn's figures. Jahn was only able to propagate the organism on rabbit dung, but it is easily cultivated on various media developed more recently.

The isolates were originally classified as *Polyangium thaxteri*. This assignment to the genus *Polyangium* is consistent with the shape of the vegetative cells and myxospores, the etching of the agar by the swarm colony, and the structure of the fruiting bodies. It differs only in the production of stalks. But 16S rRNA sequence analysis (Spröer et al., 1999) clearly showed that the organism belongs in the *Chondromyces* group and not in the *Polyangium–Sorangium* cluster.

In the first stage of fruiting a large, yellow, globular mass is formed that clearly reminds one of a *Chondromyces*; however, the new bacterium differs substantially from *Chondromyces* species, which produce well-developed, long stalks with sporangioles, or chains of sporangioles, radiating in clusters from the tip of the stalk. In addition, in contrast to all *Chondromyces* species, this organism degrades chitin very efficiently and therefore should be transferred to a genus of its own.

There is a remote possibility that the present species is identical with one of the little known *Polyangium* species, e.g., *Polyangium aureum* or *Polyangium parasiticum*. However, the sporangioles of those species are considerably smaller, and a stalk has never been mentioned for them. The question can no longer be decided, because reference strains are not available.

Genus VI. **Sorangium** *(Jahn 1924) gen. nov., nom. rev.*

HANS REICHENBACH

So.ran'gi.um. Gr. masc. n. *soros* heap, pile; Gr. neut. n. *angion* vessel; M.L. neut. n. *Sorangium* piled up vessels.

Vegetative cells cylindrical with rounded or somewhat squarish ends. **Sporangioles spherical to polyhedral, in sori of variable size**, yellow, orange, brown, or black, but never bright red. **Myxospores like vegetative cells in shape**, optically refractile. **Cellulose decomposers**.

Type species: **Sorangium cellulosum** (Brockman 1989b) *comb. nov.* (*Polyangium cellulosum* (ex Imshenetski and Solntseva 1936) Brockman 1989b, 495.)

FURTHER DESCRIPTIVE INFORMATION

Jahn created the genus *Sorangium* to comprise species with sori composed of relatively small, angular sporangioles. He also established a family for the genus, the *"Sorangiaceae"*. However, this strict separation of the genera *Sorangium* and *Polyangium* was probably a misjudgment, and most of his *Sorangium* species are now classified in the older genus *Polyangium*. One subgroup among the old *Polyangium* and *Sorangium* species includes efficient cellulose degraders, and it is suggested here that the genus name *Sorangium* be used for them, and exclusively so. In the author's experience cellulose degradation is a unique and very stable characteristic, so that a separate genus *Sorangium* for such organisms may be justified. There are other unusual characteristics that distinguish *Sorangium* from *Polyangium*, such as growth on inorganic nitrogen compounds as the sole nitrogen source, absence of lanosterol synthesis, no etching of the agar surface, much elevated kanamycin resistance, and a different pattern of secondary metabolites. At the moment, only one species, *S. cellulosum* will be described although it appears to be a complex of several morphological and physiological variants that may represent different species, as will be discussed in more detail below.

Until recently, *S. cellulosum* was the only established cellulose degrader among myxobacteria. But now a new genus and species, *Byssophaga cruenta*, is being added to this group (see above). In their pioneering article on cellulose-decomposing myxobacteria, Krzemieniewska and Krzemieniewski (1937a) mentioned two forms of *Archangium* that decomposed cellulose. However, they were not sure whether the fruiting bodies of those strains were not just immature specimens of a *Sorangium*, and therefore did not name them. This seems to be the correct interpretation. Other myxobacteria stated to be cellulose degraders might have been contaminants in cellulose-decomposing cultures.

List of species of the genus Sorangium

1. **Sorangium cellulosum** (Brockman 1989b) *comb. nov.* (*Polyangium cellulosum* (ex Imshenetski and Solntseva 1936, 1115) Brockman 1989b, 495.) syn. *Sorangium compositum* Krzemieniewska and Krzemieniewski 1937a; *Polyangium compositum* Thaxter 1904, 413; *Sorangium compositum* Jahn 1924, 74; *Sorangium nigrescens* Krzemieniewska and Krzemieniewski 1937a, 21; *Sorangium nigrum* Krzemieniewska and Krzemieniewski 1937a, 22.
cel.lu.lo'sum. M.L. n. *cellulosum* cellulose.

Vegetative cells (Fig. BXII.δ.112) cylindrical with rounded or somewhat squarish ends, 0.8–1.2 × 3–8 μm. Sporangioles (Fig. BXII.δ.113) spherical to polyhedral, 15–40 μm in diameter, more or less densely packed in sori of variable size. When produced on filter paper, sporangioles often in long chains and stripes along decaying cellulose fibers, of many different colors: yellow, orange, brown, black, even colorless. When growing on an agar surface, e.g., on yeast agar (VY/2-), sporangioles may be single and scattered over the surface; fruiting bodies often arise also deep within the agar. Many strains show subdivision of the sori into clusters or packets of sporangioles. Fruiting bodies are produced on filter paper in enormous numbers, often forming a continuous mass in which individual sori can hardly be distinguished. Myxospores are similar to vegetative cells in shape, but are shorter (2–4 μm) and optically refractile. Swarm colonies on agar (Fig. BXII.δ.114) usually have a well-developed pattern of radiating veins. Agar surface normally not etched, but sometimes slightly depressed or ripped open by contraction of the firmly adhering slime sheet of the swarm. Congo red is not adsorbed, but may stain fruiting bodies upon longer exposure.

S. cellulosum readily decomposes crystalline cellulose and can be cultivated on filter paper as the only carbon source placed on a mineral salts agar (e.g., ST21-agar) with an inorganic nitrogen source (preferably KNO_3, but $(NH_4)_2SO_4$ can be used). Grows faster when an organic nitrogen source is supplied, e.g., tryptically digested casein, but many strains then require an additional carbon source, such as glucose, starch, or cellulose. All strains appear to degrade starch and xylan, and most of them degrade chitin very efficiently. Proteolytic activity, e.g., on skim milk agar, varies among individual strains from none to very strong. Yeast cells in yeast agar (VY/2) are attacked but only partly degraded, so that lysis zones remain rather turbid. Grows moderately on streaks of autoclaved *E. coli* on water agar but not on living bacteria. All strains are resistant to kanamycin sulfate, often up to exceedingly high concentrations (1000 μg/ml), a fact which can facilitate isolation. Tolerates a lower pH (5.8–6.2) than do most myxobacteria.

S. cellulosum grows well in liquid media (e.g., Gerth et al., 1994, 1996), first as small nodules and flakes, then—usually after many transfers—in homogeneous cell suspensions. Generation times range between 6 and 12–14 hours (30°C). Large-scale fermentations up to 100 m^3 have been performed successfully. These organisms produce a wide variety of bioactive secondary metabolites and are the source of many interesting compounds, such as epothilone, soraphen, sorangicin, and tartrolon.

Strains of *S. cellulosum* were found to have very large genomes, 10–12.2 Mbp.

Very common in soil with decaying plant material and on dung of herbivorous animals. Strain So ce1871 was isolated in 2001 from soil with decaying plant material collected in 2000 on the island of Rhodes, Greece; reference strain So ce1873 came from soil collected in Egypt in 2000 and was isolated in 2001. *"Sorangium nigrum"* strain So

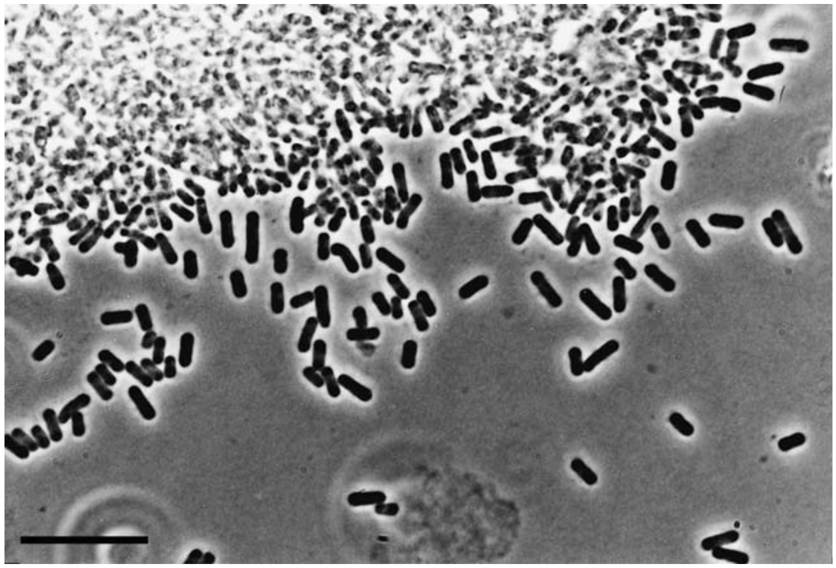

FIGURE BXII.δ.112. *Sorangium cellulosum*: vegetative cells from yeast agar, phase contrast. Bar = 13 μm.

ce1654 was isolated in 1999 from a sample from Bali, Indonesia, and reference strains So ce1695 and So ce1700 in 2000 from soil with rotting plant material collected in 1999 at different sites on the island of Rhodes, Greece.

The mol% G + C of the DNA is: 69 Bd (may be up to 70–72).

Type strain: So ce1871, DSM 14627, JCM 12641.

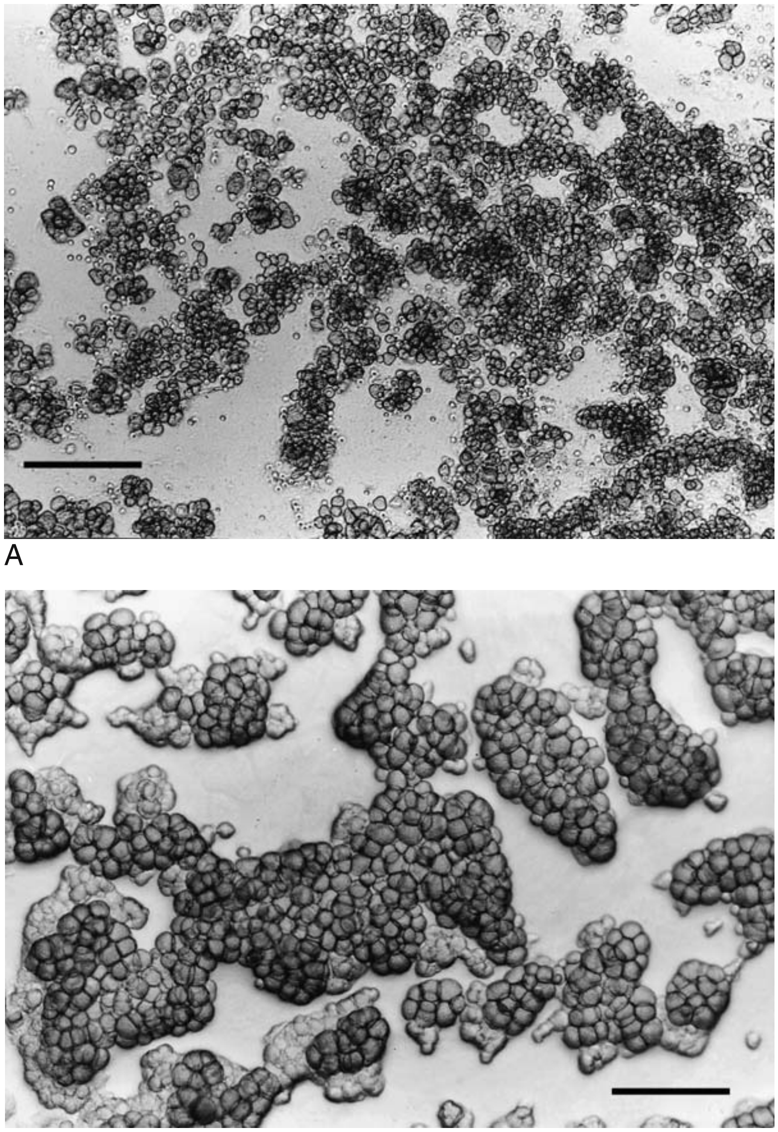
Additional Remarks: Reference strains include ATCC 15384, ATCC 25531, ATCC 25532, ATCC 25569, DSM 14671 (So ce1873).

Reference strains for *"Sorangium nigrum"* include DSM 14731 (So ce1654), DSM 14732 (So ce1695), DSM 14733 (So ce1700).

Cellulose-degrading myxobacteria are very common and have been isolated from all kinds of soils and environments from Russia and Sweden in the north to semiarid areas and tropical rain forests in the south. *S. cellulosum* clearly is a complex of several species. However, as most phenotypic characteristics of those organisms are extremely variable, all efforts at subdivision of this group of strains have failed so far. A comparative study making use of modern methods of molecular taxonomy may help to solve the problem.

The following phenotypic characteristics are potentially useful for species delimitation. (1) Size, shape, and color of fruiting bodies and sporangioles. However, fruiting bodies are always variable in size. They are sometimes sori composed of packets of sporangioles; in other cultures of the same strain they are homogeneous, and upon prolonged subcultivation may completely decay into scattered sporangioles, which sometimes form an uninterrupted, continuous mat of sporangioles when the organism is grown on filter paper. Shape and size of sporangioles is equally variable. Many strains initially produce small sporangioles that then increase substantially in size during cultivation. Polyhedral when densely packed, they become spherical when the sori are more loosely organized. However, there are fresh isolates that have tiny sporangioles and others that have large sporangioles. Such initial differences may indeed indicate the existence of different species. Color of fruiting bodies tends to become ever paler with subsequent transfers. Many strains end with pale, brownish-orange fruiting bodies. Other strains retain an intense rust brown, orange, yellow, or black color for a long time, and pigmentation of fresh isolates may be a valuable taxonomic criterion. (2) Size and shape of the vegetative cells are similar for all strains. During cultivation, especially on agar media, cells tend to become slightly but recognizably fatter. There are, however, strains with relatively short, more delicate rod-shaped cells with squarish rather than rounded ends; these strains may really represent a separate species, *"Sorangium nigrum"*, which will be discussed below. (3) Other characteristics that may be taxonomically useful are chitin degradation, which varies from zero to very strong among different strains; growth on casein peptone as the only carbon and nitrogen source, which occurs in about 25% of strains; lysis of proteins, e.g., in skim milk agar; and the degree of kanamycin resistance. The unsatisfactory aspect of all those variable characteristics is that they vary independently, so that no stable patterns have become recognizable so far.

The variants and species discussed below are to be evaluated against this background.. Cellulose-decomposing myxobacteria were discovered independently in two laboratories in the 1930s. The earliest publication was by Imshenetski and Solntseva (1936), who named their organism *Polyangium cellulosum*. The bacterium produced red-brown fruiting bodies, sori were 40–45 × 110–160 μm and consisted of 12–40 roundish to polygonal orange sporangioles, 8–42, mostly 20–25 μm in diameter. The vegetative cells were cylindrical rods with rounded ends, 0.8–1 × 3.5–8.5 μm. The myxospores were similar in shape and measured 0.7–0.8 × 3-2–3.5 μm. Old sporangioles sometimes contained a drop of an oily liquid. The optimal growth temperature was 18–22°C, and development was much slower at 30°C. (The fact that the bacterium was isolated from soil in Russia exposed to a cold, continental climate may explain this unusually low optimal temperature.) The description of *Polyangium cellulosum* fits a large proportion



A
B

FIGURE BXII.δ.113. *Sorangium cellulosum*: fruiting bodies; (*A*) slide mount from filter paper on mineral salts agar, (*B*) on surface of yeast agar. Bar in $A = 125$ μm; bar in $B = 100$ μm.

of the author's 2000 *Sorangium* isolates. A strain has been deposited that corresponds to the original species definition in the color and structure of its fruiting bodies.

In the following year, Krzemieniewska and Krzemieniewski (1937a, b) published the results of their almost decade-long studies on cellulose decomposing myxobacteria. They recognized that *"P. compositum"*, which, following Jahn, they now named *"Sorangium compositum"*, was a cellulose decomposer (see comments on *Polyangium sorediatum*). The fruiting bodies of their strains were orange yellow. The sori were sometimes subdivided into packets of sporangioles; at other times, they were not. Krzemieniewska and Krzemieniewski distinguished two variants, one with smaller sporangioles, 8–12 (6–16) × 7–18 μm in size, and one with larger sporangioles, 10–15 (7–18) × 8–20 μm. A third, faster growing variant with small sporangioles, 6–13 × 7–14 μm, produced fruiting bodies that were scattered over the swarm from the beginning and did not arise gradually from the center outward. The vegetative cells of all three types were cylindrical rods, 0.6–0.9 × 2.6–6 μm. In young cultures on cellulose the rods were much wider, 1.1–1.4 μm; in young sporangioles, the rods were very short, 0.8 × 1.3 μm. The sporangioles sometimes contained globules of a fatty material. *"Sorangium compositum"* of Krzemienieska and Krzemieniewski differs from *Polyangium cellulosum* in the color of its fruiting bodies and has smaller sporangioles, but it may still belong to the same species. Krzemieniewska and Krzemieniewski also discovered that their own *"S. spumosum"* was a cellulose decomposer. However, there is some uncertainty about that species (see comments on *Polyangium spumosum*). The cellulose degrading strains produced flesh red fruiting bodies in a colorless slime matrix, up to 400 μm, containing sporangioles of 16–24 μm diameter in one isolate and 9–15 μm in another. The sporangioles had a colorless wall. The vegetative cells measured 1.1–1.5 × 2.7–6 μm. This species was found by them to be the most com-

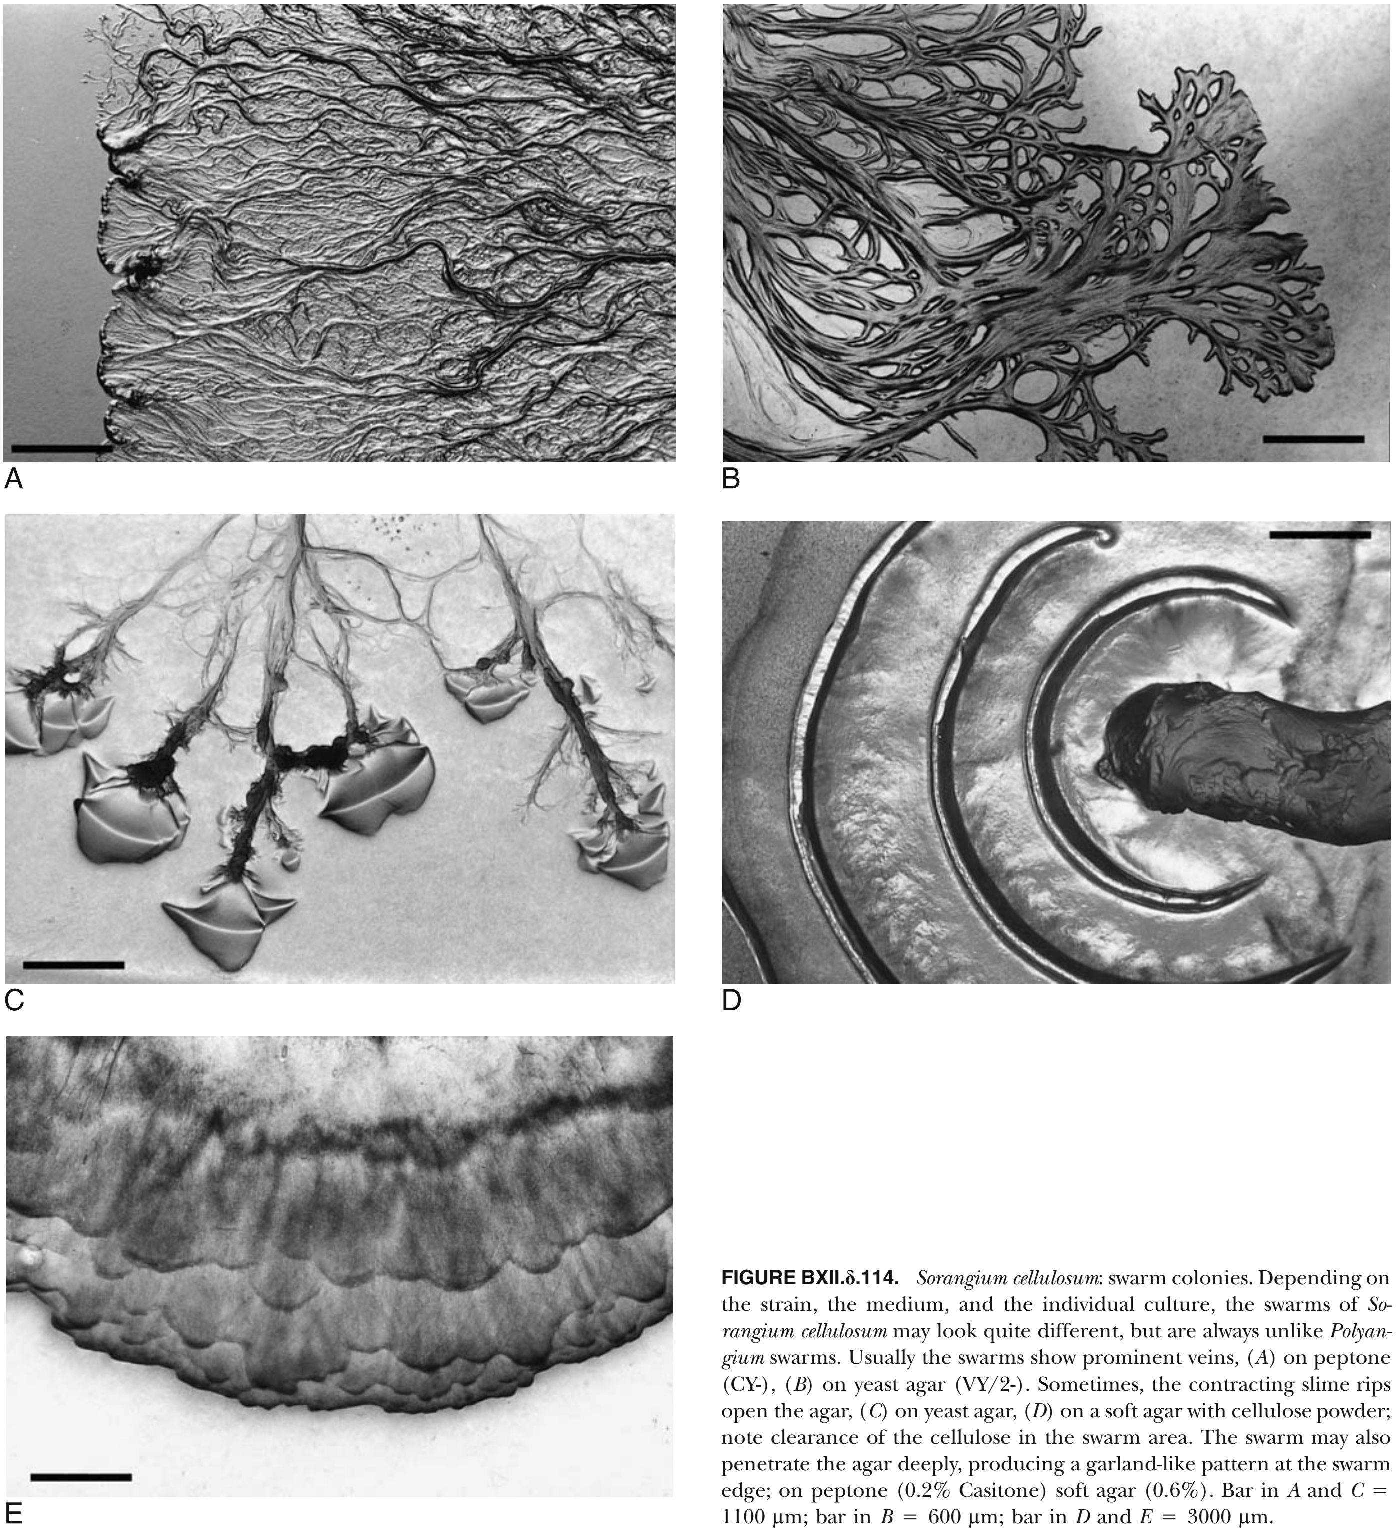


FIGURE BXII.δ.114. *Sorangium cellulosum*: swarm colonies. Depending on the strain, the medium, and the individual culture, the swarms of *Sorangium cellulosum* may look quite different, but are always unlike *Polyangium* swarms. Usually the swarms show prominent veins, (*A*) on peptone (CY-), (*B*) on yeast agar (VY/2-). Sometimes, the contracting slime rips open the agar, (*C*) on yeast agar, (*D*) on a soft agar with cellulose powder; note clearance of the cellulose in the swarm area. The swarm may also penetrate the agar deeply, producing a garland-like pattern at the swarm edge; on peptone (0.2% Casitone) soft agar (0.6%). Bar in *A* and *C* = 1100 μm; bar in *B* = 600 μm; bar in *D* and *E* = 3000 μm.

mon of all *Sorangium* species. Its status, however, is not clear. Krzemieniewska and Krzemieniewski described two other cellulose-decomposing *Sorangium* species. The first was *"Sorangium nigrescens"* Krzemieniewska and Krzemieniewski 1937a, 21. Mature sori were gray brown to blackish, with the color originating from the cell mass. Packets of sporangioles were about 200 μm wide, in a colorless slime matrix. Sporangioles were 5–12 × 5–15 μm, mostly 6–10 μm in diameter. Vegetative cells were 0.2–1.4 × 2.5–6.5 μm. While strains with fruiting bodies of that color do exist, their status as a species has still to be established. The second new species was *"Sorangium nigrum"* Krzemieniewska and Krzemieniewski 1937a, 22 (Fig. BXII.δ.115). The fruiting bodies were pitch black. Sporangioles were 9–16 × 9–

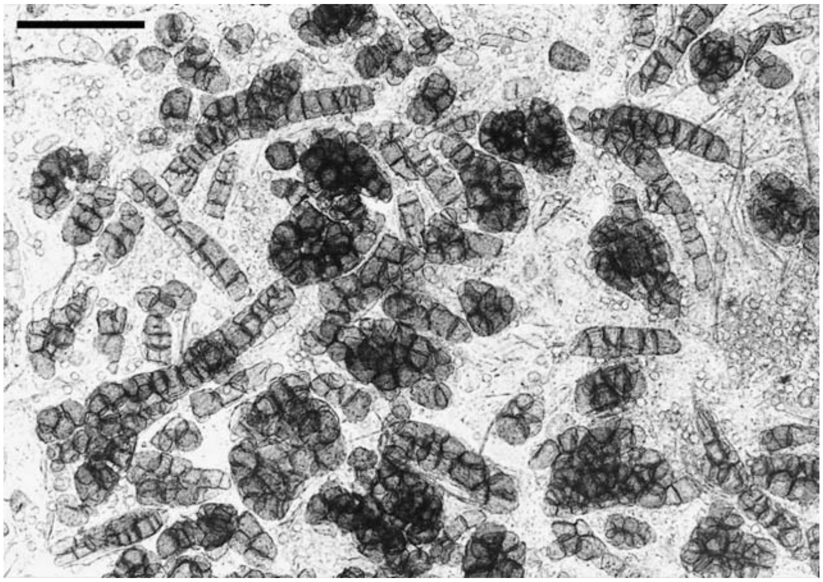

FIGURE BXII.δ.115. *"Sorangium nigrum"*: fruiting bodies, slide mount, from filter paper on mineral salts agar. Bar = 125 μm.

22 μm, mostly 16–18 μm, with rather stout walls, arranged in chains and strands along decaying cellulose fibers. Vegetative cells were 1.1–1.3 × 2.5–5.5 μm. Strains with such characteristics are often isolated. Swarm colonies on yeast agar (VY/2-) tend to become completely converted into fruiting bodies after some time. On filter paper, roundish sori are usually produced in addition to the strings and strands. The vegetative cells typically show somewhat squarish rather than rounded ends, and are often rather short. The author's impression is that this is a valid, distinguishable species, but molecular data should be presented before it is accepted. The author has deposited three characteristic strains.

Finally, a number of variants of *S. cellulosum* have been described. Mishustin (1938), who isolated cellulose degraders from Russian soils, distinguished four variants, mainly by the color of fruiting bodies. *Polyangium cellulosum* biovar fuscum—which he regarded as identical with the organism of Imshenetski and Solntseva (1936)—had brown fruiting bodies, biovar ferrugineum had dark red or red-brown fruiting bodies, biovar fulvum had pinkish brown to reddish yellow fruiting bodies, and biovar luteum had yellowish orange fruiting bodies. There also were slight differences in the dimensions of sori, sporangioles, and vegetative cells, but all measurements overlapped. Strains with fruiting bodies of all those colors are abundant, but their taxonomic status is open. Pronina (1962) isolated cellulose degraders from spoiled material in a paper mill. She, too, described a number of variants (biovars) of *S. cellulosum*. Five of those had vegetative cells with slightly pointed ends and thus may not have been *Sorangium* strains at all (biovar flavovirens, biovar glaucum, biovar helvolum, biovar ochraceum, biovar album). *S. cellulosum* biovar umbrinum was brown on filter paper and on agar, but had very short rods of 1.0 × 2.7 μm; biovar aurescens was pale orange to pale brown and also had short vegetative cells of 0.7 × 2.7 μm; and biovar cremeum was pink on cellulose, and pale yellow to gray on agar; its vegetative cells measured 0.7 × 3.2 μm. The sporangioles were in all cases extremely small, 2.3–6 μm. In addition, the colors were in most instances quite atypical. It is not possible to decide now whether any of those organisms were really cellulose degrading members of the genus *Sorangium*.

Family IV. **Nannocystaceae** *fam. nov.*

Hans Reichenbach

Nan.no.cys.ta' ce.ae. M.L. fem. n. *Nannocystis* type genus of the family; *-aceae* ending to denote a family; M.L. pl. fem. n. *Nannocystaceae* the *Nannocystis* family.

Vegetative cells are short, stout, cylindrical to somewhat bulging rods with rounded to squarish ends. Fruiting bodies consist of spherical to ellipsoidal, sometimes irregular sporangioles. Most of the sporangioles are solitary, scattered on top and within the agar plate; many strains also produce dense clusters, sheets, and packets of sporangioles. The size of the sporangioles usually varies very widely. **Myxospores are very short rods, ellipsoidal, or spherical. Swarm colonies etch and corrode the agar** to varying degrees, depending on the medium, from shallow depressions and pits (on yeast agar) to deep holes and channels, often transforming the agar plate into a spongy mass down to the bottom of the dish.

Of the proteolytic–bacteriolytic nutritional type. All strains grow well on yeast agar (VY/2-) and on streaks of living or au-

toclaved *E. coli* on water agar. Many strains also grow on casein peptone (CY-) agar. Agar corrosion is particularly dramatic on streaks of living and autoclaved *E. coli* and on CY-agar if the strain is grown on that medium. Sporangioles are usually produced abundantly on streaks of autoclaved *E. coli*. Because of agar corrosion, sporangioles are difficult to see under the dissecting microscope. However, when the swarm is covered with a drop of water, the sporangioles become clearly visible. The *Nannocystis* species appear not to utilize mono- and disaccharides but depend totally on peptones and proteins for growth. Do not degrade chitin. Synthesize cholestenols (Kohl et al., 1983; Zeggel, 1993), geosmin (Trowitzsch et al., 1981), and the iron chelator nannochelin (Kunze et al., 1992).

This family belongs to the third suborder of the *Myxococcales*, the *Nannocystineae*, together with the family *Kofleriaceae*. The suborder can currently be defined only by 16S rRNA sequence analysis, which clearly shows the separation of the organisms classified here from other myxobacteria (Spröer et al., 1999). The family, however, contains only one genus, *Nannocystis*, and is clearly defined by its phenotypic characteristics.

Some of the more unusual myxobacteria belong to this taxonomic group, in particular the psychrophilic myxobacteria (Dawid et al., 1988).

Type genus: **Nannocystis** Reichenbach 1970, 137.

Genus I. **Nannocystis** *Reichenbach 1970, 137*[AL]

HANS REICHENBACH

Nan.no.cys'tis. Gr. masc. n. *nannos* dwarf; Gr. fem. n. *kystis* bladder; M.L. fem. n. *Nannocystis* tiny bag.

Characteristics as given for the family. *Nannocystis* is perhaps the most common of all myxobacteria. It may be obtained from soil, decaying plant material, and similar substrates. It was overlooked for a long time because of its tiny sporangioles; it is best isolated on streaks of living *E. coli* on water agar. The swarm colonies of *Nannocystis* do not adsorb Congo red. The phenotypic characteristics of *Nannocystis* strains are extremely variable, which makes distinguishing species difficult. Only two species are named in this edition. But a number of variants listed under *N. exedens* may qualify as species of their own. Representative strains have been deposited for further study.

Type species: **Nannocystis exedens** Reichenbach 1970, 137.

Key to the species of the genus *Nannocystis*

1. Sporangioles of very different sizes; spherical, ellipsoidal, or irregular in shape; solitary or in groups, sheets, and packets.
   N. exedens
2. Sporangioles rather uniform in size, very small, mostly spherical, always solitary.
   N. pusilla

List of species of the genus Nannocystis

1. **Nannocystis exedens** Reichenbach 1970, 137[AL]
   ex.e'dens. L. v. *exedere* to eat away; L. present part. *exedens* eating away, corroding (the agar).

   Vegetative cells (Fig. BXII.δ.116) are short, stout, cylindrical, or slightly bulging rods with rounded or squarish ends, 1.1–2 × 1.5–5 µm. Move by gliding as is typical for myxobacteria (Fig. BXII.δ.117).

   The fruiting bodies are solitary sporangioles (Fig. BXII.δ.118), spherical, ellipsoidal, or irregular, of very different size from very small, 3.5 × 6 µm containing just four or five myxospores, to rather large, 15 × 30 to 40 × 110 µm. Sometimes a fine, regular striation can be seen on the surface. Many strains produce, in addition to solitary sporangioles scattered on and within the agar plate, sporangioles

(*B*), surface of a culture plate (at higher magnification) on which large irregularly shaped sporangia are seen on top of the agar and small ovoid ones are seen within it. Oblique illumination. Bar = 30 μm. (*C*), slide mount showing ovoid sporangia from within the agar. Phase-contrast micrograph. Bar = 50 μm. (*D*), small sporangium at high magnification. The myxospores within it are clearly recognizable. Phase-contrast micrograph. Bar = 13 μm. (*E*), ovoid sporangium from within the agar. A fine striation on its surface is shown. Phase-contrast micrograph. Bar = 12 μm.

that are arranged in loose or dense groups, sheets, and tightly packed sori. Such strains may represent different species and are described in more detail below. The sporangioles may be colorless, yellowish, or light to dark red-brown.

Myxospores (Fig. BXII.δ.119) are ellipsoidal to almost spherical, dark to optically refractile, and seem not to be surrounded by a capsule. Freeze-fracturing of sporangioles (Fig. BXII.δ.120) reveals a thick, compact wall in the electron microscope. A characteristic folding of the surface membranes on the myxospores gives them a walnut-like appearance.

On agar media, the organisms always penetrate the plate deeply, but the appearance of the swarm colonies depends on the medium used. On yeast agar (VY/2-) usually large, shallow depressions are produced without much agar corrosion. When the organism is grown on streaks of living or autoclaved *E. coli* on water agar, the agar is corroded in a highly variable and most striking pattern with holes, channels, and tunnels (Fig. BXII.δ.121). This pattern somewhat resembles the etching of the agar produced by *Polyangium* strains. However, the *Polyangium* pattern is much coarser,

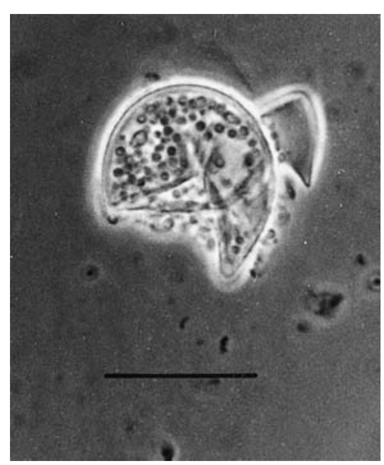

FIGURE BXII.δ.119. *Nannocystis exedens* crushed sporangium with spherical myxospores. Phase-contrast micrograph. Bar = 16 μm.

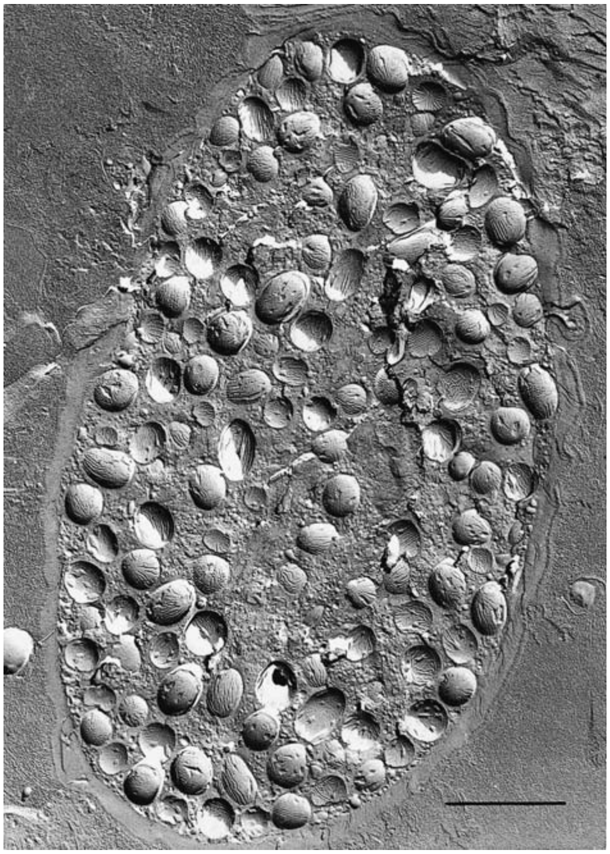

FIGURE BXII.δ.120. *Nannocystis exedens* sporangium with myxospores. The sporangium is surrounded by a thick wall. The surface membranes of the ovoid myxospores show a pattern of folds. Zeiss EM 10 B electron micrograph of a freeze fracture specimen. Bar = 3.2 μm. (Courtesy of I. Geffers.)

and the erosion of the agar plate is rarely as intense as with *Nannocystis*. Agar destruction is extreme on casein peptone (CY-) agar; however, not all strains grow on this medium. Development is normally slow, and the agar is transformed into a spongy mass; the swarms become bright red, orange, or orange brown.

Nannocystis can also be grown in liquid media, in which it forms tiny flakes or even homogeneous cell suspensions (e.g., Behrens et al., 1976; Kohl et al., 1983; Kunze et al., 1992).

An unusual retro element has been discovered in the genome of *N. exedens* (Lampson and Rice, 1997). There are two different satellite msDNAs, the genes of which are not flanked by the usual reverse transcriptase genes. Further, a set of somewhat variable repeated sequences related to msDNA were demonstrated throughout the chromosome.

The mol% G + C of the DNA is: 70–72 (Bd, T_m) (Behrens et al., 1976).

Type strain: Na e1, ATCC 25963, DSM 71.

GenBank accession number (16S rRNA): M94279.

Additional Remarks: Reference strains include ATCC 25965 (Na e17); ATCC 35989 (Na e465).

As mentioned, *Nannocystis* strains are extremely variable in their phenotypic appearance, so that the group cannot yet be classified into more than two species. However, in the author's collection of about 1900 strains, certain characteristics appear to be connected with specific types of organisms. The following is an effort to bring some order into that assembly. The types are named as subspecies but may in fact represent species. It must be emphasized that the sporangioles regarded as typical for the variants always occur in a background of small, scattered sporangioles. Typical sporangioles are best observed on streaks of autoclaved *E. coli* on water agar.

a. **Nannocystis exedens** *subsp.* **exedens** *subsp. nov.*

Sporangioles small to moderately large, mostly spherical to ellipsoidal, colorless, yellowish brown or reddish, scattered.

b. **Nannocystis exedens** *subsp.* **aggregans** *subsp. nov.*
aggregans. L. present part. *aggregans* herding together.

Sporangioles small to moderately large, mostly spherical to ellipsoidal; brownish, in large, often branched, densely packed, sheet-like groups connected by a thin brown slime matrix (Fig. BXII.δ.122). The groups of sporangioles are usually only seen on streaks of autoclaved *E. coli.* 16S rRNA sequence comparison seems to support a separate position of this variant (Spröer et al., 1999). Strain Na a1 is from Franconia, Germany.

Type strain: Na a1, DSM 14639.

c. **Nannocystis exedens** *subsp.* **cinnabarina** *subsp. nov.*
cinnabarina. L. fem. adj. *cinnabarina* cinnabar red.

Sporangioles reddish, sometimes rather large and mostly spherical, may be produced in rather extended, sheet-like, dense groups, but often are scattered. Intensely red spherical globules of a fatty or oily material are seen between the sporangioles, but only on streaks of autoclaved *E. coli* (Fig. BXII.δ.123). Strain Na c1 is from Rhodos, Greece.

Type strain: Na c1, DSM 14641.

d. **Nannocystis exedens** *subsp.* **glomerata** *subsp. nov.*
glomerata. L. fem. part. perf. *glomerata* packed or pressed together.

Sporangioles small to moderately large, in small, more or less spherical, tightly packed sori (Fig. BXII.δ.124). Strain Na g1 is from Rajasthan, India.

Type strain: Na g1, DSM 14640.

e. **Nannocystis exedens** *subsp.* **pulla** *subsp. nov.*
pulla. L. fem. adj. *pulla* dark brown.

Sporangioles are small to moderately sized, narrow ellipsoidal to irregular, solitary or connected to one another in a net-like pattern, sooty-brown (Fig. BXII.δ.125). Strain Na a145 is from the Alsace, France.

Type strain: Na a145, DSM 14629.

2. **Nannocystis pusilla** *sp. nov.*
pu.sil′la. L. fem. adj. *pusilla* tiny.

Characteristics as described for the genus and *N. exedens* with the exception that the sporangioles are uniformly tiny, 8–15 μm large, scattered or in small, loose groups and short strings (Fig. BXII.δ.126). Strain Na p29 is from California, USA.

The mol% G + C of the DNA is: not determined.

Type strain: Na p29, DSM 14622, JCM 12635.

Additional Remarks: Reference strains include DSM 14621 (Na p23), from California, USA.

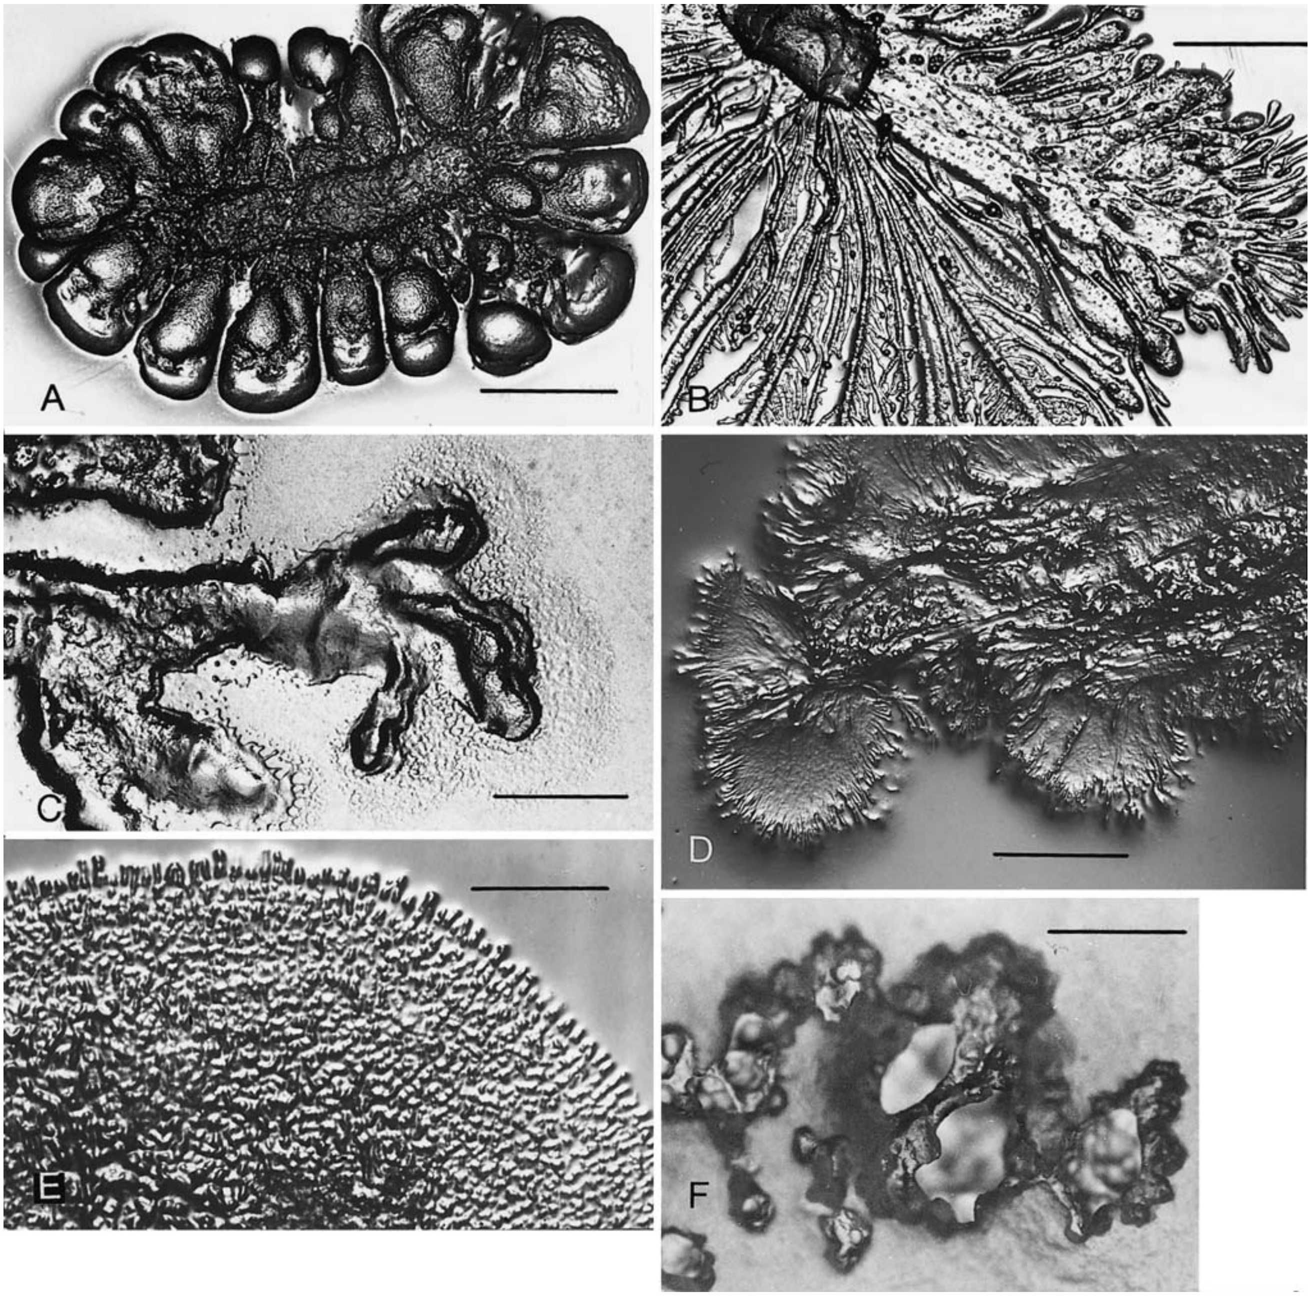

FIGURE BXII.δ.121. *Nannocystis exedens* swarm colonies. (*A*), small 4–week-old swarm colony on an agar medium containing low concentrations of casein peptone. The organism produced a series of deep bubblelike caverns within the agar plate. Bar = 6 mm. (*B*), swarm on a streak of autoclaved yeast on water agar. The organism etched a system of feathery branched trenches into the agar surface. Bar = 6 mm. (*C*), tip of a trench. Family V. **Kofleriaceae** *fam. nov.*

HANS REICHENBACH

Ko.fle.ri.a' ce.ae. M.L. fem. n. *Kofleria* type genus of the family; *-aceae* ending to denote a family; M.L. pl. fem. n. *Kofleriaceae* the *Kofleria* family.

Vegetative cells are slender, cylindrical rods with rounded ends. Swarm colonies with radial veins that resemble those of the *Cystobacteraceae*. Does not adsorb Congo red. Does not etch the agar but may pull it apart. Fully developed fruiting bodies have not yet been seen, but probably consist of sporangioles. **Of the proteolytic–bacteriolytic nutritional type**.

Type genus: **Kofleria** *gen. nov.*

FURTHER DESCRIPTIVE INFORMATION

The vegetative cells of the *Kofleriaceae* resemble those of the *Polyangiaceae*, but the swarm colonies are different. These organisms were erroneously classified as *Polyangium vitellinum* strains (e.g., Pl vt1), but a 16S rRNA study clearly placed them in the suborder *Nannocystineae* (Spröer et al., 1999). This made it necessary to establish a new genus (*Kofleria*). As this genus is distant from *Nannocystis*, its classification in a new family seems justified.

It appears that some truly marine, halophilic myxobacteria also belong to this family (Moyer et al., 1995; Iizuka et al., 1998).*

Presently only one genus is distinguished in this family. The marine organisms may contribute further genera.

**Editorial Note:* After this chapter was finished, a genus *Haliangium* with two new species *H. ochraceum* and *H. tepidum*, was proposed for the marine organisms belonging to this family (Fudou et al., 2002).

Genus I. **Kofleria** *gen. nov.*

HANS REICHENBACH

Ko.fle' ria. M.L. fem. n. *Kofleria* in honor of Ludwig Kofler, the Austrian scientist who, in 1913, described the first species of the genus.

Vegetative cells are long, slender, cylindrical rods with rounded ends. **Swarm colonies with radial veins in a tough slime sheet**, with numerous small to very large globular masses, or knobs, all over the swarm. Congo red is not adsorbed; the agar is not etched. Mature fruiting bodies have not been observed but appear to consist of sporangioles. Cells within the knobs consist of long, cylindrical rods, optically refractile. Of the proteolytic–bacteriolytic nutritional type. Chitin degraders. Found in soil and similar substrates.

Type species: **Kofleria flava** (ex Kofler 1913) *sp. nov. nom. rev.*

List of species of the genus Kofleria

1. **Kofleria flava** (ex Kofler 1913) *sp. nov. nom. rev.*
fla' va. L. fem. adj. *flava* yellow.

Vegetative cells are slender, cylindrical rods with rounded ends, often rather long, 0.6–0.7 × 4–6 μm (Fig. BXII.δ.127).

Swarm colonies produce a tough, more or less greenish-yellow slime sheet and prominent veins resembling a *Cystobacter* swarm. When cut, the slime layer tends to contract. The agar is not etched but is sometimes ripped open by the shrinking slime sheet.

Mature fruiting bodies have apparently not yet been observed. In the swarm colonies many large, greenish yellow spherical or slightly irregular globular masses, or knobs, arise (Fig. BXII.δ.128), with a smooth or bumpy surface, often constricted at the base or on a short stalk. The cells within those structures aggregate and stick together in spherical or convoluted masses; these cells are optically refractile, resemble vegetative cells in shape and size, but often are somewhat irregular in outline. Some of them may represent myxospores; others are clearly degenerate forms. The surface of the knobs often shows a boundary layer. The spherical cell masses within those knobs may have a thin envelope, like an immature sporangiole wall; their diameter varies between 40 and 120 μm. The size of the knobs is 200–600 μm. They may be interpreted as immature or degenerate fruiting bodies or may be the survival form of the organism.

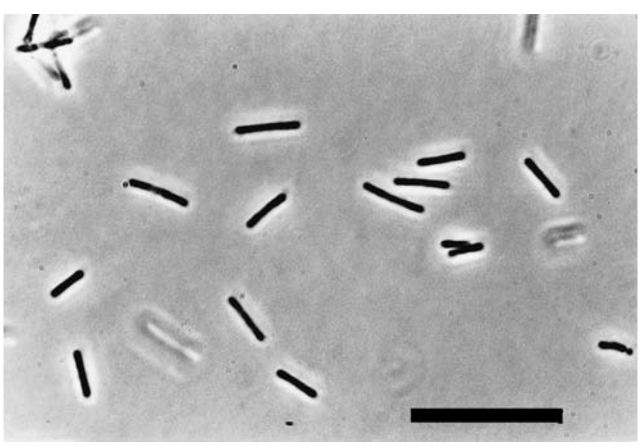

FIGURE BXII.δ.127. *Kofleria flava*: vegetative cells, in phase contrast. Bar = 10 μm.

Of the proteolytic-bacteriolytic nutritional type. Degrades chitin vigorously. Starch is hydrolyzed; cellulose is not attacked.

Rather uncommon. So far 11 strains of these myxobacteria have been isolated, four of which, however, come from the same site. The sources were mainly soil with decomposing plant material but include goat dung and the bark of a *Ficus* tree. The samples came from Germany, Spain, Greece, Siberia, North and South India, and Arizona and Pennsylvania in the USA. Obviously the organism has a worldwide distribution. Strain Pl vt1 was isolated in 1988 from a soil sample from Pennsylvania. The reference strains were obtained in 1998 from soil from Siberia (Pl vt4), in

FIGURE BXII.δ.128. *Kofleria flava*: globular masses in swarm colonies, often elevated on a stout slime stalk (*C*). (*A*) Bar = 160 μm; (*B*) Bar = 260 μm; and (*C*) Bar = 320 μm.

2001 from soil from Arizona (Pl v10), and in 2001 from the bark of a *Ficus glomerata* from Karnataka, India (Pl vt11).

The mol% G + C of the DNA is: not determined.

Type strain: Pl vt1, DSM 14601, JCM 12632.

Additional Remarks: References strains include DSM 14659 (Pl vt4); DSM 14602 (Pl vt10); DSM 14620 (Pl vt11).

Initially these organisms were classified as *Polyangium vitellinum* because of the yellow color of the knobs. Further studies showed that these strains must be a different species. The absence of bright orange sporangioles, the greenish yellow color of the knobs and swarms, and the habitat did not fit the description of *Polyangium vitellinum.* Most likely the bacterium is identical to Kofler's (1913) *"Polyangium flavum"*, later renamed by Jahn (1924)—without ever having seen it—*"Archangium flavum"*. Kofler's note that *"Polyangium flavum"*, when observed by the naked eye, could easily be mistaken for *Myxococcus virescens* except that the surface of the "fruiting bodies" is not so smooth but rather bumpy, corresponds exactly to the author's observations. Furthermore, the yellow color of Kofler's organism, the size of the knobs (600 × 400 μm), the lack of "cysts", i.e., sporangioles, and the sticking together of the cells in clumps when the "fruiting bodies" are squeezed is consistent with strains in the author's collection. Only the length of the cells (2–4 μm) given by Kofler is rather short but not beyond the usual variability of the population. Unfortunately, he did not describe their shape.

Kofler's organism was mentioned by Krzemieniewska and Krzemieniewski (1927). They obtained it from forest soil and described two new forms of the bacterium, one with a colorless, stiff envelope around the fruiting body. In addition, they pointed out that the vegetative cells were cylindrical rods with rounded ends. Krzemieniewska and Krzemieniewski were indeed probably describing *Kofleria flava.* A later report of *"Archangium flavum"* from India (Singh and Singh, 1971) is less likely to have been this organism, as the vegetative cells had slightly tapering ends. However, identity cannot be ruled out.

When the 16S rRNA sequence of strain Pl vt1 was determined and analyzed (Spröer et al., 1999), it became clear that the bacterium occupied a rather isolated position connected with *Nannocystis* at a deep level. This made the taxonomic adjustments necessary as presented here.

Class V. **Epsilonproteobacteria** *class. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Ep.si.lon.pro.te.o.bac.te′ ri.a. Gr. n. *epsilon* name of fifth letter of Greek alphabet; Gr. n. *Proteus* ocean god able to change shape; Gr. n. *bakterion* a small rod; M.L. fem. pl. n. *Epsilonproteobacteria* the class of bacteria having 16S rRNA gene sequences related to those of the members of the order *Campylobacterales*.

The class *Epsilonproteobacteria* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the class contains the order *Campylobacterales*.

Type order: **Campylobacterales** *ord. nov.*

Order I. **Campylobacterales** *ord. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Cam.py.lo.bac.ter.a′ les. M.L. masc. n. *Campylobacter* type genus of the order; *-ales* ending to denote order; M.L. fem. n. *Campylobacterales* the *Campylobacter* order.

The order *Campylobacterales* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the order contains the families *Campylobacteraceae*, *Helicobacteraceae*, and *"Nautiliaceae"*.

Actively growing cells generally curved or spiral-shaped, except for *Thiovulum*. Metabolically and ecologically diverse; includes human and animal pathogens. *Nautilia* and *Caminibacter* are anaerobic marine thermophiles.

Type genus: **Campylobacter** Sebald and Véron 1963, 907 emend. Vandamme, Falsen, Rossau, Hoste, Segers, Tytgat and De Ley 1991a, 98.

Family I. **Campylobacteraceae** Vandamme and De Ley 1991, 453[VP]

PETER VANDAMME, FLOYD E. DEWHIRST, BRUCE J. PASTER AND STEPHEN L.W. ON

Cam.py.lo.bac.ter.a′ ce.ae. M.L. masc. n. *Campylobacter* type genus of the family; suff. *-aceae* denoting family; M.L. masc. pl. n. *Campylobacteraceae*, the *Campylobacter* family.

Curved, S-shaped, or **spiral rods** that are 0.2–0.8 × 0.5–5 µm. Gram negative. Nonsporeforming. Cells in old cultures may form spherical or coccoid bodies. Mostly motile with a **characteristic corkscrew-like motion** by means of a single, **polar, unsheathed flagellum** at one or both ends of the cell.

Microaerophilic, with a respiratory type of metabolism. Some taxa grow also under aerobic or anaerobic conditions. Optimal temperature is 30–37°C. **Chemoorganotrophs. Carbohydrates are neither fermented nor oxidized.** Fumarate is reduced to succinate. Colonies are usually nonpigmented. Serum or blood enhances growth but is not necessary. **Energy is obtained from amino acids or tricarboxylic acid cycle intermediates, not carbohydrates.** Mostly oxidase positive. Methyl red and Voges–Proskauer negative, and no production of indole. Most species reduce nitrate and do not hydrolyze hippurate.

Menaquinones are the only respiratory quinones detected, with menaquinone-6 (three different structural types) and menaquinone-5 as major components. Internal transcribed spacers or intervening sequences occur in the 16S or 23S ribosomal RNA genes of strains of several species. Most species occur in man or animals, or both, primarily in the reproductive organs, intestinal tract, and oral cavity. Some species are considered true pathogens and are a significant cause of diarrheal disease; some species are associated with periodontal disease.

The mol% G + C of the DNA is: 27–47.

Type genus: **Campylobacter** Sebald and Véron 1963, 907 emend. Vandamme, Falsen, Rossau, Hoste, Segers, Tytgat and De Ley 1991a, 98.

FURTHER DESCRIPTIVE INFORMATION

The family *Campylobacteraceae* comprises the genera *Campylobacter*, *Arcobacter*, and *Sulfurospirillum*, and the generically misclassified species *Bacteroides ureolyticus*(Fig. BXII.ε.1). As described below, *B. ureolyticus* phylogenetically belongs to this family and shares most of its characteristics with other members of this family. It resembles *Campylobacter* species in its respiratory quinone content, its DNA base ratio, and most of its phenotypic characteristics but differs from campylobacters in its fatty acid composition and its proteolytic metabolism. *B. ureolyticus* was not formally reclassified pending the isolation and thorough taxonomic characterization of additional *B. ureolyticus*-like bacteria, and is thus considered species *incertae sedis*.

The delineation of this bacterial family was primarily based on phylogenetic criteria and is not supported by biochemical, chemotaxonomic, or ultrastructural characteristics. The genera *Helicobacter* and *Wolinella* are the closest phylogenetic neighbors of members of the *Campylobacteraceae*. Genus level identification is primarily achieved via the identification of strains to the species level.

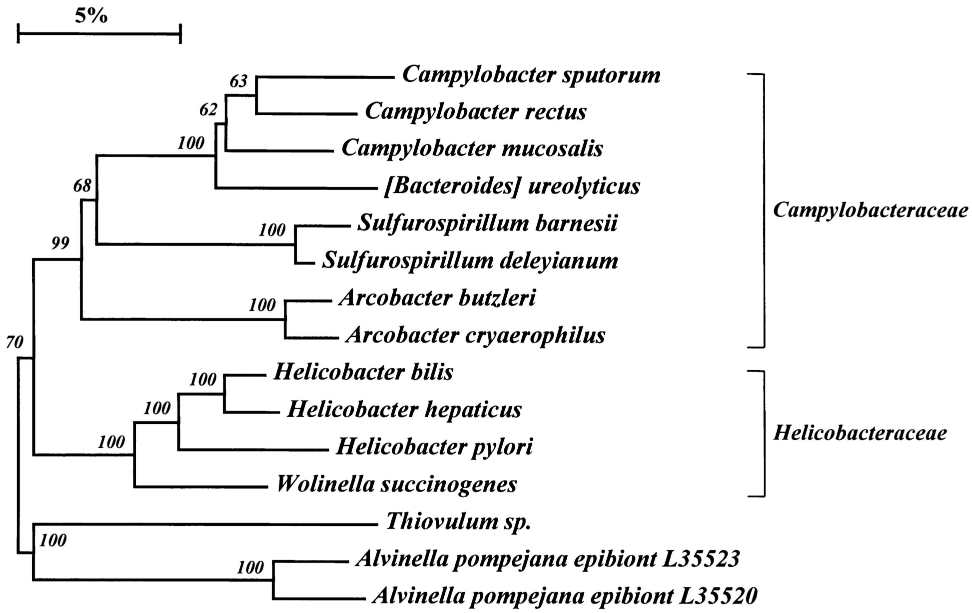

FIGURE BXII.ε.1. Phylogeny of the family *Campylobacteraceae.* The family *Campylobacteraceae* forms a coherent phylogenetic group in the *Epsilonproteobacteria* that is comprised of members of the genera *Campylobacter*, the misclassified *Bacteroides ureolyticus*, *Arcobacter*, and *Sulfurospirillum.* Bar = 5% difference in 16S rDNA nucleotide sequences. The Neighbor-Joining method was used for tree construction. One hundred bootstrap trees were generated, and bootstrap confidence levels (shown as percentages above the nodes) were determined.

Key to the genera of the family Campylobacteraceae

1. The mol% G + C content of the DNA is 29–47. Optimal growth is between 30 and 37°C, in microaerobic to anaerobic conditions. Menaquinone-6 and a methyl-substituted menaquinone-6 are the major respiratory quinones. No hydrolysis of casein or gelatin. Most strains do not hydrolyze urea. Isolated primarily from the reproductive organs, intestinal tract, and oral cavity of humans and animals. Internal transcribed spacers or intervening sequences occur in 16S and 23S rRNA genes of a variety of species.
   Genus *Campylobacter*
2. The mol% G + C content of the DNA is 27–31. Optimal growth between 15 and 30°C, in microaerobic to aerobic conditions. Menaquinone-6 and a second menaquinone-6, the detailed structure of which has not been determined, are the major respiratory quinones. No hydrolysis of casein or gelatin. Most strains do not hydrolyze urea. Isolated primarily from the reproductive organs and intestinal tract of man and animals. Internal transcribed spacers or intervening sequences have not been reported.
   Genus *Arcobacter*
3. The mol% G + C content of the DNA is 32–42. Optimal growth between 20 and 37°C, in microaerobic to anaerobic conditions. Menaquinone-6 and a methyl-substituted menaquinone-6 are the major respiratory quinones. Utilization of sulfur as electron acceptor. Free-living, found in freshwater and marine environments. Internal transcribed spacers or intervening sequences have not been reported.
   Genus *Sulfurospirillum*
4. The mol% G + C content of the DNA is 28–30. Optimal growth between 30 and 42°C, in microaerobic to anaerobic conditions. Menaquinone-6 and a methyl-substituted menaquinone-6 are the major respiratory quinones. Hydrolysis of casein, gelatin, and urea. Isolated primarily from superficial ulcers, soft-tissue infections, the urogenital tract, and oral cavity of humans.
   Species incertae sedis Bacteroides ureolyticus

Genus I. **Campylobacter** *Sebald and Véron 1963, 907,[AL] emend. Vandamme, Falsen, Rossau, Hoste, Segers, Tytgat and De Ley 1991a, 98*

Peter Vandamme, Floyd E. Dewhirst, Bruce J. Paster and Stephen L.W. On

Cam.py' lo.bac.ter. Gr. adj. *campylo* curved; Gr. n. *bacter* rod; M.L. masc. n. *Campylobacter* a curved rod.

Cells of most species are **slender, spirally curved rods**, 0.2–0.8 × 0.5–5 μm; cells of some species are predominantly curved or straight rods. The rods may have one or more spirals and can be as long as 8 μm. They also appear S-shaped and gull-winged when two cells form short chains. Nonsporeforming. Cells in old cultures may form spherical or coccoid bodies. Cells have a multilaminar polar membrane at both ends of the cell that is located under the cytoplasmic membrane. Gram negative. Cells of most species are motile with a characteristic **corkscrewlike motion** by means of a single polar **unsheathed flagellum** at one or both ends of the cell. The flagella may be 2–3 times the length of the cells. Cells of other species are nonmotile (*Campylobacter gracilis*) or have multiple flagella (*Campylobacter showae*). Occasionally differences in the number of flagella shown by cells in a single culture are seen (*Campylobacter hyointestinalis*).

Microaerophilic, with a respiratory type of metabolism. Several species require anaerobiosis for optimal growth and grow only microaerobically in the presence of fumarate with formate or hydrogen. Require an oxygen concentration between 3% and 15% and a CO_2 concentration of 35%. Growth at 35–37°C, not at 4°C. **Chemoorganotrophs. Carbohydrates are neither fermented nor oxidized.** No acid or neutral end products produced. Serum or blood enhances, but is not required for, growth. **Energy is obtained from amino acids or tricarboxylic acid cycle intermediates, not carbohydrates.** Gelatin, casein, starch, and tyrosine are not hydrolyzed. Methyl red and Voges–Proskauer negative. **Oxidase activity** is present in all species except *C. gracilis* and sporadic isolates of *Campylobacter concisus* and *C. showae*. **Arylsulfatase activity is reported in some species**, but no lipase or lecithinase activity. Most species **reduce nitrate**. Pigments are not produced. Most species are pathogenic for man and animals. **Found in the reproductive organs, intestinal tract, and oral cavity of humans and animals.**

Internal transcribed spacers or intervening sequences (IVS) were first reported in rRNA genes of *Campylobacter* strains by Van Camp et al. (1993). Intervening sequences were present in the 16S rRNA genes of all *C. sputorum* strains (Van Camp et al., 1993; On et al., 1998) and some *C. hyointestinalis* subsp. *lawsonii* strains (Harrington and On, 1999) were examined. The IVS occurs in a 7-base stem-loop that is centered at position 210 (*E. coli* numbering). The length of the IVS replacing the 7-base stem-loop is 240 bases. Dewhirst and Paster (unpublished) have found IVS's in the type strain of *C. curvus* (147 bases), a different IVS in a *C. curvus*-like strain (SU C10; 208 bases), and in a *C. rectus*-like strain (CCUG 19168, 196 bases). Linton et al. (1994a) reported on the presence of an IVS (152 bases) in the 16S rRNA genes of some *C. helveticus* strains. 23S rRNA genes of all *C. fetus* strains examined (Van Camp et al., 1993), and the 23S rRNA genes of some of the *C. jejuni* and *C. upsaliensis* strains examined (Van Camp et al., 1993) have IVS elements. Hurtado and Owen (1997a) reported on intervening sequences in 23S rRNA genes of strains of *C. jejuni* (both subspecies), *C. coli*, *C. helveticus*, *C. fetus*, *C. sputorum*, and *C. upsaliensis*.

The mol% G + C of the DNA is: 29–47.

Type species: **Campylobacter fetus** (Smith and Taylor 1919) Sebald and Véron 1963, 907 (*Vibrio fetus* Smith and Taylor 1919, 301.)

Further descriptive information

The genera *Campylobacter*, *Arcobacter*, *Sulfurospirillum*, and the generically misclassified species *Bacteroides ureolyticus*, constitute the family *Campylobacteraceae* and belong to the *Epsilonproteobacteria*. Within the genus *Campylobacter*, the group of the thermophilic (or more accurately, thermotolerant) campylobacters (*C. jejuni*, *C. coli*, *C. lari*, *C. upsaliensis*, and *C. helveticus*) forms a distinct subcluster (Fig. BXII.ε.2). *C. fetus* and *C. hyointestinalis* are also close relatives, while the remaining species form a loose assemblage of predominantly hydrogen-requiring organisms. Low but significant DNA–DNA hybridization values (which vary with the hybridization techniques used) have been reported between (i) *C. fetus* and *C. hyointestinalis*; (ii) *C. jejuni* and *C. coli* (reviewed by Vandamme and Goossens, 1992); (iii) *C. upsaliensis* and *C. helveticus* (Stanley et al., 1992); and (iv) *C. showae* and *C. rectus* (Etoh et al., 1993); the level of DNA–DNA hybridization toward and between all other species were reported as not substantial.

Campylobacter cells are typically helically curved and have a very characteristic corkscrew-like darting type of motility, which is observed with phase contrast or darkfield microscopy. The growth medium becomes alkaline (pH 8.5–9.0), and coccoid forms occur under these unfavorable conditions. The coccoid forms are considered by many to be degenerative forms rather than a dormant stage of the organism and are difficult to detect using PCR methods. Increase of viable numbers of aged coccoid cultures is attributed to multiplication of residual viable cells (Hazeleger et al., 1994; Bovill and Mackey, 1997).

The outer cell membrane is double-layered, loosely fitted over the cell wall and has a wavy morphology. The cytoplasmic membrane is thickened at the polar region. This polar membrane can be seen at both ends of the cell and a similar structure has been reported in other bacteria (Smibert, 1978). In contrast, *C. rectus* exhibits a distinct cell wall structure in which the outer membrane is covered with a distinctive array of hexagonally packed macromolecular subunits (Lai et al., 1981).

Campylobacter species have a respiratory metabolism. *C. fetus* oxidizes citrate, *cis*-aconitate, isocitrate, α-ketoglutarate, succinate, fumarate, malate, and oxaloacetate. A complete tricarboxylic acid (TCA) cycle has been demonstrated. There is no oxidation or fermentation of carbohydrates. Energy for *C. fetus* is obtained from TCA intermediates and from amino acids such as glutamate and aspartate that can be deaminated to TCA intermediates. Mendz et al. (1997) reported on the role of pyruvate in the energy and biosynthesis metabolism of *Campylobacter* species. The important role of pyruvate was illustrated by the variety of products formed using pyruvate as the sole substrate and by the existence of anaplerotic sequences and anabolic pathways that employ pyruvate.

All campylobacters grow under microaerobic conditions. Several species (*C. concisus*, *C. curvus*, *C. rectus*, *C. mucosalis*, *C. showae*, *C. gracilis*, and, partly, *C. hyointestinalis*) require hydrogen or formate as an electron donor for microaerobic growth and some species grow preferentially under anaerobic conditions (Han et al., 1991). Hydrogen stimulates growth of the majority of species when inoculated on common agar bases. Cytochromes *b*, *c*, and carbon monoxide-binding cytochrome *c* have all been reported

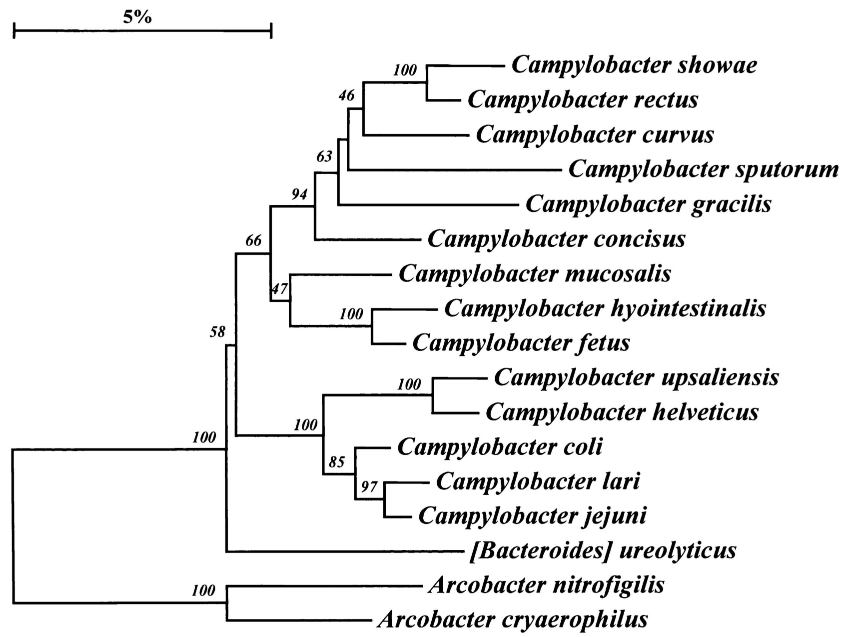

FIGURE BXII.ε.2. Phylogeny of *Campylobacter* species. The phylogenetic relationships of the named species of the genus *Campylobacter* and the misclassified *Bacteroides ureolyticus* are shown above. Bar = 5% difference in 16S rDNA nucleotide sequences. The Neighbor-Joining method was used for tree construction. One hundred bootstrap trees were generated, and bootstrap confidence levels (shown as percentages above the nodes) were determined.

in *Campylobacter* species, but not types *a* and *d*; the presence of cytochrome *o*, is controversial (Goodhew et al., 1988; Han et al., 1992). Many species also have catalase activity.

Menaquinone-6 (2-methyl-3-farnesyl-farnesyl-1,4-naphthoquinone) and a methyl-substituted menaquinone-6 (2, [5 or 8]-dimethyl-3-farnesyl-farnesyl-1,4-naphthoquinone) have been reported as major respiratory quinones in *Campylobacter* species (Moss et al., 1984, 1990b; Vandamme et al., 1995a).

Plasmids have been described in a variety of species including *C. jejuni*, *C. coli*, *C. upsaliensis*, *C. mucosalis*, *C. hyointestinalis*, and *C. fetus* (Taylor et al., 1981; Boosinger et al., 1990; Goossens et al., 1990a; Varga, 1991; Waterman et al., 1993). Tetracycline and kanamycin resistance were shown to be plasmid-mediated and transferable (Taylor et al., 1981; Cabrita et al., 1992; Velazquez et al., 1995).

Several serological typing systems have been developed but are focused primarily on *C. jejuni* and *C. coli* (reviewed by Patton and Wachsmuth, 1992). In addition, bacteriophage typing, biotyping, plasmid profiling, and a variety of DNA based typing methods such as pulsed field gel electrophoresis of large genomic fragments, ribotyping, and PCR based genomic fingerprinting, have all been used in epidemiological studies (Griffiths and Park, 1990; Mazurier et al., 1992; Patton and Wachsmuth, 1992; Owen et al., 1993).

Thermophilic campylobacters cause gastroenteritis in humans. In particular, *C. jejuni* is known worldwide as a major enteropathogen causing as much enteric disease in man as *Salmonella* and *Shigella*. *C. jejuni* infects people of all ages. It is more frequently diagnosed in children than adults and the seasonal incidence shows it to be higher in the summer and fall than in winter or spring (Butzler and Skirrow, 1979). The organism is found in the intestinal tract of a wide variety of animals. Enteric infection in animals has been reported. Transmission is most likely oral or fecal–oral. *Campylobacter* enteritis is a foodborne disease with meat, milk, and water as most important vehicles. Other members of the thermophilic species group are *C. coli*, *C. lari*, and *C. upsaliensis*, all of which are known to cause enteritis in humans and to be carried in the intestinal tract of a variety of animals, in particular pigs, pets (cats and dogs), and poultry. Varying isolation rates—which may be due to genuine differences in prevalence, to inappropriate isolation or identification procedures, or to any combination of these factors—have been reported. *C. jejuni* infection is a known antecedent of Guillain–Barré syndrome and is associated with axonal degeneration, slow recovery, and severe residual disability (Rees et al., 1995b; Jacobs et al., 1996; Nachamkin et al., 1998). *C. rectus* and other oral species are associated with periodontal disease in humans, and may cause infections in other parts of the body. *C. fetus* and *C. hyointestinalis* are primarily important in veterinary medicine, causing sporadic abortion in cattle and abortion in sheep (*C. fetus* subsp. *fetus*), abortion and reproductive problems in cattle (*C. fetus* subsp. *venerealis*), and enteric disease in pigs (*C. hyointestinalis*). *C. fetus* subsp. *fetus* also causes bacteremia in humans. Thus far, *C. mucosalis* and *C. helveticus* are the only species not isolated from human infections.

The pathogenicity mechanisms by which campylobacters cause gastroenteritis are unclear, and a good animal model is not available. As with other enteropathogens, motility, chemotaxis, adherence, invasion, and toxin production have been recognized as virulence properties (Ketley, 1997). Flagella, lipopolysaccharides, outer membrane proteins, and a carbohydrate moiety may act as adhesins. An enterotoxin immunologically related to cholera toxin, a heat-labile trypsin-sensitive cytotoxin, a cytotoxin active on Vero and HeLa cells, a cytolethal distending toxin, a shiga-like toxin, a hemolytic toxin, and a hepatotoxin have all been documented. Their role in disease remains unclear (Griffiths and Park, 1990; Ketley, 1995, 1997, Wassenaar, 1997).

C. jejuni and *C. coli* are susceptible to a variety of antimicrobial agents including macrolides, fluoroquinolones, aminoglycosides, chloramphenicol, and tetracycline (Nachamkin, 1995). Eryth-

romycin is the drug of choice for treating *C. jejuni* gastrointestinal infections, with ciprofloxacin as an alternative. However, considerable percentages of *C. coli* strains are resistant to erythromycin and emergence of fluoroquinolone resistance has been reported.

Enrichment and Isolation Procedures

Isolation of *Campylobacter* species can be accomplished by two methods. The first involves filtration of the cells through membrane filters with a pore size of 0.45, 0.65, or 0.8 μm using a nonselective agar medium or broth medium. *Campylobacter* cells are small and highly motile and can penetrate the filter. All agar plates or broth cultures must be incubated in a microaerobic atmosphere preferably containing both CO_2 and H_2. Commercial products are available for establishing microaerobic environments. Microaerobic atmospheres without hydrogen will not allow growth of some *Campylobacter* species on commonly used agar bases.

The second method for isolating campylobacters is the use of selective agar media. A variety of different selective media has been described, some using blood agar, others a blood-free agar base as basal medium (Goossens et al., 1989; Griffiths and Park, 1990; Aspinall et al., 1993; Corry et al., 1995). However, none of these selective supplements supports growth of all of the *Campylobacter* species. Selective media reported to be suitable for the isolation of all thermophilic campylobacters including *C. upsaliensis* were reported by Burnens and Nicolet (1992) and Aspinall et al. (1996).

Incubation of inoculated media at 42–43°C will increase selectivity by the elimination or inhibition of many, but not all, other intestinal organisms and is particularly useful for the isolation of the thermotolerant campylobacters. It will, however, inhibit growth of some other *Campylobacter* species.

There is no gold standard for the routine isolation of all *Campylobacter* species. Simultaneous application of a microaerobic atmosphere containing hydrogen with a filtration method and a selective base is methodologically the optimal solution. However, *C. jejuni* and *C. coli*, the predominant species in human infection, can be readily grown in a microaerobic atmosphere on selective media without the necessity of using hydrogen. In order to evaluate the presence of other, less common species, appropriate culture conditions need to be applied.

Maintenance Procedures

Stock cultures of *Campylobacter* species can be maintained under microaerobic conditions by weekly transfer onto common blood agar bases. Addition of blood to media may increase survival. Cultures may be stored for many years by lyophilization, freezing at 80°C, or in liquid nitrogen. Cryoprotective agents such as 10% glycerol or DMSO should be added to cultures before freezing, and heavy cell concentrations should be used.

Differentiation of the genus *Campylobacter* from other genera

Classical biochemical differentiation of the genus *Campylobacter* from related genera such as *Arcobacter* and *Helicobacter* is primarily achieved via the identification of the individual species. However, in general, campylobacters can be differentiated from arcobacters by the lower optimal growth temperatures (25–30°C compared to 30–42°C) and the aerotolerance of arcobacters. Analysis of respiratory quinones enables a clear differentiation of *Campylobacter* strains from *Arcobacter* or *Helicobacter* strains but is of limited value in a routine diagnostic laboratory.

Taxonomic Comments

Since the creation of *Campylobacter* as a genus in 1963, a variety of Gram-negative, microaerobic to anaerobic, asaccharolytic, and oxidase-positive bacteria have been included in the genus. Phylogenetic work based on ribosomal RNA gene sequence analysis or hybridization experiments revealed within this ill-defined genus the presence of three independent subdivisions, each of which were subsequently given separate genus rank (Lau et al., 1987; Paster and Dewhirst, 1988; Thompson et al., 1988; Goodwin et al., 1989a; Vandamme et al., 1991a). The name *Campylobacter* was preserved for the lineage containing *C. fetus*, the type species. The genus *Arcobacter* was proposed to accommodate *C. nitrofigilis* and *C. cryaerophilus* and, later, *C. butzleri*, while the genus *Helicobacter* was proposed for *C. pylori* and *C. mustelae*, and, subsequently, *C. cinaedi* and *C. fennelliae*. In addition, several so-called free-living campylobacters (Laanbroek et al., 1977; Wolfe and Pfennig, 1977) were found to constitute a separate fourth branch and were later classified into the genus *Sulfurospirillum* (Schumacher et al., 1992). Since the 1991 revision of its taxonomy and nomenclature, the classification of the genus *Campylobacter* is primarily phylogeny based. It should be emphasized that this phylogeny-driven taxonomy unified species with extremely different cellular morphologies and a range in DNA base ratio that exceeds that of most well-defined genera. Although the present classification has been generally accepted, these anomalies remain unexplained.

There are taxonomic problems at the species and infraspecific level. The name *C. sputorum* subsp. *mucosalis* was validly published but subsequent DNA–DNA hybridization and 16S rRNA gene sequence analysis demonstrated that the more recent classification of this organism as a separate species, *C. mucosalis*, is correct (Roop et al., 1985a; Thompson et al., 1988). Also, although the names *C. sputorum* subsp. *sputorum* and *C. sputorum* subsp. *bubulus* have standing in nomenclature, recent taxonomic analyses demonstrated that it is more appropriate to abandon this subspecies classification and to consider both taxa as a single biovar: *C. sputorum* biovar sputorum. The organism previously known as *"Campylobacter fecalis"*, and a newly described taxon, represent two additional biovars of *C. sputorum* (biovar faecalis and biovar paraureolyticus, respectively) (On et al., 1998).

Another problem concerns the taxonomic position of phenotypically unusual thermophilic campylobacters referred to as nalidixic acid-sensitive campylobacters, urease-positive thermophilic campylobacters, and others (Endtz et al., 1997). One dimensional whole-cell protein electrophoresis (Owen et al., 1988; Vandamme et al., 1991b), rRNA gene sequence analysis (Alderton et al., 1995), and semiquantitative DNA–DNA hybridization (Mégraud et al., 1988) indicated that these taxa are closely related to, or belong to, *C. lari*, and these strains have been referred to as *C. lari* variants. Quantitative DNA–DNA hybridization experiments between *C. lari* and a reference strain of the urease-positive thermophilic *Campylobacter* group proved that it indeed belonged to *C. lari* (Vandamme et al., 1997c). Subsequent work reported by Endtz et al. (1997) described a striking heterogeneity among and within the different groups of *C. lari* variants. The exact relationships between genuine *C. lari* strains and the various biochemical variants and protein electrophoretic subtypes should be explored further by means of DNA–DNA hybridization experiments.

In addition, the separation of *C. jejuni* subsp. *jejuni* and *C. coli* remains an important taxonomic problem. These taxa are re-

markably similar by virtue of their overall phenotype and genotype and are often found in the same ecologic and pathologic niches. The most reliable and commonly used test is the hippurate hydrolysis test done according to the method of Hwang and Ederer (1975) as described by Harvey (1980), in which *C. coli* is negative. However, some strains of *C. jejuni* subsp. *jejuni* also give a negative result. Additional useful tests are hydrogen sulfide production in triple sugar iron agar and growth on a minimal medium (On et al., 1996). In contrast with *C. jejuni* subsp. *jejuni*, *C. coli* usually utilizes propionate when a commercial identification system (API Campy, bioMérieux, France) is used (Occhialini et al., 1996). Growth in 8% glucose and brilliant green media are not reliable traits for species identification (Skirrow and Benjamin, 1980). The complexity of this taxonomic area has been emphasized by data showing that strains first described as *C. hyoilei* (associated with porcine proliferative enteritis) are, in fact, *C. coli* (Vandamme et al., 1997c), despite a higher 16S rRNA gene sequence similarity to *C. jejuni* (Alderton et al., 1995). Moreover, the description of strains that closely resemble *C. coli*, yet are genotypically more divergent from the type strain (60% DNA–DNA relatedness) (Morris et al., 1985) than is usual, further emphasizes the problems associated with the taxonomy of the "thermotolerant campylobacters". There is a need for better genotypic and phenotypic markers to further investigate relationships among members of this group. Further studies are required to evaluate the taxonomic (and indeed clinical) significance of both genomically divergent *C. coli*-like strains (Morris et al., 1985), and pig isolates that may be referred to as a *"hyoilei"* variant of *C. coli* (Vandamme et al., 1997c).

The organisms listed in the "Other Organisms" section in the first edition of *Bergey's Manual of Systematic Bacteriology* have all been formally classified. *"Campylobacter fecalis"* is a distinct biovar of *C. sputorum*. The nitrogen-fixing organisms from salt marsh plants (McClung and Patriquin, 1980) and the aerotolerant campylobacters (Neill et al., 1985) are now classified as *Arcobacter* species (Vandamme et al., 1991a). "*Spirillum* 5175" and the free-living organism described by Laanbroek et al. (1977) are classified in the genus *Sulfurospirillum* (Schumacher et al., 1992).

Acknowledgments

Floyd E. Dewhirst and Bruce J. Paster were supported by NIH grants DE-11443 and DE10374. We thank H.G. Trüper for clarifying the etymology of several *Campylobacter* taxa.

Differentiation of the species of the genus *Campylobacter*

Biochemical characteristics useful in distinguishing the various species of the genus *Campylobacter* are listed in Table BXII.ε.1. Additional descriptive characteristics are given in Table BXII.ε.2.

A variety of different methods has been applied for the identification of *Campylobacter* species; these methods have been recently reviewed by On (1996). Several authors studied the suitability of cellular fatty acid analysis for the differentiation and identification of campylobacters (reviewed by Vandamme and Goossens, 1992). Gas–liquid chromatography groups of *Campylobacter* species were defined by Lambert et al. (1987) and Goodwin et al. (1989b). Several of these gas–liquid chromatography groups consisted of more than one species, and several species have strains in different GLC groups. Additional phenotypic tests were often required for identification to the species level.

DNA probe- and PCR-based identification assays have been described for *C. fetus* (Ezaki et al., 1988; Chevrier et al., 1989; Wesley et al., 1991; Bastyns et al., 1994; Blom et al., 1995; Eaglesome et al., 1995; Hum et al., 1997); *C. hyointestinalis* (Chevrier et al., 1989; Gebhart et al., 1989; Wesley et al., 1991; Bastyns et al., 1994); *C. mucosalis* (Gebhart et al., 1989; Bastyns et al., 1994); *C. concisus* (Bastyns et al., 1995b); *C. sputorum* (Bastyns et al., 1994); *C. jejuni* (Stucki et al. 1995; Occhialini et al., 1996; Day et al., 1997; Gonzalez et al., 1997a; Linton et al., 1997; Vandamme et al., 1997c; van Doorn et al., 1997); *C. coli* (Gonzalez et al., 1997a; Linton et al., 1997; Vandamme et al., 1997c; van Doorn et al., 1997); *C. lari* (Linton et al. 1996; Oyarzabal et al., 1997; van Doorn et al., 1997); *C. upsaliensis* (Lawson et al., 1997; van Doorn et al., 1997); and *C. helveticus* (Stanley et al., 1992; Lawson et al., 1997). Broad-spectrum molecular identification schemata based on restriction fragment analysis of PCR amplicons derived from 16S (Cardarelli-Leite et al., 1996) and 23S (Hurtado and Owen, 1997a) rRNA genes have also been described.

List of species of the genus Campylobacter

1. **Campylobacter fetus** (Smith and Taylor 1919) Sebald and Véron 1963, 907^{AL} (*Vibrio fetus* Smith and Taylor 1919, 301.) *fe'tus*. L. masc. n. *fetus* fruit; L. gen. masc. n. *fetus* of a fetus.

Slender curved rods that are 0.2–0.3 × 1.5–5 μm. They appear comma-, S-, and gull-shaped. The ends of the cells are pointed. Loosely wound spiral filaments up to 8 μm long appear in old cultures. Spherical or coccoid forms are also found in old cultures especially when grown on agar plates.

Very actively motile with a characteristic darting and corkscrewlike motion. Motility and rotation of the cells are so rapid the curvature of the cells may be overlooked. Best observed with a phase-contrast microscope.

Several types of colonies are found on agar on primary isolation (Bryner et al., 1962). Smooth colonies, the most frequently found, are small, 0.5 mm in diameter, round, slightly raised, smooth, colorless, and slightly translucent. "Cut-glass" colonies are 1 mm in diameter, round, raised, translucent, and granular with reflecting facets. Rough colonies are rare and similar to smooth colonies with the exception of being granular and more opaque. Mucoid colonies are similar to smooth and cut-glass colonies but are

[a]Symbols: +, 95–100% strains positive; −, 0–11% strains positive; V, test result varies between defined infrasubspecific taxa (see text for details); F, 14–50% strains positive; M, 60–93% strains positive; I, irreproducible. All data are based on reactions obtained by using recommended, standardized procedures (On and Holmes 1991, 1992, 1995).

viscid. On primary isolation, colonies sometimes occur as a thin veil of confluent growth that is translucent and a very light gray or tan color. Colonies on blood agar are nonhemolytic, round, 1 mm in diameter, smooth, raised, convex, and grayish white in appearance. Strains will grow on media containing 1.0–1.5% ox-bile and at 30°C, but not on media containing 0.04% triphenyl-tetrazolium chloride. Most strains are tolerant to 0.032% methyl orange and 0.1% sodium deoxycholate.

Although the two subspecies of *C. fetus* are associated with distinct diseases in animals, their differentiation is not straightforward. Classical biochemical tests useful for the differentiation of these taxa are tolerance to glycine and the ability to produce hydrogen sulfide. Whole-cell protein

electrophoresis does not separate the two taxa (Vandamme et al., 1991b). Salama et al. (1992a) reported the genomes of *C. fetus* subsp. *fetus* strains to be smaller (1.1 Mb) than those of *C. fetus* subsp. *venerealis* strains (1.3–1.5 MB). General differences between the *Sma*I-based macrorestriction profiles of the two subspecies have also been noted (Hum et al., 1997). A PCR-based assay designed for species and subspecies identification was 98% specific (Hum et al., 1997).

Erythromycin, ampicillin, or third-generation cephalosporins are usually effective against *C. fetus* infections (Neuzil et al., 1994). Aminoglycosides, ampicillin, and chloramphenicol have been successfully used to treat central nervous system or other serious infections caused by *C. fetus*.

The mol% G + C of the DNA is: 32–36 (T_m).

Type strain: CIP 5396, ATCC 27324, CCUG 6823, DSM 5361, LMG 6442, NCTC 10842.

GenBank accession number (16S rRNA): LO4314, M65012.

a. **Campylobacter fetus** *subsp.* **fetus** Véron and Chatelain 1973, 126[AL] (*Vibrio fetus* biovar intestinalis Florent 1959, 955; *Vibrio foetusovis* Buxton 1929, 47; *Campylobacter fetus* subsp. *intestinalis* Smibert 1974, 209.)

Morphology and characteristics as for species except as noted. Intermediate-sized spirals with an average wavelength of 1.8 μm and an average amplitude of 0.55 μm (Karmali et al., 1981a). Several types of colonies are found on agar on primary isolation (Bryner et al., 1962). Smooth colonies are 1 mm in diameter, colorless to slightly cream colored. Rough colonies are small, round, finely granular, opaque and white to cream or tan colored. They are 1–2 mm in diameter. "Cut-glass" colonies do not develop in primary cultures. Smooth colonies incubated for 6–8 days become mucoid. Upon subculture, smooth cut-glass and rough cut-glass colonies appear, as well as smooth colonies. On primary isolation, colonies are frequently low, flat, grayish to tan colored, and translucent with an irregular edge. They spread along the direction of the streak and coalesce. They may also form a thin veil of confluent growth on agar plates. Colonies on blood agar are nonhemolytic, round, 1–2 mm in diameter, smooth, convex, and grayish white or light tan colored. Grow on media containing 0.05% safranin and 64 mg/l cefoperazone.

Pathogenic. Cause of abortion in sheep and sporadic abortion in cattle, as well as a cause of human blood and, occasionally, gastrointestinal infections. Transmitted orally. Isolated from the placentas and stomach content of fetuses from aborted sheep and cattle and from the blood, intestinal content, and bile of infected ewes and cattle. Isolated from blood, spinal fluid, aborted fetuses, and abscesses from most parts of the body of humans. This organism will grow in the intestinal tract and gallbladder of man and animals (Bryner et al., 1964).

The mol% G + C of the DNA is: 33–36 (T_m).

Type strain: CIP 5396, ATCC 27324, CCUG 6823, DSM 5361, LMG 6442, NCTC 10842.

GenBank accession number (16S rRNA): LO4314, M65012.

b. **Campylobacter fetus** *subsp.* **venerealis** (Florent 1959) Véron and Chatelain 1973, 126[AL] (*Vibrio fetus* biovar venerealis Florent 1959, 955; *Campylobacter fetus* subsp. *fetus* Smibert 1974, 209.)

ve.ne′re.al.is. L. *venereus* from Venus goddess of love; L. adj. *veneral* L. gen. n. *venerealis* of Venus, goddess of love.

Morphology and characteristics are for species except as noted. Large spirals with an average wavelength of 2.43 μm and an average amplitude of 0.73 μm (Karmali et al., 1981a). Approximately 67% and 7% of strains will grow on 0.05% safranin- and 64 mg/l cefoperazone-containing media (On et al., 1996), respectively.

Pathogenic. A cause of abortion and infertility in cattle. Transmitted venereally. Found in the vaginal mucus of infected cows, the semen and prepuce of bulls, and in the placenta and tissues of aborted bovine fetuses. Pathogenic for cattle, guinea pigs, hamsters, and embryonated chicken eggs. Rarely isolated from human blood. Not pathogenic for rabbits, mice, or rats when injected intraperitoneally. Will not multiply in the intestinal tract of man and animals (Bryner et al., 1964).

The mol% G + C of the DNA is: 33–36 (T_m).

Type strain: CIP 68.29, ATCC 19483, CCUG 538, LMG 6443, NCTC 10354.

GenBank accession number (16S rRNA): L14633, M65011.

2. **Campylobacter coli** (Doyle 1948) Véron and Chatalain 1973, 127[AL] (*Vibrio coli* Doyle 1948, 50; *Campylobacter hyoilei* Alderton, Korolik, Coloe, Dewhirst and Paster 1995, 65.)

co′li. Gr. n. *colon* large intestine, colon; M.L. gen. n. *coli* of the colon.

Small, tightly coiled spiral, S-shaped or curved cells, 0.2–0.3 × 1.5–5.0 μm that transform rapidly to coccoid forms with age, or exposure to toxic concentrations of oxygen (Ng et al., 1985; Moran and Upton, 1987). Colonies are round, 1–2 mm in diameter, raised, convex, smooth, and glistening. On moist media, colonies are flat, grayish, and spread in the direction of the streak. Most, but not all strains are nonhemolytic. As with *C. jejuni*, the hemolytic activity (where noted) is usually cell-associated, with a possible secreted component also involved (Wassenaar, 1997). Blood enhances, but is not essential for, culture. Strains grow on solid media containing 1.0–1.5% ox-bile, 0.02% safranin, 32 mg/l cephalothin, and 0.04% triphenyl-tetrazolium chloride. Reduction of the latter substrate is also observed. Most (~76%) strains are resistant to 100 U/l 5-fluorouracil. As with *C. jejuni* subsp. *jejuni*, the proportion of strains that are resistant to the antibiotics nalidixic acid, tetracycline, chloramphenicol, kanamycin, and erythromycin (and related compounds) may significantly vary. However, in comparison with *C. jejuni*, a greater percentage of *C. coli* strains exhibit resistance to erythromycin. The genetic mechanisms determining these traits have been reviewed by Taylor (1992a, b) and Taylor and Courvalin (1988); several (tetracycline, chloramphenicol, kanamycin) are known to be plasmid borne. Aarestrup et al. (1997) showed that >90% of isolates from humans, pigs, and broiler chickens were sensitive to ampicillin (16 mg/l), apramycin (4 mg/l), carbadox (4 mg/l), chloramphenicol (8 mg/l), colistin (16 mg/l), enrofloxacin (16 mg/l), gentamicin (1 mg/l), nalidixic acid (128 mg/l), neomycin (4 mg/l), olaquindox (8 mg/l), spectinomycin (16 mg/l), spiramycin (128 mg/l), and tetracycline (2 mg/l). Aarestrup et al. (1997) determined that

13.8% and 61.7% of isolates showed resistance to streptomycin and tylosin, respectively, beyond the maximum minimal inhibitory concentration (MIC: 128 mg/l) used. *In vitro* activities of 47 antimicrobial agents toward *C. coli* were determined by Gebhart et al. (1985b).

As with *C. jejuni*, plasmid carriage in *C. coli* demonstrates considerable variation by virtue of plasmid presence in a given population, number, and size range (Tenover et al., 1985). It has been noted that conjugative plasmids conferring resistance to tetracycline, kanamycin, and chloramphenicol are more common in *C. coli* than in *C. jejuni* (Taylor, 1992b).

Differentiating *C. coli* from *C. jejuni* subsp. *jejuni* is difficult. The most common biochemical test used for this purpose is hippurate hydrolysis, for which *C. coli* is negative. However, some strains of *C. jejuni* subsp. *jejuni* also give a negative result. Additional tests that are of use were discussed above.

The taxonomic position of 11 isolates from lesions of proliferative enteritis in pigs was studied by Alderton et al. (1995), who considered the strains to represent a species closely related to both *C. coli* and *C. jejuni*. These authors subsequently proposed the name *Campylobacter hyoilei* for these strains. However, the taxonomic position of *C. hyoilei* was reevaluated by Vandamme et al. (1997c) using a range of phenotypic and genotypic methods, and, crucially, a classical quantitative DNA–DNA hybridization method. These data showed *C. hyoilei* to be indistinguishable from *C. coli*. Vandamme et al. (1997c) proposed that the two species be regarded as synonymous, with *C. coli* taking nomenclatural precedence. It was nonetheless noted that strains originally described as *C. hyoilei* may represent a variant of *C. coli* that is highly adapted for the porcine enteric tract, with pathologic consequences for the animal.

Pathogenic. Causes diarrhea, septicemia, and occasionally abortion in humans. May cause diarrhea in pigs and monkeys and abortion in rodents. Has been associated with hepatitis in certain bird species. Certain strains have been associated with proliferative enteritis in pigs.

The mol% G + C of the DNA is: 31–35 (T_m).

Type strain: CIP 7080, ATCC 33559, CCUG 11283, LMG 8847, NCTC 11366.

GenBank accession number (16S rRNA): L04312, M59073, L19738.

3. **Campylobacter concisus** Tanner, Badger, Lai, Listgarten, Visconti and Socransky 1981, 442[VP]
con.ci′sus. L. part. adj. *concisus* brief, concise.

Cells are small and curved, 0.5 × 4 μm, with rounded ends. Rapid darting motility by means of a single polar flagellum. A membrane-like polar cap occurs at the ends of the cells. Colonies are convex, translucent, 1 mm in diameter, with entire edges. The agar is not pitted by the colonies. Does not grow microaerobically on common agar bases in an atmosphere without hydrogen. Will not grow in semisolid medium (0.16% agar), in air, or in an atmosphere containing $O_2/CO_2/N_2$ (5:10:85). Anaerobic growth occurs with formate and fumarate in the medium. Formate is oxidized to hydrogen and CO_2; and fumarate is reduced to succinate, which accumulates in the medium. Growth is stimulated by nitrate, formate, and fumarate. End products of metabolism when grown in a medium with formate and fumarate are acetate, succinate, and H_2. Strains do not grow on MacConkey agar or on media containing 3.5% NaCl, 32 mg/l cephalothin, 64 mg/l cefoperazone, or 0.04% triphenyl-tetrazolium chloride. Most strains (70–80%) produce alkaline phosphatase and grow on media containing 0.032% methyl orange and 0.05% sodium fluoride. A few strains (14–29%) grow in the presence of 0.01% Janus green and 0.005% basic fuchsin.

Minimum inhibitory concentrations of antibiotics are (μg/ml): bacitracin, 128; chloramphenicol, 4.0; clindamycin, 24; colistin, 0.5–1.0; erythromycin, 4.0; gentamicin, 24; kanamycin, 12; metronidazole, 0.5–2.0; minocycline, 2; nalidixic acid, 64–128; neomycin, 16–32; penicillin, 0.5–4.0; polymyxin, 0.25–1.0; rifampin, 16–64; streptomycin, 12; tetracycline, 12; and vancomycin, 128. *C. concisus* strains were shown to be chemotactic toward formate (Paster and Gibbons, 1986). Whole-cell protein electrophoresis and DNA–DNA hybridization experiments (Vandamme et al., 1989; Van Etterijk et al., 1996) revealed that this is a heterogeneous species comprising many protein electrophoretic and several genotypic subgroups. The species is also phenotypically diverse (On et al., 1996), making definitive identification difficult. Found in the gingival crevices of humans with gingivitis, periodontitis, and periodontosis; in normal and diarrheic feces of humans, in human blood, and in human stomach and esophagus specimens.

The mol% G + C of the DNA is: 37–41 (T_m).

Type strain: FDC 484, ATCC 33237, CCUG 13144, LMG 7788, NCTC 11485.

GenBank accession number (16S rRNA): L04322.

4. **Campylobacter curvus** (Tanner, Listgarten and Ebersole 1984) Vandamme, Falsen, Rossau, Hoste, Segers, Tytgat and De Ley 1991a, 98[VP] (*Wolinella curva* Tanner, Listgarten and Ebersole 1984, 279.)
curv′us. L. adj. *curvus* curved.

Cells are small and curved, 0.5–1 × 2–6 μm, with rounded or tapered ends. Helical or straight cells also occur. A membrane-like polar cap occurs at the ends of the cells. Rapid darting motility. Motile by means of a single polar flagellum or bipolar flagella. Translucent colonies are produced on blood agar bases. Different colony types are observed: small pinpoint colonies, 1 mm in diameter or spreading colonies up to 5 mm in diameter. Agar pitting is medium dependent; this trait was not seen in anaerobic, 3-d-old cultures on 5% blood agar (On et al., 1996).

Does not grow microaerobically on common agar bases in an atmosphere without hydrogen. Will not grow in air, in a CO_2-enriched atmosphere, or in an atmosphere containing $O_2/CO_2/N_2$ (5:10:85) on common agar bases. Anaerobic growth occurs with formate and fumarate in the medium. Hydrogen and formate are used as energy sources. Formate is oxidized to hydrogen and CO_2; and fumarate is reduced to succinate. Fumarate, nitrate, aspartate, asparagine, and malate serve as electron acceptors. Membrane-bound cytochrome *b*, cytochrome *c*, and CO-binding cytochrome *c*, and soluble cytochrome *c* and CO-binding cytochrome *c* are present. Strains grow in the presence of 0.005% basic fuchsin and 0.04% triphenyl-tetrazolium chloride; reduction of the latter is concurrently seen in many strains (60%). Most strains (80%) will grow on media containing 64 mg/l cefoperazone, 0.1% potassium perman-

ganate, and 0.01% Janus green. Alkaline phosphatase activity has been detected in 40% of strains.

Minimum inhibitory concentrations of antibiotics are (µg/ml): bacitracin, >128; chloramphenicol, 2–4; clindamycin, 0.5–1; colistin, 4; erythromycin, 2; gentamicin, 2; kanamycin, 4–8; metronidazole, 1–2; minocycline, 2–4; nalidixic acid, 64–128; neomycin, 4–8; penicillin, 32; polymyxin B, 8; rifampin, 128 to >128; streptomycin, 2; tetracycline, 1; and vancomycin, >128. Strains were isolated from lesions in human oral cavities, from a blood culture, peritoneal fluid, and from normal and diarrheic feces of humans.

The mol% G + C of the DNA is: 43–47 (T_m).

Type strain: VPI 9584, ATCC 35224, CCUG 13146, DSM 6644, LMG 7609.

GenBank accession number (16S rRNA): L04313.

5. **Campylobacter gracilis** (Tanner, Badger, Lai, Listgarten, Visconti and Socransky 1981) Vandamme, Daneshvar, Dewhirst, Paster, Kersters, Goossens and Moss 1995a, 151[VP] (*Bacteroides gracilis* Tanner, Badger, Lai, Listgarten, Visconti and Socransky 1981, 442.)
gra' cil.is. L. adj. *gracilis* slim, slender, thin.

Cells are small and straight, 0.4 × 4–6 µm, with rounded or tapered ends. Nonmotile. Intracytoplasmic, electron-dense inclusions, some membrane-bound, approximately 40 nm in diameter have been observed. Translucent colonies are produced on blood agar bases. Different colony types are observed: small pinpoint colonies, 1 mm in diameter or spreading colonies up to 5 mm in diameter. Agar pitting is medium dependent; this trait was not seen in anaerobic, 3-d-old cultures on 5% blood agar (On et al., 1996).

Optimal growth in anaerobic conditions. Does not grow microaerobically on common agar bases in an atmosphere without hydrogen. Will not grow in air, in a CO_2-enriched atmosphere, or in an atmosphere containing $O_2/CO_2/N_2$ (5:10:85) on common agar bases. Anaerobic growth occurs with formate and fumarate in the medium. Hydrogen and formate are used as energy sources. Formate is oxidized to hydrogen and CO_2, and fumarate is reduced to succinate. Fumarate, nitrate, nitrite, neutral red, benzyl viologen aspartate, asparagine, and malate serve as electron acceptors. Membrane-bound cytochrome *b*, cytochrome *c*, and CO-binding cytochrome *c*, and soluble cytochrome *c* and CO-binding cytochrome *c* are present. Strains will grow in the presence of 0.1% potassium permanganate and 0.05% basic fuchsin. Strains do not grow in the presence of 0.04% triphenyl-tetrazolium chloride, or 64 mg/l cefoperazone. A few strains (14%) grow on 0.01% Janus green medium. Alkaline phosphatase activity is not detected.

C. gracilis is the only oxidase-negative *Campylobacter* species. However, the pattern of cytochromes found in *C. gracilis* resembles that reported for other *Campylobacter* species in that it possesses cytochromes *b, c*, and CO-binding cytochrome *c* and does not possess detectable cytochromes *a* and *d*. Oxidase activity, as determined in the Kovacs test, is associated with cytochrome *c* and oxygen respiration, which is present in all *Campylobacter* species. Possible explanations for the failure to detect oxidase activity may be an incapability of the reagent to penetrate the cellular membranes, or the presence of a low-potential cytochrome *c* that cannot oxidize this reagent.

A group of bile-resistant *C. gracilis*-like organisms was recently reclassified in a novel genus *Sutterella* (Wexler et al., 1996a). This taxon is phylogenetically distinct from the campylobacters. Cellular fatty acid analysis, differences in dehydrogenase enzymes mobilities, and higher resistance to antimicrobial agents are useful to distinguish *Sutterella* strains from *C. gracilis*.

Minimum inhibitory concentrations of antibiotics are (µg/ml): bacitracin, >128; chloramphenicol, 2–8; clindamycin, 0.25–0.5; colistin, 0.5–1; erythromycin, 1–2; gentamicin, 2–4; kanamycin, <0.50–2; metronidazole, 0.12–1; minocycline, <0.5–2; nalidixic acid, 16–128; neomycin, 16–32; penicillin, 1–32; polymyxin B, <0.25–1; rifampin, 4–32; streptomycin, 1–2; tetracycline, 1–8; vancomycin, >128, amoxicillin/clavulanate, 0.06–0.5; cefoxitin, 1–16; ceftizoxime, 0.25–1; ceftriaxone, 0.016–0.25; meropenem, 0.03; piperacillin, 2–26; piperacillin/tazobactam, 0.016–4; and ticarcillin/clavulanate, 0.016. In general, *C. gracilis* is very susceptible to antimicrobial agents active against anaerobic bacteria.

Strains have been isolated from gingival crevices and from visceral, head, and neck infections; in soft tissue abscesses; pneumonia; empyema; and an ischial wound in humans. The association of *C. gracilis* with serious deep tissue infection, coupled with a high frequency of antibiotic resistance, suggests that its pathogenic role might be underestimated.

The mol% G + C of the DNA is: 44–46 (T_m).

Type strain: FDC 1084, ATCC 33236, CCUG 27720.

GenBank accession number (16S rRNA): L04320.

6. **Campylobacter helveticus** Stanley, Burnens, Linton, On, Costas and Owen 1993a, 398[VP] (Effective publication: Stanley, Burnens, Linton, On, Costas and Owen 1992, 2302.)
hel.ve' ti.cus. L. adj. *helveticus* referring to Swiss, after the country of first isolation.

Cells are small curved, S-shaped, or helical rods, 0.2 × 1.5–3 µm, with rounded ends. Rapid darting motility. Motile by means of single bipolar flagella. Translucent, flat colonies, pinpoint to 0.5 mm in diameter are produced on blood agar bases after 48 h. Swarming may occur on moist agar surfaces. Grows microaerobically in the absence of hydrogen. Will not grow in air or in a CO_2-enriched atmosphere. The species is phenotypically, genotypically, and phylogenetically similar to *C. upsaliensis*, also a common inhabitant of domestic pets. *C. helveticus* grows on media containing 1.0–1.5% ox-bile and 100 U/l 5-fluorouracil, but not on potato starch or MacConkey agars. Sensitive to 32 mg/l cephalothin; some strains (22–44%) resistant to 64 mg/l cefoperazone.

Strains have been isolated from feces of diarrheic and asymptomatic domestic cats, more rarely from dogs. Pathogenicity is unknown.

The mol% G + C of the DNA is: 34 (T_m).

Type strain: ATCC 51209, CCUG 30682, LMG 12638, NCTC 12470.

GenBank accession number (16S rRNA): U03022.

7. **Campylobacter hominis** Lawson, On, Logan and Stanley 2001, 658[VP]
hom.in' is. L. gen. n. *hominis* of man, from which the bacterium was first isolated.

Cells are small and straight, 0.25–0.5 × 0.5–1.8 µm (after 10 days of incubation) with blunt ends. Nonmotile. Some isolates produce irregular fimbria-like structures which are 4–8 nm wide and >1.0 µm long. Gray pinpoint colonies may be convex and entire or spreading and irregular on blood agar base media. No agar pitting is observed. Optimal growth in anaerobic conditions at 37°C. No growth in anaerobiosis at room temperature, 25°C, or 42°C. Poor growth, if any, under microaerobiosis with 2% hydrogen. Will not grow in air, in a CO_2-enriched atmosphere, or in an atmosphere containing 5% O_2, 10% CO_2 and 85% N_2 on common agar bases. Strains grow in the presence of 0.1% sodium fluoride, but not in the presence of 0.04% triphenyltetrazolium chloride. Alkaline phosphatase activity has not been detected. Strains have been isolated from asymptomatic human feces. Pathogenicity, if any, is unknown.

The mol% G + C of the DNA is: 32–33 (T_m).

Type strain: CH001A, LMG 19568, NCTC 13146.

GenBank accession number (16S rRNA): AJ251584.

8. **Campylobacter hyointestinalis** Gebhart, Edmonds, Ward, Kurtz and Brenner 1985a, 535[VP] (Effective publication: Gebhart, Edmonds, Ward, Kurtz and Brenner 1985b, 718.)
hy.o.in.tes' tin.al.is. Gr. n. *hys, hyos* a hog; M.L. adj. *intestinalis* pertaining to the intestines; M.L. gen. n. *hyointestinalis* of a hog's intestine.

Cells are loosely spiraled, curved rods with characteristic darting motility due to a single polar flagellum. Occasionally, cells with two flagella at one pole have been observed. Cells are 0.2–0.5 × 1.2–2.5 µm. Filamentous forms, not coccoid bodies, are seen in old cultures. After 48 h of incubation, colonies are 1.5–2.0 mm in diameter, circular, and convex and do not swarm on moist media; they typically have a dirty yellowish color and are slightly mucoid.

When grown on common blood agar bases, only some strains grow microaerobically without hydrogen. All strains grow microaerobically in the presence of hydrogen. Many strains are weakly α-hemolytic; this is normally accompanied by a greenish hue around the bacterial growth. Strains grow in the presence of 1.0% ox-bile and 0.032% methyl orange. Most strains (~85%) are sensitive to cephalothin (32 mg/l).

Whole-cell protein electrophoretic analysis has revealed considerable protein electrophoretic diversity within this species and it has been suggested that this diversity offers potential for typing studies (Vandamme et al., 1990, 1991b; On et al., 1993). In addition, pulsed-field gel electrophoresis of large genomic fragments was shown to be a useful typing method (Salama et al., 1992b; On and Vandamme, 1997). Plasmids of about 38 mDa and 1.6 mDa in size were reported in some strains by Boosinger et al. (1990). Selective media were developed by different researchers (reviewed by Ohya et al., 1988). On and Vandamme (1997) reported additional groups of *C. hyointestinalis*-like bacteria; the exact taxonomic status of the "subgroup 3" and "subgroup 4" strains is at present unknown.

Minimum inhibitory concentrations of antibiotics are (µg/ml): bacitracin, >128; chloramphenicol, 2–8; clindamycin, 0.25–0.5; colistin, 0.5–1; erythromycin, 1–2; gentamicin, 2–4; kanamycin, <0.5–2; metronidazole, 0.12–1; minocycline, <0.5–2; nalidixic acid, 16 to >128; neomycin, 16–32; penicillin, 1–32; polymyxin B, <0.25–1; rifampin, 4–32; streptomycin, 1–2; tetracycline, 1–8; vancomycin, >128, amoxicillin/clavulanate, 0.06–0.5; cefoxitin, 1–16; ceftizoxime, 0.25–1; ceftriaxone, 0.016–0.25; meropenem, 0.03; piperacillin, 2–26; piperacillin/tazobactam, 0.016–4; and ticarcillin/clavulanate, 0.016. *In vitro* activities of 47 antimicrobial agents toward *C. hyointestinalis* were determined by Gebhart et al. (1985b). Isolated from the intestines of pigs and hamsters, the stomach of pigs, and cattle, deer, and human feces. May be associated with porcine proliferative enteritis and diarrhea in animals and humans. Pathogenicity is not known.

The mol% G + C of the DNA is: 31–36 (T_m).

Type strain: 80-4577-4, ATCC 35217, CCUG 14169, LMG 7817, NCTC 11608.

GenBank accession number (16S rRNA): M65010, AF097689.

a. **Campylobacter hyointestinalis** *subsp.* **hyointestinalis** (Gebhart, Edmonds, Ward, Kurtz and Brenner 1985b) On, Bloch, Holmes, Hoste and Vandamme 1995, 773[VP] (*Campylobacter hyointestinalis* Gebhart, Edmonds, Ward, Kurtz and Brenner 1985b, 718.)

Morphology and characteristics as for species, except as noted. Strains grow in the presence of 0.01% Janus green. Most strains grow in the presence of 1.5% oxbile. Alkaline phosphatase activity has not been reported. Isolated from the intestines of pigs and hamsters, and cattle, deer, and human feces. May be associated with porcine proliferative enteritis and diarrhea in animals and humans. Pathogenicity is not known.

The mol% G + C of the DNA is: 33–36 (T_m).

Type strain: 80-4577-4, ATCC 35217, CCUG 14169, LMG 7817, NCTC 11608.

GenBank accession number (16S rRNA): M65010, AF097689.

b. **Campylobacter hyointestinalis** *subsp.* **lawsonii** On, Bloch, Holmes, Hoste and Vandamme 1995, 773[VP]
law.so' ni.i. N.L. gen. n. *lawsonii* of Lawson, in honor of Gordon H.K. Lawson, a bacteriologist at Edinburgh University whose studies on enteric disease in pigs led to the delineation of *Campylobacter mucosalis* and the unculturable bacterium *Lawsonia intracellularis.*

Cells are loosely spiraled, curved rods. Cells are 0.2 × 1.42 µm. Morphology and characteristics as for species, except as noted. Few (11%) strains can grow on 1.5% bile media. Alkaline phosphatase activity has been seen in ~22% of strains. 44% of strains can grow on 0.01% Janus green medium. Isolated from the stomach of pigs. Pathogenicity is not known.

The mol% G + C of the DNA is: 31–33 (T_m).

Type strain: CHY 5, CCUG 34538, LMG 14432, NCTC 12901.

GenBank accession number (16S rRNA): AF097685.

9. **Campylobacter jejuni** (Jones, Orcutt and Little 1931) Véron and Chatelain 1973, 128[AL] (*Vibrio jejuni* Jones, Orcutt and Little 1931, 861; *Vibrio hepaticus* Mathey and Rissberger 1964 1339; *Campylobacter fetus* subsp. *jejuni* Smibert 1974, 209.)
je.ju' ni. M.L. gen. neut. n. *jejuni* of the jejunum.

Small, tightly coiled spiral or S-shaped cells (average wavelength 1.12 µm and average amplitude of coils is 0.48 µm) which transform rapidly to coccoid forms with age, or exposure to toxic concentrations of oxygen (Ng et

al., 1985; Moran and Upton, 1987). Electron microscopic studies reveal a ring-shaped cellular form that may represent an intermediate form between spiral and coccoid cells (Ng et al., 1985). Two types of colonies may be observed (Smibert, 1965, 1969). The first has a low, flat, grayish, finely granular, and translucent appearance with an irregular edge, and a tendency to spread along the direction of the streak, and to swarm and coalesce. The second is round (1–2 mm diameter), raised, convex, smooth, shiny, with an entire, translucent edge and a darker, opaque center. Most strains are weakly hemolytic on blood agar (Arimi et al., 1990; On et al., 1996), but this characteristic may be affected by composition and pH of the base medium used, the gas composition of the atmosphere, and the period and temperature of incubation (Arimi et al. 1990; Misawa et al., 1995). Hemolytic activity has been reported for rabbit, human, cattle, sheep, goat, horse, and chicken blood (Misawa et al., 1995) and appears to be principally cell associated, although a secreted component may also be involved (see Wassenaar, 1997 for a detailed overview). All strains will grow in the presence of 1.0% ox-bile. No growth is observed at 25°C. Strains are motile by means of a single polar flagellum (at one or both ends of the cell) which seems to be an important virulence factor, necessary for colonization of the intestinal tract (Ketley, 1997). In addition, phase and antigenic variation of the flagellar protein may serve as a means of evading the immunogenic response of the host. Variation of the flagellin gene loci (*flaA* and *flaB*) may be detected by PCR-based methods and used in molecular epidemiological studies (Nachamkin et al., 1993; Ayling et al., 1996; Meinersmann et al., 1997). Recombination may affect the stability of the *flaA*-based methods and possibly acts as a mechanism by which the immunogenic repertoire of a given strain is increased (Harrington et al., 1997).

The mol% G + C of the DNA is: 28–33 (T_m).

Type strain: CIP 702, ATCC 33560, CCUG 11284, LMG 8841, NCTC 11351.

GenBank accession number (16S rRNA): L04315, M59298.

a. **Campylobacter jejuni** *subsp.* **jejuni** (Jones, Orcutt and Little 1931) Véron and Chatelain 1973, 128[AL] (*Vibrio jejuni* Jones, Orcutt and Little 1931, 861; *Vibrio hepaticus* Mathey and Rissberger 1964, 1339; *Campylobacter fetus* subsp. *jejuni* Smibert 1974, 209.)

Cell walls contain D-galactose only, D-galactose and D-glucose, or D-galactose, D-glucose, and D-mannose (Smibert, 1970). Strains grow on solid media containing 1.0–1.5% ox-bile, and 0.02% safranin. Reduction and tolerance of 0.04% triphenyl-tetrazolium chloride is observed in 90% of strains. Most (90–95% respectively) strains grow in the presence of 100 mg/l 5-fluorouracil and 32 mg/l cephalothin. Older literature reports most strains as being sensitive to 16 mg/l nalidixic acid (Karmali et al., 1981b) but increasing fluoroquinolone resistance has been observed and the proportion of resistant strains now varies significantly (Reina et al. 1994; Koenraad et al., 1995; Aarestrup et al., 1997). Similar observations of resistance to other quinolones (ciprofloxacin, enrofloxacin, norfloxacin, etc.) have also been reported. Resistance may be conferred by mutations in the target gene, *gyrA* (Piddock and Guant, 1996). Strains may also differ in their susceptibility to other antibiotics such as tetracycline, erythromycin, chloramphenicol, and kanamycin. The genetic mechanisms underlying these traits have been reviewed (Taylor and Courvalin, 1988; Taylor, 1992a, b). Aarestrup et al. (1997) showed that >90% of isolates from humans, cattle, chickens, and pigs were sensitive to ampicillin (16 mg/l), apramycin (2 mg/l), carbadox (0.5 mg/l), chloramphenicol (8 mg/l), colistin (16 mg/l), enrofloxacin (4 mg/l), erythromycin (4 mg/l), gentamicin (1 mg/l), nalidixic acid (32 mg/l), neomycin (1 mg/l), olaquindox (4 mg/l), spectinomycin (64 mg/l), spiramycin (8 mg/l), streptomycin (2 mg/l), tetracycline (1 mg/l), and tylosin (128 mg/l).

Two broad classes of antigens are recognized: heat-stable (HS) or somatic O-antigens, and heat-labile (HL) antigens. These form the basis of two recognized serotyping schemes, described by Penner et al. (1983) for HS antigens, and Lior et al. (1982) for HL antigens. The major component of the HS antigens is generally accepted as being lipopolysaccharide-based (Mills et al., 1992), although some workers have proposed that a capsule may be involved (Chart et al., 1996). The principal component of the HL antigen is traditionally believed to be the flagellar protein, although other somatic antigens appear to be involved in the recognition of HL-based serogroups (Taylor et al., 1988; Alm et al., 1991). However, *flaA* PCR-restriction fragment length polymorphism analysis showed limited correlation with HL serotyping suggesting that flagella may not be the major HL antigen (Mohran et al., 1996).

Considerable variation in the prevalence, number, and size of plasmids found in *C. jejuni* subsp. *jejuni* has been described. Between 19% (Austen and Trust, 1980) and 95% (Lee et al., 1994b) of strains may harbor 1–5 plasmids (Tenover et al., 1985), which range between 2.0 (Tenover et al., 1985) and 208 kb (Lee et al., 1994b) in size. Resistance to the antibiotics kanamycin, tetracycline, and chloramphenicol is often plasmid-mediated (Taylor, 1992b).

Pathogenic. Causes abortion in sheep; abortions in other animals, such as cattle and goats, have also been reported. May cause diarrhea in animals and has been associated with hepatitis in some bird species. In humans it is generally regarded as the most common bacterial cause of gastroenteritis worldwide; it also causes septicemia and abortion. Infection with certain strains of *C. jejuni* subsp. *jejuni* may be a predisposing factor to the development of the neurological disorders Guillain-Barré (GBS) (Kaldor and Speed, 1984; Nachamkin et al., 1998) and Miller-Fisher syndromes (MFS) (Roberts et al., 1987). Molecular mimicry is postulated as the mechanism for pathogenesis of these neuropathies; a trisaccharide moiety that resembles human gangliosides has been found in different HS serotypes recovered from GBS and MFS patients (Salloway et al., 1996). Strains are also found as normal intestinal flora of poultry and other bird species, cattle, sheep, pigs, goats, dogs, rabbits, and monkeys.

The mol% G + C of the DNA is: 30–33 (T_m).

Type strain: CIP 702, ATCC 33560, CCUG 11284, LMG 8841, NCTC 11351.

GenBank accession number (16S rRNA): L04315, M59298.

b. **Campylobacter jejuni** *subsp.* **doylei** Steele and Owen 1988, 316[VP]

doy.le′i. M.L. gen. n. *doylei* in honor of L.P. Doyle, an American veterinarian.

Cells may be spiral, S-shaped or, less frequently, straight rods. Cultures often demonstrate considerable pleomorphism that increases with age. Colonies are pinpoint to 1 mm diameter, grayish, smooth, glistening, and convex after 2–3 days growth on blood agar. Optimal growth temperature is 35–37°C; strains do not grow at 25°C and poorly, if at all, at 42°C. Reduction of, and tolerance to, 0.04% triphenyl-tetrazolium chloride observed in 40% of strains (On et al., 1996). Strains will not grow on solid media containing 0.02% safranin or 32 mg/l cephalothin. Principal tests differentiating this subspecies from *C. jejuni* subsp. *jejuni* are given in Table BXII.ε.1. These taxa can also be distinguished by numerical analysis of both whole-cell protein electrophoretograms (Vandamme et al., 1992a), and *Hae*III restriction digest patterns (Owen et al., 1985).

In disk susceptibility tests, all strains are susceptible to penicillin (2 U), erythromycin (15 µg), and tetracycline (10 µg). Most strains are inhibited by nalidixic acid (30 µg). Pathogenicity unknown; has been isolated from ulcerated gastric tissue, diarrhea, and blood cultures of humans, notably infants (Steele and Owen, 1988; Lastovica, 1996).

The mol% G + C of the DNA is: 28–31 (T_m).

Type strain: 093, CCUG 24567, LMG 8843, NCTC 11951.

GenBank accession number (16S rRNA): L14630.

10. **Campylobacter lanienae** Logan, Burnens, Linton, Lawson and Stanley 2000, 870[VP]

lan.i.en′ae. L. n. *laniena* abattoir, after place of work of human carriers from whom the bacterium was first isolated.

Cells are slender, slightly spiral rods with rounded ends and are 1.2–2.4 µm long. Characteristic darting motility due to a single bipolar flagellum. Pinpoint colonies are visible on blood agar media after three days of incubation at 37°C. The colonies are smooth, entire, and translucent and cause some greening of blood agar through alpha-hemolytic activity. Optimal growth in microaerobic conditions. Growth is weak under anaerobic conditions. Microaerobic growth at 42°C, but not at 25°C. Catalase produced. Nitrate and selenite reduced. No hydrolysis of indoxyl acetate. The 16S rDNA sequence of *C. lanienae*, and thus its phylogenetic position, is remarkably similar to that of *C. hyointestinalis* subsp. *lawsonii* (Fig. BXII.ε.2). A 16S rDNA-based PCR test developed for the specific detection of *C. lanienae* cross-reacts with *C. hyointestinalis* subsp. *lawsonii* (S.L.W. On, unpublished observations). Extensive DNA–DNA hybridization experiments, however, confirmed that *C. hyointestinalis* subsp. *hyointestinalis* and *C. hyointestinalis* subsp. *lawsonii* strains represent a single species distinct from *C. lanienae* (P. Vandamme, unpublished observations). Strains have been isolated from asymptomatic human feces. Pathogenicity, if any, is unknown.

The mol% G + C of the DNA is: 36 (T_m).

Type strain: LMG21527, NCTC 13004.

GenBank accession number (16S rRNA): AF043425.

11. **Campylobacter lari** (corrig.) Benjamin, Leaper, Owen and Skirrow 1984, 270[VP] (Effective publication: Benjamin, Leaper, Owen and Skirrow 1983, 237 (*Campylobacter laridis* Benjamin, Leaper, Owen and Skirrow 1984, 270.)

la′ri. L. n. *Larus* gull; L. gen. n. *lari* of a gull.

Cells are small, curved, S-shaped, or helical rods, 0.3 × 1.7–2.4 µm, with rounded ends. Rapid transformation to coccoid forms in cultures exposed to air. Rapid darting motility. Motile by means of single bipolar flagella. Translucent, convex colonies, 1–1.5 mm in diameter are produced on blood agar bases after 48 h. Swarming may occur on very moist agar surfaces. Grows microaerobically in the absence of hydrogen. Anaerobic growth is observed in the presence of trimethylamine *N*-oxide hydrochloride. Will not grow in air or in a CO_2-enriched atmosphere. Strains grow in the presence of 1.0–1.5% ox-bile, 0.05% sodium fluoride, 32 mg/l cephalothin, and 64 mg/l cefoperazone. Most strains (93%) grow on, and reduce, 0.04% triphenyltetrazolium chloride medium. No growth on MacConkey agar.

C. lari was originally referred to as the group of nalidixic acid-resistant thermophilic campylobacters (NARTC group). These strains are primarily differentiated from other thermophilic *Campylobacter* species by their resistance to nalidixic acid, their anaerobic growth in the presence of trimethylamine *N*-oxide hydrochloride, and later also by the absence of indoxyl acetate hydrolysis. However, nalidixic acid-susceptible strains (NASC strains), urease-producing thermophilic strains (UPTC strains), and urease-producing, nalidixic acid-susceptible strains (UP-NASC strains) were later identified as *C. lari* variants by a variety of methods. Additional quantitative DNA–DNA hybridization experiments are required to establish the relationships between the different subgroups of strains presently classified as *C. lari* variants.

C. lari infections can be treated with aminoglycosides, erythromycin, clindamycin, and chloramphenicol; strains are generally resistant to third-generation cephalosporins, vancomycin, penicillin, and trimethoprim-sulfamethoxazole (Simor and Wilcox, 1987). Strains have been isolated from intestinal contents of seagulls and other animals, river water, and shellfish. Occasionally isolated from human diarrheic feces. Pathogenicity is unknown.

The mol% G + C of the DNA is: 31–33 (T_m).

Type strain: ATCC 35221, CCUG 23947, DSM 11375, LMG 8846, NCTC 11352.

GenBank accession number (16S rRNA): L04316.

12. **Campylobacter mucosalis** (Lawson, Leaver, Pettigrew and Rowland 1981) Roop, Smibert, Johnson and Krieg 1985a, 191[VP] (*Campylobacter sputorum* subsp. *mucosalis* Lawson, Leaver, Pettigrew and Rowland 1981, 385.)

mu.co.sa′lis. M.L. adj. *mucosalis* pertaining to the (*tunica*) *mucosa* mucous membrane.

Cells are short, irregularly curved, 0.25–0.30 × 1–3 µm. Motile by means of a single, polar flagellum. In old cultures, coccoid cells and filamentous forms 7–8 µm long are seen. Colonies are 1.5 mm in diameter, circular, raised with a flat surface, and have a dirty yellowish color. On moist agar, colonies tend to swarm along the line of inoculation.

Does not grow microaerobically on common agar bases in an atmosphere without hydrogen. Grows anaerobically

in an atmosphere containing hydrogen and fumarate. Requires hydrogen as an electron donor. Formate may replace hydrogen for growth of most strains (Lawson et al., 1981). Anaerobic growth requires fumarate as an electron acceptor. Converts fumarate to succinate. Oxygen utilization by cell suspensions is greatly increased in the presence of hydrogen and formate. Utilization of oxygen with these substrates is unaffected by cyanide. Cells contain large amounts of cytochrome c_{553}, which is reduced when cell suspensions are incubated with hydrogen or formate. When exposed to air the reduced cytochrome *c* is reoxidized. Lactate, succinate, and NADH give slight reduction of cytochrome *c* while methanol, malate, glutamate, and serine are inactive. It is not affected by cyanide (Lawson et al., 1981). Strains grow on potato starch medium, and on media containing 1.0% ox-bile and 0.032% methyl orange. Most (70–90%) strains grow in the presence of 0.01% Janus green and 0.005% basic fuchsin.

Serological analysis shows that strains of this organism are closely related antigenically (Lawson et al., 1975). Antisera prepared against five strains agglutinated homologous and heterologous cells. When antisera were absorbed with one strain, the antisera reacted only with homologous cells. An antigenic analysis has been reported (Lawson et al., 1977) and three serovars, A, B, and C, have been described (Lawson et al., 1981). These three different serovars were shown to have strikingly distinct whole-cell protein patterns, but a high level of DNA–DNA hybridization was reported between representative strains (Costas et al., 1987; Vandamme et al., 1990). Selective media were developed by different researchers (reviewed by Ohya et al., 1988).

Minimum inhibitory concentrations of antibiotics are (μg/ml): bacitracin, >128; chloramphenicol, 2–8; clindamycin, 0.25–0.5; colistin, 0.5–1; erythromycin, 1–2; gentamicin, 2–4; kanamycin, <0.5–2; metronidazole, 0.12–1; minocycline, <0.5–2; nalidixic acid, 16 to >128; neomycin, 16–32; penicillin, 1–32; polymyxin B, <0.25–1; rifampin, 4–32; streptomycin, 1–2; tetracycline, 1–8; vancomycin, >128, amoxicillin/clavulanate, 0.06–0.5; cefoxitin, 1–16; ceftizoxime, 0.25–1; ceftriaxone, 0.016–0.25; meropenem, 0.03; piperacillin, 2–26; piperacillin/tazobactam, 0.016–4; and ticarcillin/clavulanate, 0.016. *In vitro* activities of 47 antimicrobial agents toward *C. mucosalis* were determined by Gebhart et al. (1985b).

Pathogenicity unknown. Originally believed to be a causal agent of proliferative enteritis in pigs but subsequent studies have identified *Lawsonia intracellularis* as the principal pathogen in this disease. Human infections with this organism have been reported but were shown to be caused by misidentified *C. concisus* strains (On, 1994; Anderson et al., 1996). Isolated from the intestinal mucosa of pigs with porcine intestinal adenamatosis, necrotic enteritis, regional ileitis, and proliferative hemorrhagic enteropathy; also isolated from the porcine oral cavity.

The mol% G + C of the DNA is: 36–38 (T_m).

Type strain: FS253/72, ATCC 43264, CCUG 6822, LMG 6448, NCTC 11000.

GenBank accession number (16S rRNA): L06978.

13. **Campylobacter rectus** (Tanner, Badger, Lai, Listgarten, Visconti and Socransky 1981) Vandamme, Falsen, Rossau, Hoste, Segers, Tytgat and De Ley 1991a, 98[VP] (*Wolinella recta* Tanner, Badger, Lai, Listgarten, Visconti and Socransky 1981, 441.)
rect′ us. L. adj. *rectus* straight.

Cells are small and straight, 0.5 × 2–4 μm, with rounded ends. Rapid darting motility. Motile by means of a single polar flagellum. The outer surface is covered with a distinctive array of hexagonal, packed, macromolecular subunits, each about 17 nm in diameter. Translucent colonies are produced on blood agar bases. Different colony types are observed: small pinpoint colonies, 1 mm in diameter, or spreading colonies up to 5 mm in diameter. Agar pitting is medium dependent but most (80%) strains exhibit this trait after 3 d of anaerobic growth on 5% blood agar (On et al., 1996).

Optimal growth in anaerobic conditions. Does not grow microaerobically on common agar bases in an atmosphere without hydrogen. Will not grow in air, in a CO_2-enriched atmosphere, or in an atmosphere containing $O_2/CO_2/N_2$ (5:10:85) on common agar bases. Anaerobic growth occurs with formate and fumarate in the medium. Hydrogen and formate are used as energy sources. Formate is oxidized to hydrogen and CO_2; fumarate is reduced to succinate. Fumarate, nitrate, nitrite, neutral red, benzyl viologen aspartate, asparagine, and malate serve as electron acceptors. Membrane-bound cytochrome *b*, cytochrome *c*, and CO-binding cytochrome *c*, and soluble cytochrome *c* and CO-binding cytochrome *c* are present. Strains do not grow in the presence of 0.04% triphenyl-tetrazolium chloride, 0.01% Janus green or 64 mg/l cefoperazone. Alkaline phosphatase is not produced.

The mol% G + C of the DNA is: 42–46 (T_m).

Type strain: FDC 371, ATCC 33238, CCUG 20446, DSM 3260, LMG 18219.

GenBank accession number (16S rRNA): L04317, L06973.

14. **Campylobacter showae** Etoh, Dewhirst, Paster, Yamamoto and Goto 1993, 638[VP]
sho′ wae. L. n. *showae* referring to Showa University, Japan, where several of the first strains were isolated.

Cells are small and straight, 0.5–0.8 × 2–5 μm, with rounded ends. Motile by means of polar bundles of two to five flagella. Rapid darting motility. Translucent colonies are produced on blood agar base media.

Optimal growth in anaerobic conditions. Does not grow microaerobically on common agar bases in an atmosphere without hydrogen. Will not grow in air, in a CO_2-enriched atmosphere, or in an atmosphere containing $O_2/CO_2/N_2$ (5:10:85) on common agar bases. Anaerobic growth occurs with formate and fumarate in the medium. Fumarate is reduced to succinate. Fumarate, nitrate, and nitrite serve as electron acceptors. Strains grow in the presence of 0.05% sodium fluoride but not in the presence of 64 mg/l cefoperazone or 0.04% triphenyl-tetrazolium chloride. Alkaline phosphatase activity has not been detected. Strains have been isolated from human dental plaque and from infected root canals. Pathogenicity is unknown.

The mol% G + C of the DNA is: 44–46 (T_m).

Type strain: SU A4, ATCC 51146, CCUG 30254, LMG 12635.

GenBank accession number (16S rRNA): L06974.

15. **Campylobacter sputorum** (Prévot 1940) Véron and Chatelain 1973, 128[AL] emend. Roop, Smibert, Johnson and

Krieg 1986, 348 emend. On, Atabay, Corry, Harrington and Vandamme 1998, 203 (*Vibrio sputorum* Prévot 1940, 85.)
spu.to'rum. L. n. *sputum* spit, sputum; L. gen. pl. n. *sputorum* of sputa.

Slender, curved or spiral rods, 0.3–0.5 × 2–4 μm. Cells are usually S-shaped or gull-winged in appearance, but comma-shaped and unusually long (8 μm) cells are also observed. The ends of the cells are usually rounded. Motile with a characteristic darting and corkscrew-like movement by means of a single flagellum. Colonies of 3-d-old cultures on blood agar media are 1–2 mm in diameter, smooth, shiny, low convex, and round. Bacterial growth on blood agar usually shows a greenish hue, and it is accompanied by weak α-hemolytic activity. Growth in broth is light and easily dispersed. Strains may be cultured under microaerobic or anaerobic gaseous conditions. Anaerobic growth occurs in media containing fumarate only, formate and fumarate, or fumarate in the presence of hydrogen gas. Alkaline phosphatase is not produced. Neither growth nor reduction of triphenyl-tetrazolium chloride medium is detected. Strains will grow on media containing 0.032% methyl orange. Strains do not give reproducible results when tested for the ability to grow on media containing 3.5–4.0% NaCl, or 1.0–2.0% ox-bile.

Strains isolated from the human oral cavity and the genital tract of bulls were initially believed to be related at the subspecies level on the basis of their extensive biochemical similarities, and named *C. sputorum* subsp. *sputorum* and *C. sputorum* subsp. *bubulus* (Véron and Chatelain, 1973), respectively. Subsequent DNA homology studies (Tanner et al., 1981; Roop et al. 1985b) revealed a high level of DNA–DNA relatedness between these two taxa and between these taxa and *"C. fecalis"* (from sheep feces). Limited biochemical variation between these taxa had been noted (catalase production, and growth on 3.5% NaCl and 1.0% ox-bile media). Roop et al. (1985b) therefore proposed that the aforementioned taxa be referred to as source-specific biovars of *C. sputorum* (biovar sputorum, biovar bubulus, and biovar faecalis, respectively). The legitimacy of biovar bubulus as a distinct taxon was questioned when the tests used to distinguish biovar sputorum from biovar bubulus were found to be poorly reproducible, even when using highly standardized conditions for testing (On et al., 1994, 1998). The absolute validity of the "source-specific biovar" concept was also challenged since some *C. sputorum* strains from sheep and pigs cannot be distinguished from those of bovine and human origin (On et al., 1994, 1998). The recent identification of urease-positive isolates of *C. sputorum* from cattle feces resulted in the proposal of a new biovar structure, defined by reactions in two simple and reproducible tests (catalase and urease). The proposed biovar classification also agrees with the results of protein profile analysis (On et al., 1994, 1998).

Campylobacter sputorum biovar sputorum strains conform to the description of the species *C. sputorum*. Neither catalase nor urease is produced. Found in the oral cavity, feces (normal and diarrheic), and abscesses (and other skin lesions) of humans, the genital tract of bulls, aborted tissue of sheep, and the feces of sheep and pigs. Pathogenicity unknown. The reference strain is VPI S-17 (LMG 7795, NCTC 11528). GenBank accession numbers of the 16S rRNA gene sequences are X67775 (VPI S-17) and L04319 (ATCC 33491).

Campylobacter sputorum biovar faecalis strains conform to the description of the species *C. sputorum*. Catalase, but not urease, is produced. The biovar name refers to the fecal habitat. Isolated from the feces of sheep and cattle. Pathogenicity unknown. The recommended reference strain is LMG 8531 (CCUG 17761, NCTC 11415).

Campylobacter sputorum biovar paraureolyticus strains conform to the description of the species *C. sputorum*. Urease, but not catalase, is produced. The biovar name paraureolyticus indicates its resemblance to *Bacteroides ureolyticus*, a urease-producing bacterium closely related to other *Campylobacter* spp. Isolated from the feces of cattle and from human diarrhea. Pathogenicity unknown. Recommended reference strains are LMG 11764 (human) and LMG 17590 (CCUG 37579) (bovine). GenBank accession no. of the 16S rRNA gene sequence of strain LMG 17590 is AF022768.

The mol% G + C of the DNA is: 30–33 (T_m).
Type strain: VPI S 17, ATCC 35980, CCUG 9728, LMG 7795, NCTC 11528.
GenBank accession number (16S rRNA): X67775.

16. **Campylobacter upsaliensis** Sandstedt and Ursing 1991b, 331[VP] (Effective publication: Sandstedt and Ursing 1991a, 42.)
up.sa.li.en' sis. L. adj. *upsaliensis* referring to Uppsala, a Swedish city.

Cells are small, curved, S-shaped, or helical rods, 0.3–0.4 × 1.2–3 μm, with rounded ends. Rapid darting motility. Motile by means of a single polar flagellum or bipolar flagella. Transformation to coccoid forms in cultures exposed to air. Translucent, convex colonies, pinpoint to 1–2 mm in diameter are produced on blood agar bases after 48 h. Swarming may occur on very moist agar surfaces.

Grows microaerobically in the absence of hydrogen. Will not grow in air or in a CO_2-enriched atmosphere. Goossens et al. (1990a) reported that about 20% of 99 strains did not grow at 42°C; it therefore seems appropriate to consider this species as thermotolerant, not thermophilic. Strains grow on potato starch- and charcoal-based media, and on media containing 1.0–1.5% ox-bile and 100 U/l 5-fluorouracil. Strains do not grow on MacConkey agar. A few strains (11%) are resistant to cephalothin (32 mg/l).

A comprehensive overview of our present knowledge on this species was given by Bourke et al. (1998). A physical and genetic map of the genome and the complete sequence of the iron-uptake regulatory gene (*fur*) from the type strain were described by Bourke et al. (1995). Adherence to lipids and intestinal mucin were described by Sylvester et al. (1996). Selective media were reported to enable isolation of thermophilic campylobacters including *C. upsaliensis* strains (Burnens and Nicolet, 1992; Aspinall et al., 1996). A variety of plasmids has been reported in large percentages of strains (89%, Goossens et al., 1990a; 87%, Owen and Hernandez, 1990; 93%, Da Silva Tatley et al., 1992; 60%, Stanley et al., 1994a).

Minimum inhibitory concentrations of antibiotics are (μg/ml): bacitracin, >128; chloramphenicol, 2–8; clindamycin, 0.25– 0.5; colistin, 0.5–1; erythromycin, 1–2; gentamicin, 2–4; kanamycin, <0.5–2; metronidazole, 0.121; minocycline, <0.5–2; nalidixic acid, 16–128; neomycin, 16–32; penicillin, 1–32; polymyxin B, <0.25–1; rifampin, 4–32;

streptomycin, 1–2; tetracycline, 1–8; vancomycin, >128, amoxicillin/clavulanate, 0.06–0.5; cefoxitin, 1–16; ceftizoxime, 0.25–1; ceftriaxone, 0.016–0.25; meropenem, 0.03; piperacillin, 2–26; piperacillin/tazobactam, 0.016–4; and ticarcillin/clavulanate, 0.016.

Of 99 *C. upsaliensis* strains examined by Goossens et al. (1990a), all were generally susceptible to ampicillin, gentamicin, chloramphenicol, cefoperazone, colistin, vancomycin, rifampin, trimethoprim, and tetracycline; ten strains were resistant to erythromycin. Strains are isolated from blood specimens of humans, from feces from humans with gastrointestinal illness, and from asymptomatic humans, dogs, and cats; strains associated with a human abortion and a breast abscess were reported. Clinical data presented by Goossens et al. (1990a, b) suggest an enteropathogenic role in humans.

The mol% G + C of the DNA is: 32–36 (T_m).

Type strain: C 231, ATCC 43954, CCUG 14913, DSM 5365, LMG 8850, NCTC 11541.

GenBank accession number (16S rRNA): L14628.

Other Organisms

1. *Bacteroides ureolyticus* Jackson and Goodman 1978, 199[AL] (*Bacteroides corrodens* Eiken 1958, 415; *Ristella corrodens* (Eiken 1958) Prévot 1966, 118.)

ur′ e.o.ly.ti.cus. M.L n. *urea* urea; Gr. adj. *lyticus* dissolving; M.L. adj. *ureolyticus* urea dissolving.

Cells are 0.5 × 1.5–4 μm. Nonmotile. Filaments exceeding 20 μm in length may occur. Cells of some strains have polar tufts of long pili in electron micrographs (Jackson et al., 1971) and exhibit "twitching" motility. The pili sometimes form a bundle and may be mistaken for flagella with light microscopy. Translucent colonies are produced on blood agar bases. Different colony types are observed: small pinpoint colonies, 1 mm in diameter or spreading colonies up to 5 mm in diameter. Agar pitting is medium dependent, but most strains (90%) exhibit this trait after 3 d of anaerobic growth on 5% blood agar (On et al., 1996).

Does not grow microaerobically on common agar bases in an atmosphere without hydrogen. Will not grow in air, in a CO_2-enriched atmosphere, or in an atmosphere containing $O_2/CO_2/N_2$ (5:10:85) on common agar bases. Anaerobic growth occurs with formate and fumarate in the medium. Fumarate is reduced to succinate; fumarate, nitrate, and nitrite serve as electron acceptors. Strains grow on media containing 3.5–4.0% NaCl and 0.032% methyl orange. As with other preferentially anaerobic *Campylobacter* species, strains are susceptible to a range of antibiotics including cephalothin (32 mg/l), carbenicillin (32 mg/l), cefoperazone (64 mg/l) and 5-fluorouracil (100 U/l). No growth is observed in the presence of 0.05% basic fuchsin. Contains cytochromes *b* and *c* (Jackson and Goodman, 1978).

Menaquinone-6 (2-methyl-3-farnesyl-farnesyl-1,4-naphthoquinone) and a methyl-substituted menaquinone-6 (2, [5 or 8]-dimethyl-3-farnesyl-farnesyl-1,4-naphthoquinone) have been reported as major respiratory quinones (Vandamme et al., 1995a). Strains have been isolated from superficial ulcers and soft tissue infections, nongonococcal, nonchlamydial urethritis, and periodontal disease. Its pathogenicity is difficult to assess because the strains are mostly recovered from mixed infections. Nevertheless, a potential pathogenic role is suggested by its predominance in mixed infections and its strong proteolytic activity, which may enable tissue destruction.

B. ureolyticus was included in a polyphasic taxonomic study to elucidate its taxonomic status (Vandamme et al., 1995a). This species resembles campylobacters in its respiratory quinone content, its DNA base ratio, and most of its phenotypic characteristics; it differs from campylobacters in its fatty acid composition and its proteolytic metabolism. Bootstrapping analysis of the 16S rRNA gene sequence-derived phylogeny separated *B. ureolyticus* from the *Campylobacter* clade in only 61% of trees generated. This organism was not formally reclassified pending the isolation and thorough taxonomic characterization of additional *B. ureolyticus*-like bacteria. The inclusion of *B. ureolyticus* in the genus *Campylobacter* would considerably extend the phenotypic heterogeneity of this genus. Exclusion from the genus *Campylobacter* would entail the creation of a monotypic taxon with the ability to digest casein and gelatin as differential features from the genus *Campylobacter*. *B. ureolyticus*-like oral isolates that were shown to be heterogeneous on the basis of phenotypic and biochemical criteria (Duerden et al., 1989) have been described. The taxonomic structure and position of these and other *B. ureolyticus*-like strains need further investigation.

The mol% G + C of the DNA is: 28–30 (T_m).

Deposited strain: ATCC 33387, DSM 20703, NCTC 10941.

GenBank accession number (16S rRNA): L04321.

The *Campylobacter mucosalis*-like strain CCUG 20705 was isolated from a porcine intestine in the United Kingdom and was originally identified as *C. mucosalis*. It occupied a distinct position in a dendrogram derived from DNA–rRNA hybridization experiments (Vandamme et al., 1991a). No significant DNA–DNA hybridization between CCUG 20705 and *C. mucosalis* reference strains (P. Vandamme, unpublished data) was detected although the 16S rRNA gene sequence of this strain (L14629) is about 98% similar to that of the type strain of *C. mucosalis* (Linton et al., 1994a).

Campylobacter sp. strain PGC 40-6AT, isolated from a pig stomach, was reported as one of several genetically similar isolates. A number of studies have remarked on its distinct phylogenetic position, suggesting it to represent a novel species. However, a study examining the phylogenetic position and diversity of the 16S rRNA gene from *C. hyointestinalis*, closely clustered PGC 40-6AT with six other sequences derived from reference strains of *C. hyointestinalis* subsp. *lawsonii* (Harrington and On, 1999). Since the latter subspecies is most commonly associated with porcine stomach tissue, these authors considered PGC 40-6AT identified as a strain of *C. hyointestinalis* subsp. *lawsonii*.

Genus II. **Arcobacter** *Vandamme, Falsen, Rossau, Hoste, Segers, Tytgat and De Ley 1991a, 99^{VP} emend. Vandamme, Vancanneyt, Pot, Mels, Hoste, Dewettinck, Vlaes, Van Den Borre, Higgins, Hommez, Kersters, Butzler and Goossens 1992b, 355*

Peter Vandamme, Floyd E. Dewhirst, Bruce J. Paster and Stephen L.W. On

Ar′co.bac.ter. L. n. *arcus* bow; Gr. n. *bacter* rod; M.L. masc. n. *Arcobacter* a curved rod.

Cells are slender, curved rods, 0.2–0.9 × 0.5–3 µm long; S-shaped or helical cells are often present. Nonsporeforming. Cells in old cultures may form spherical or coccoid bodies and loose spiral filaments up to 20 µm long. Gram negative. Motile with a **characteristic corkscrew-like motion** by means of a single **polar unsheathed flagellum** at one or both ends of the cell.

Optimal growth under microaerobic conditions, with a respiratory type of metabolism. **Able to grow in aerobic conditions.** Hydrogen is not required for microaerobic growth. Grows anaerobically. **Growth at 15 and 30°C, not at 4°C; growth is variable at 37°C. Chemoorganotrophs. Carbohydrates are neither fermented nor oxidized.** No acidic or neutral end products produced. Serum or blood enhances, but is not essential for, growth. **Energy is obtained from amino acids or tricarboxylic acid cycle intermediates, not carbohydrates. Oxidase activity is present; most strains produce catalase.** Most strains grow in the presence of 0.032% methyl orange. **Indoxyl acetate is hydrolyzed.** No hydrolysis of gelatin, casein, starch, hippurate, and tyrosine. Methyl red and Voges–Proskauer negative. No arylsulfatase or lecithinase activity. Pigments are not produced. **Habitat is extremely diverse**. Some species are pathogenic for humans and animals and are found in the reproductive organs and aborted fetuses of various animals and in the intestinal tract of man and animals. Detected in water reservoirs, sewage, oil field communities, and saline environments; one species is a plant-associated nitrogen fixer.

Internal transcribed spacers or intervening sequences in rRNA genes have not been reported.

The mol% G + C of the DNA is: 27–31.

Type species: **Arcobacter nitrofigilis** (McClung, Patriquin and Davis 1983) Vandamme, Falsen, Rossau, Hoste, Segers, Tytgat and De Ley 1991a, 100 (*Campylobacter nitrofigilis* McClung, Patriquin and Davis 1983, 610.)

Further descriptive information

Arcobacter, *Campylobacter*, the generically misclassified species *Bacteroides ureolyticus*, and *Sulfurospirillum* constitute the family *Campylobacteraceae* and belong to the *Epsilonproteobacteria* (Fig. BXII.ε.3). *Arcobacter* is a most unusual genus, unifying species associated with disease or considered pathogenic in humans and animals, and a plant-associated nitrogen-fixing bacterium. This combination of plant- and animal-associated species within one genus is rarely seen among *Proteobacteria*. Although primarily known as human- and animal-associated bacteria that are of relevance in food microbiology, arcobacters were shown to be abundantly present in certain environmental niches including water reservoirs, sewage, oil field communities, and certain saline environments. Their role in the environment is not well documented, but some of these organisms were shown to be sulfide oxidizers (with the production of sulfur). It has been suggested that these organisms play a role in the sulfur cycle by reoxidizing sulfide formed by microbial sulfate or sulfur reduction (Voordouw et al., 1996).

Menaquinone-6 (2-methyl-3-farnesyl-farnesyl-1,4-naphthoquinone) and a second menaquinone-6, the detailed structure of which has not been determined, were reported as major respiratory quinones (Moss et al., 1990b).

Few typing studies have thus far been presented. A serotyping scheme based on heat-labile antigens using slide agglutination was developed by Lior and Woodward (1991). A biotyping scheme which involved four biochemical characteristics: the ability to produce urease, rapid hydrogen sulfide formation, DNase activity, and the utilization of sodium acetate was presented subsequently by the same authors (Lior and Woodward, 1993). In addition, genotypic methods such as ribotyping (Kiehlbauch et al., 1991b; Taylor et al., 1992b), pulsed field gel electrophoresis of macrorestriction fragments (Lior and Wang, 1993), and random and repetitive motif based polymorphic DNA analyses (Lior and Wang, 1993; Vandamme et al., 1993a) were performed on limited numbers of strains.

Little is known about virulence factors of *Arcobacter* strains. Musmanno et al. (1997) examined 18 isolates of *A. butzleri* from river water samples. Toxin profiles based on cytotonic, cytotoxic, and cytolethal distending factors were determined after analysis responses in Vero and CHO cells. Adhesivity and invasivity tests

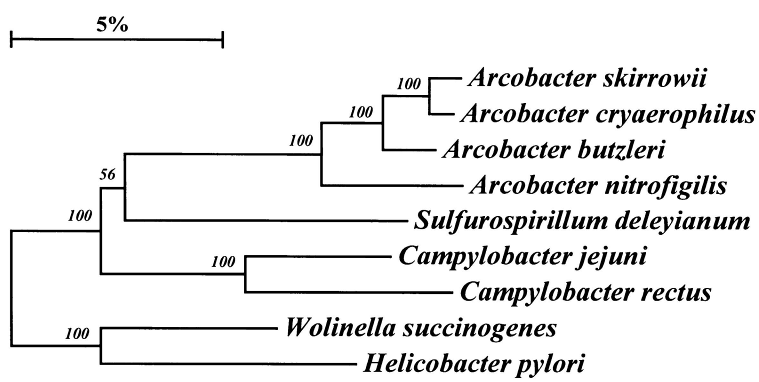

FIGURE BXII.ε.3. Phylogeny of *Arcobacter* species. The phylogenetic relationships of the named species of the genus *Arcobacter* compared to other selected members of the family *Campylobacteraceae* and family *Helicobacteraceae*. Bar = 5% difference in 16S rDNA nucleotide sequences. One hundred bootstrap trees were generated, and bootstrap confidence levels (shown as percentages above the nodes) were determined.

were performed on HeLa and Intestine 407 cells. All but one strain induced cytotoxic effects on cells in culture. The cytotoxic-negative strain caused elongation of CHO cells (a cytotonic-like effect). This strain was the only one that adhered to cells *in vitro*. Invasiveness was never observed.

In spite of accumulating evidence, little is known about the true distribution of arcobacters in human, animal, and environmental samples. Arcobacters may be readily overgrown by other bacteria, frequently by campylobacters, if inappropriate isolation methods are used. From an ecological perspective, this genus comprises two subgroups of species, those associated with human and animal disease, and those either associated with plants or free-living. Three species, *A. cryaerophilus*, *A. butzleri*, and *A. skirrowii*, have been isolated from feces of humans and various animals with diarrhea, from cattle with mastitis, and from a variety of meat products of animal origin. These species have been also associated with enteritis, recurrent cramps, bacteremia, endocarditis, peritonitis, appendicitis, abortion, and mastitis (Wesley, 1996). Evidence that arcobacters may be true pathogens is derived from a number of observations: (i) arcobacters are associated with clear clinical symptoms in the absence of other enteropathogens; (ii) in animals, arcobacters are more frequently recovered from aborted pig litters and from infertile sows with vaginal discharge than from healthy animals; (iii) experimental infection lowered conception rates in sows artificially inseminated with arcobacter-containing sperm and caused inflammation only in the inoculated udder of a dairy cow; (iv) *A. butzleri* in particular can colonize the intestine and other internal organs of neonatal pigs (Wesley et al., 1996). *A. nitrofigilis* and several unnamed arcobacters are free-living or plant-associated bacteria occurring in saline environments, sludge of wastewater plants, and oil field communities, and may play an important role in sulfur or nitrogen cycles (McClung et al., 1983; Teske et al., 1996; Voordouw et al., 1996; Snaidr et al., 1997).

Enrichment and Isolation Procedures

Arcobacters may be isolated using selective media or filtration methods described for the isolation of *Campylobacter* species. However, these methods are suboptimal for growth of arcobacters, which may be overgrown by campylobacters present in the same specimens. Samples should be incubated at 24–30°C to enhance the selectivity of the procedure, and an enrichment step has been recommended (Atabay et al., 1998a).

Isolation of *Arcobacter* strains was originally described by Ellis et al. (1977) using a two-stage isolation method. *Leptospira* EMJH medium supplemented with 5-fluorouracil modified by the addition of 1% rabbit serum and 0.15% agar was used as the initial selective and enrichment medium. This semisolid medium was incubated at 30°C in air. Growth was seen as a distinct zone below the surface of the medium. Subsequently, an aliquot was withdrawn from the growth zone and inoculated onto a selective solid agar medium consisting of a blood agar base supplemented with 7% lysed horse blood and 125 μg/ml carbenicillin. The plates were then incubated at 30°C in a microaerobic atmosphere.

A selective medium developed for the isolation of arcobacters was recently described by de Boer et al. (1996) and is based on their swarming capacity in semisolid media. The enrichment broth contains *Brucella* broth (Difco) as a basal medium supplemented with lysed horse blood (5%), piperacillin (75 mg/l), cefoperazone (32 mg/l), trimethoprim (20 mg/l), and cycloheximide (100 mg/l). Mueller Hinton broth (Oxoid) supplemented with 0.25% agar and the same antibiotic supplement is used as the isolation medium. An aliquot of 40 μl of the enrichment culture is pipetted onto the center of the agar layer, and plates are incubated for two to three days at 24°C. Growth of arcobacters typically appears as gray, translucent zones of motility (de Boer et al., 1996).

Atabay and Corry used sensitive methods of isolation that allowed them to detect a wide range of *Campylobacter* and *Arcobacter* species from chicken carcasses (Atabay and Corry, 1997; Atabay et al., 1998a). These methods involved the use of different selective agents and/or lower concentrations of antibiotics in the isolation media. Hydrogen was also included in the microaerobic atmosphere, samples were plated onto nonselective blood agar, and incubation was carried out at various temperatures (most often 30°C and 37°C). Arcobacters were isolated only at 30°C, under aerobic conditions after enrichment. Modified CCDA (mCCDA) did not support the growth of arcobacters and strains of *A. skirrowii* were recovered only on nonselective blood agar. The reason for the failure to recover any of the *Arcobacter* strains on mCCDA could be sensitivity to the inhibitory substance(s) present in mCCDA and/or the synergistic inhibitory effect of the combination of inhibitors (cefoperazone and sodium deoxycholate). The *A. skirrowii* strains were sensitive to deoxycholate and this probably explains why they grew in CAT broth (which does not contain deoxycholate) but were isolated only from blood agar and not mCCDA or CAT agar (Atabay et al., 1998a).

Maintenance Procedures

Cultures may be stored for many years by lyophilization, by freezing at −80°C, or by storage in liquid nitrogen. Cryoprotective agents such as 10% glycerol or DMSO should be added to cultures before freezing, and heavy cell concentrations should be used. Grown cultures can be kept at room temperature in air but should be transferred weekly.

Differentiation of the genus *Arcobacter* from other genera

Classical biochemical differentiation of the genus *Arcobacter* from related genera such as *Campylobacter* and *Helicobacter*, is primarily achieved via the identification of the individual species. However, in general, arcobacters can be differentiated from campylobacters by their lower optimal growth temperatures (25–30°C compared to 30–42°C for campylobacters) and aerotolerance. Analysis of respiratory quinones enables a clear differentiation of *Arcobacter* strains from *Campylobacter* strains but is of limited value in a routine diagnostic laboratory.

Taxonomic Comments

In 1985, Neill et al. (1985) performed an exhaustive phenotypic analysis of a large number of aerotolerant *Campylobacter* strains. Without insight into the phylogenetic and genotypic relationships of the organisms, these authors concluded that the group of aerotolerant campylobacters was more distantly related to any of the existing *Campylobacter* species than these species were to each other and emphasized that the aerotolerant campylobacters formed a heterogeneous group. These conclusions were confirmed by rRNA-based phylogenetic analyses and by integrated phenotypic, genotypic, and chemotaxonomic studies of, in part, the same isolates (Thompson et al., 1988; Kiehlbauch et al., 1991a; Vandamme et al., 1991a, 1992b). As a result, the genus *Arcobacter* was separated from the *Campylobacter* genus and three animal-associated species were described: *A. cryaerophilus*, *A. butz-*

leri, and *A. skirrowii* (Kiehlbauch et al., 1991a; Vandamme et al., 1991a, 1992b).

Few taxonomic problems are left. The phylogeny of these bacteria is well known and the relationships among the four named species have been examined by DNA–DNA hybridization experiments and by a variety of different chemotaxonomic and genotypic methods (see below). Two genotypic and chemotaxonomic subgroups were described within *A. cryaerophilus* (Kiehlbauch et al., 1991a; Vandamme et al., 1992b) but were not formally named pending the availability of simple diagnostic tests. Novel strains, some of which remained uncultured, that cluster phylogenetically among other *Arcobacter* strains have been described (Teske et al., 1996; Voordouw et al., 1996; Snaidr et al., 1997). Their relationships toward named *Arcobacter* species remain to be established.

Differentiation of the species of the genus *Arcobacter*

Biochemical characteristics useful in distinguishing the four named species of the genus *Arcobacter* are listed in Table BXII.ε.3.

Whole-cell protein electrophoresis (Vandamme et al., 1992b) and numerical analysis of 67 phenotypic characters (On and Holmes, 1995) correlated with percentage of DNA–DNA hybridization and were able to differentiate all species. Whole-cell fatty acid analysis was not able to distinguish *A. butzleri* from *A. cryaerophilus* subgroup 2, but differentiated all other *Arcobacter* taxa (Vandamme et al., 1992b).

16S rRNA-based DNA probes (Wesley et al., 1995) and PCR assays (Harmon and Wesley, 1997), ribotyping (Kiehlbauch et al., 1991b), and restriction fragment length polymorphism analysis of a PCR-amplified fragment of the gene coding for 16S rRNA (Cardarelli-Leite et al., 1996) or 23S rRNA (Hurtado and Owen, 1997a) differentiated *A. butzleri* from other arcobacters but did not differentiate *A. cryaerophilus* from *A. skirrowii*. Using a variable 23S rRNA region, Bastyns et al. (1995a) developed genus- and species-specific PCR assays that differentiated *A. butzleri*, *A. cryaerophilus*, and *A. skirrowii*. Finally, Snaidr et al. (1997) described a set of genus-specific PCR primers that enabled detection of the four named species and an unnamed *A. nitrofigilis*-like taxon.

List of species of the genus Arcobacter

1. **Arcobacter nitrofigilis** (McClung, Patriquin and Davis 1983) Vandamme, Falsen, Rossau, Hoste, Segers, Tytgat and De Ley 1991a, 100[VP] (*Campylobacter nitrofigilis* McClung, Patriquin and Davis 1983, 610.)
ni.tro.fig′i.lis. L. n. *nitrum* nitrate; L. v. *figo* to fix; L. adj. suff. *ilis* able to; M.L. adj. *nitrofigilis,* able to fix (nitrogen as) nitrate.

Cells are small curved rods, 0.2–0.9 × 1–3 μm. Rapid corkscrew-like motility by means of a single polar flagellum. Occasionally longer, helical cells are observed. Coccoid forms develop in old cultures.

Colonies of 48 h cultures are 2–3 mm in diameter, circular and convex, and have a beige to off-white color.

Grows in media containing 2–70 g/l NaCl. Optimal growth with 10–40 g/l NaCl. Nitrogenase activity. Sulfide production from cysteine. A brown, water-soluble pigment is produced from tryptophan. Indole negative. Does not hydrolyze esculin. Incapable of growth in the presence of 1% glycine. Does not grow at 37°C under aerobic or microaerobic conditions. Grows on media containing 0.05% sodium fluoride, but not on charcoal-based media, or media containing 1.0– 2.0% ox bile. Sensitive to nalidixic acid (32 mg/l), cephalothin (32 mg/l), cefoperazone (64 mg/l), and carbenicillin (32 mg/l).

Isolated from the roots and root-associated sediments of *Spartina alterniflora* growing in marshes with approximately oceanic salinity. Fixes nitrogen.

The mol% G + C of the DNA is: 28–29 (T_m).
Type strain: C1, CCUG 15893, LMG 7604.
GenBank accession number (16S rRNA): L14627.

2. **Arcobacter butzleri** (Kiehlbauch, Brenner, Nicholson, Baker, Patton, Steigerwalt and Wachsmuth 1991a) Vandamme, Vancanneyt, Pot, Mels, Hoste, Dewettinck, Vlaes, Van Den Borre, Higgins, Hommez, Kersters, Butzler and

TABLE BXII.ε.3. Differential characteristics of the species of the genus *Arcobacter*[a]

Characteristic	*Arcobacter nitrofigilis*	*Arcobacter butzleri*	*Arcobacter cryaerophilus*	*Arcobacter skirrowii*
Urease	+	−	−	−

Goossens 1992b, 355[VP] (*Campylobacter butzleri* Kiehlbauch, Brenner, Nicholson, Baker, Patton, Steigerwalt and Wachsmuth 1991a, 384.)
butz' ler.i. N.L. gen. n. *butzleri* of Butzler, in honor of Jean-Paul Butzler, a Belgian microbiologist who was one of the first scientists to emphasize the importance of *Campylobacter* infections in humans.

Curved cells, 0.2–0.4 × 1–3 µm. Rapid darting motility. Motile by means of a single polar flagellum at one or both ends of the cell.

Colonies grown for 48 h under optimal conditions are 2–4 mm in diameter, convex with an entire edge. Bacterial growth has a whitish appearance. Strains will grow on charcoal-based and potato starch media, and on media containing 0.001% sodium arsenite, 32 mg/l carbenicillin, 64 mg/l cefoperazone, and 0.05% sodium fluoride. Most (91–96%) strains reduce nitrate and grow on, and reduce, 0.04% triphenyl-tetrazolium chloride. Indoxyl acetate is hydrolyzed.

Isolated from human blood and diarrheic feces; from feces of various animals with diarrhea including nonhuman primates, pigs, horses, cattle, an ostrich, and a tortoise; from bovine and porcine abortions; from various food products including ground pork, chicken, and turkey samples; from surface and drinking water reservoirs and canal waters. Associated with enteritis, abdominal cramps, bacteremia, and appendicitis in humans; enteritis and abortion in animals.

The mol% G + C of the DNA is: 28–31 (T_m).

Type strain: CDC D2686, CCUG 30485, LMG 10828.

3. **Arcobacter cryaerophilus** (Neill, Campbell, O'Brien, Weatherup and Ellis 1985) Vandamme, Falsen, Rossau, Hoste, Segers, Tytgat and De Ley 1991a, 100[VP] (*Campylobacter cryaerophilus* Neill, Campbell, O'Brien, Weatherup and Ellis 1985, 354.)
cry.ae.ro' phi.lus. Gr. n. *cruos* cold; Gr. n. *aero* air; Gr. n. *philos* friend; L. adj. *cryaerophilus* friend of cold and air.

Curved cells, 0.2–0.4 × 1–3 µm. Rapid darting motility. Motile by means of a single polar flagellum at one or both ends of the cell.

Colonies grown for 48 h under optimal conditions are 1–3 mm in diameter, convex with an entire edge. Mostly with a dirty yellow pigment. Strains grow on nutrient agar; most (93–100%) strains grow on charcoal-based and potato starch media. Strains grow on media containing 0.001% sodium arsenite, 32 mg/l cephalothin, 100 U/l 5-fluorouracil, and 0.02% safranin. Strains vary (66%) in their ability to reduce nitrate.

Two subgroups, referred to as subgroup 1 or group 1A, and subgroup 2 or group 1B, have been described (Kiehlbauch et al., 1991a; Vandamme et al., 1992b, respectively). These subgroups differ in their whole-cell protein and fatty acid patterns, and in the restriction fragment length polymorphisms of the ribosomal RNA genes. The DNA–DNA hybridization levels within these subgroups ranged from 56 to 100%, while values from 46 to 69% were found among strains of the different subgroups. These subgroups were not given formal names pending the availability of simple diagnostic tests. On et al. (1996) observed that most strains of subgroup 2 could grow under aerobic or microaerobic conditions at 37°C, in contrast with subgroup 1 strains, but this result seems to be highly method dependent.

Isolated from cases of human bacteremia and diarrhea; from chicken carcasses; from bovine, ovine, and porcine abortions; from porcine feces, and from mastitis in cattle. Pathogenicity is unknown.

The mol% G + C of the DNA is: 28–30 (T_m).

Type strain: Neill A 169/B, CCUG 17801, LMG 7536; CDC D2610.

GenBank accession number (16S rRNA): L14624.

Additional Remarks: LMG 10829 is a well-characterized reference strain of subgroup 2.

4. **Arcobacter skirrowii** Vandamme, Vancanneyt, Pot, Mels, Hoste, Dewettinck, Vlaes, Van Den Borre, Higgins, Hommez, Kersters, Butzler and Goossens 1992b, 355[VP]
skir.ro' wi.i. N.L. gen. n. *skirrowii* of Skirrow, in honor of Martin B. Skirrow, a British microbiologist who was the first to describe a simple isolation method for *Campylobacter jejuni* obtained from stool specimens, which enabled most laboratories to routinely culture the organism.

Curved cells, 0.2–0.4 × 1–3 µm. Rapid darting motility. Motile by means of a single polar flagellum.

Colonies grown for 48 h under optimal conditions are 2–3 mm in diameter, and have a flat irregular shape. Bacterial growth has a grayish appearance and is not usually as profuse as in other *Arcobacter* spp. Strains grow on charcoal-based and potato starch media, and on media containing up to 2.0% ox-bile, and 32 mg/l cephalothin and 64 mg/l cefoperazone. Nitrate is reduced. Most strains (73%) are resistant to 0.001% sodium arsenite. No growth is observed in the presence of 0.05% basic fuchsin.

Isolated from preputial fluids of bulls; from bovine, ovine, and porcine abortions; from diarrheic feces of various animals with diarrhea including sheep, cattle; from chicken carcasses. Pathogenicity is unknown.

The mol% G + C of the DNA is: 29–30 (T_m).

Type strain: Skirrow 449/80, CCUG 10374, LMG 6621.

GenBank accession number (16S rRNA): L14625.

Other Organisms

Voordouw et al. (1996) examined oil field communities by cloning and sequencing of PCR-amplified 16S rRNA genes. Apart from a variety of Gram-negative, sulfate-reducing bacteria, a limited number of potential sulfide oxidizers and/or microaerophiles, including arcobacters, were detected. An organism most closely related to *A. nitrofigilis* was the source of the most frequently detected bacterial sequence from oil field DNA analyzed by the culture-independent approach.

Teske et al. (1996) examined the bacterial composition of a coculture capable of sulfate reduction after exposure to oxic and micro-oxic conditions. This coculture was derived from cyanobacterial mats from Solar Lake (Sinai) that were introduced to an experimental hypersaline pond. PCR amplification of 16S ribosomal DNA fragments from the coculture, analyzed by denaturing gradient gel electrophoresis, resulted in two distinct 16S ribosomal DNA bands, one of which was derived from an *Arcobacter* strain. Molecular identification of the two components of this coculture allowed the design of specific culture conditions to separate and isolate both strains in pure culture. Curved to spiral rods, ~1–3 µm in length, characteristic for *Arcobacter* and

related bacteria, were observed. The organism grew aerobically, microaerobically, and anaerobically on agar plates and used lactate, formate, malate, acetate, and glutamate as electron donors, but not succinate, fumarate, citrate, glycolate, methanol, ethanol, glucose, or fructose. Nitrate, fumarate, and oxygen, but not sulfate, sulfite, or thiosulfate, were used as electron acceptors. Its nearest relative was *A. nitrofigilis.* The GenBank accession number of the 16S rRNA gene sequence of this strain is L42994.

Snaidr et al. (1997) investigated the bacterial community structure of activated sludge of a large municipal wastewater treatment plant by cloning and sequencing of PCR-amplified 16S rRNA genes. Representatives of the genus *Arcobacter* were present in 4% of the activated sludge samples examined. These uncultured organisms were observed in sludge samples by *in situ* hybridization with fluorescently labeled oligonucleotide probes and had the typical *Arcobacter* morphology: slender, curved to spiral rods, 0.8 × 2–3 μm. Analysis of 16S rRNA gene fragments (some of which were nearly complete) revealed *A. cryaerophilus* as the closest neighbor.

Genus III. **Sulfurospirillum** *Schumacher, Kroneck, and Pfennig 1993, 188^{VP} (Effective publication: Schumacher, Kroneck and Pfennig 1992, 291) emend. Finster, Liesack and Tindall 1997d, 1216*

JOHN F. STOLZ, RONALD S. OREMLAND, BRUCE J. PASTER, FLOYD E. DEWHIRST AND PETER VANDAMME

Sul.fu.ro.spi.ril′ lum. L. n. *sulfur* sulfur; Gr. n. *spira* a spiral; M.L. neut. n. *Sulfurospirillum* a spirillum that reduces elemental sulfur.

Slender, vibrioid to spirally curved rods, 0.1–0.5 × 1.0–3 μm. May form helical chains of two or more cells. Motile by polar flagella. Gram negative. Nonsporeforming. **Microaerobic, with respiratory oxidation of succinate, fumarate, malate, lactate, or pyruvate, but not acetate.** Oxidase positive. Carbohydrates are not oxidized or fermented. **Reduces S^0. Fumarate may be fermented under anoxic conditions.** Free living, found in freshwater and marine environments. Temperature growth range from 8 to 36°C. Based on 16S rRNA gene sequence comparisons, *Sulfurospirillum* falls in the family *Campylobacteraceae*, which belongs in the *Epsilonproteobacteria.*

Menaquinone-6, a methyl-substituted menaquinone-6 (referred to as thermoplasmaquinon-6), and **menaquinone-5** have been reported as respiratory quinones in *Sulfurospirillum deleyianum* (Collins and Widdel, 1986).

The mol% G + C of the DNA is: 32–42.

Type species: **Sulfurospirillum deleyianum** Schumacher, Kroneck, and Pfennig 1993, 188 (Effective publication: Schumacher, Kroneck and Pfennig 1992, 292.)

FURTHER DESCRIPTIVE INFORMATION

The members of the genus *Sulfurospirillum* are microaerobic sulfur reducers but exhibit metabolic versatility. *S. barnesii* has the distinction of being able to utilize selenate and, along with *S. arsenophilum*, arsenate as electron acceptors. This versatility is reflected in protein content. Zöphel et al. (1988, 1991) have identified NiFe hydrogenase, menaquinone (MK-6), a flexirubin-like pigment, fumarate reductase, and sulfur oxidoreductase in *S. deleyianum.* A pentaheme cytochrome *c* nitrate reducatase has also been purified from *S. deleyianum* (Schumacher and Kroneck 1991; Schumacher et al., 1992, 1994) and its crystal structure determined (Einsle et al., 1999). Finster et al. (1997d) detected the presence of *b* and *c* type cytochromes in *S. arcachonense.* Stolz et al. (1997) showed that protein composition, cytochrome content, and enzyme activity were affected by the electron acceptor on which cells of *S. barnesii* were grown. At least two types of cytochrome *c* (including nitrite reductase) and two types of cytochrome *b* were found associated with membrane fractions. Enzyme activities for nitrate, thiosulfate, fumarate, and selenate reduction were induced by their respective substrates (Stolz et al., 1997). Arsenate reductase activity was constitutive in washed cell suspensions (Laverman et al., 1995) and membrane fractions (D.K. Newman, personal communication). The respiratory arsenate reductase from *S. barnesii* has been purified and characterized (D.K. Newman personal communication).

ENRICHMENT AND ISOLATION PROCEDURES

There is no simple formulation for the isolation and culture of *Sulfurospirillum* species, since both freshwater and marine strains have been described and different enrichment strategies were used for their isolation. The type species, *S. deleyianum*, was isolated from an anaerobic enrichment culture for *Desulfuromonas* in which acetate was the electron donor and S^0 was the acceptor (Wolfe and Pfennig, 1977). *S. arcachonense* was enriched in medium formulated for formate-utilizing sulfur reducers (Finster et al., 1997d). This species has an obligate requirement for sodium and magnesium chloride. *S. barnesii* was isolated from enrichments using agar plates containing a minimal salts medium with 20 mM acetate and 20 mM selenate, which were incubated in the presence of hydrogen (Oremland et al., 1994). The pure culture was subsequently grown with lactate as the electron donor. *S. arsenophilum* was enriched for by using arsenate as the terminal electron acceptor (Ahmann et al., 1994).

The medium for routine growth of *S. barnesii* as modified from Oremland et al. (1994) in Stolz et al. (1997), contains (per liter): K_2HPO_4, 0.225 g; KH_2PO_4, 0.225 g; NaCl, 0.46 g; $(NH_4)_2SO_4$, 0.225 g; $MgSO_4 \cdot 7H_2O$, 0.117 g; yeast extract, 1 g; sodium lactate, 2.24 g; $NaHCO_3$, 4.2 g; $Na_2S \cdot 9H_2O$, 0.1 g; trace element solution, 10 ml; vitamin solution, 10 ml; plus the addition of the electron acceptor such as Na_2SeO_4, 3.78 g. Cysteine-HCl (0.1 g/l) may be added as a reducing agent (Oremland et al., 1994). The pH is adjusted to 7.3 prior to autoclaving. The vitamin solution, lactate, reducing agent, and bicarbonate may be filter sterilized and added separately (Oremland et al., 1994). The trace element solution contains (per liter): nitrilotriacetic acid, 1.5 g; $MgSO_4 \cdot 7H_2O$, 3 g; $MnSO_4 \cdot H_2O$, 0.5 g; NaCl, 1.0 g; $FeSO_4 \cdot 7H_2O$, 0.1 g; $CaCl_2 \cdot 2H_2O$, 0.1 g; $CoCl_2 \cdot 6H_2O$, 0.1 g; ZnCl, 0.13 g; $CuSO_4 \cdot 2H_2O$, 0.01 g; $AlK(SO_4)_2 \cdot 12H_2O$, 0.01 g; H_3BO_3, 0.01 g, $Na_2MoO_4 \cdot 2H_2O$, 0.025 g; $NiCl_2 \cdot 6H_2O$, 0.024 g; and $Na_2WO_4 \cdot 2H_2O$, 0.025 g. The vitamin mixture contains (per liter): biotin, 2 mg; folic acid, 2 mg; pyridoxine-HCl, 10 mg; riboflavin, 5 mg; thiamine, 5 mg; nicotinic acid, 5 mg; pantothenic acid, 5

mg; B_{12}, 0.1 mg; *p*-aminobenzoic acid, 5 mg; and thioctic acid, 5 mg. The liquid medium is dispensed in crimped septum-sealed tubes or bottles (125 ml) and degassed with N_2/CO_2 (80:20) for 5 minutes. The headspace is then degassed for 1 minute and the vessels sealed, crimped, and autoclaved.

Maintenance Procedures

Cells can be preserved by lyophilization (e.g., ATCC stocks) or in glycerol stocks at −20°C.

Differentiation of the genus *Sulfurospirillum* from other genera

Members of the genera *Arcobacter* and *Campylobacter* are closely related to species of *Sulfurospirillum*. The members of the genus *Sulfurospirillum* are free-living, nonpathogenic, sulfur respirers. They are further distinguished from *Arcobacter* in that all four species grow at 25°C but don' t grow at oxygen concentrations above 4%. Although they share many physiological characteristics with *Campylobacter*, it is clear from phylogenetic analysis that they form their own distinct clade (Fig. BXII.ε.4).

Taxonomic Comments

Comparative 16S rRNA gene sequence analysis has shown that members of the genus *Sulfurospirillum* form a distinct clade separate from species of the genera *Campylobacter* and *Arcobacter* (Finster et al., 1997d; Stolz et al., 1999). The *Sulfurospirillum* species fall in the family *Campylobacteraceae*, which belongs in the *Epsilonproteobacteria* (see Fig. BXII.ε.4). DNA–DNA hybridization studies confirmed that *S. barnesii*, *S. arsenophilum*, and *S. deleyianum* are separate species with DNA relatedness levels between the species ranging from 31 to 53% (Stolz et al., 1999).

Wolfe, R.S. and N. Pfennig. 1977. Reduction of sulfur by spirillum 5175 and syntrophism with *Chlorobium*. Appl. Environ. Microbiol. *33*: 427–433.

Differentiation of the species of the genus *Sulfurospirillum*

Characteristics useful in distinguishing the four named species of the genus *Sulfurospirillum* are listed in Table BXII.ε.4. *S. barnesii* can be distinguished from *S. deleyianum* by its ability to respire arsenate and selenate, pH and salinity optima, use of lactate as an electron donor, and the inability to use sulfite as an electron acceptor. *S. arsenophilum* is the smallest of the species and couples the reduction of arsenate to the complete oxidation of lactate to CO_2. It does not, however, respire selenate. *S. arcachonense* is the sole marine strain, has a lower mol% G + C content of the DNA, and respires only oxygen and elemental sulfur.

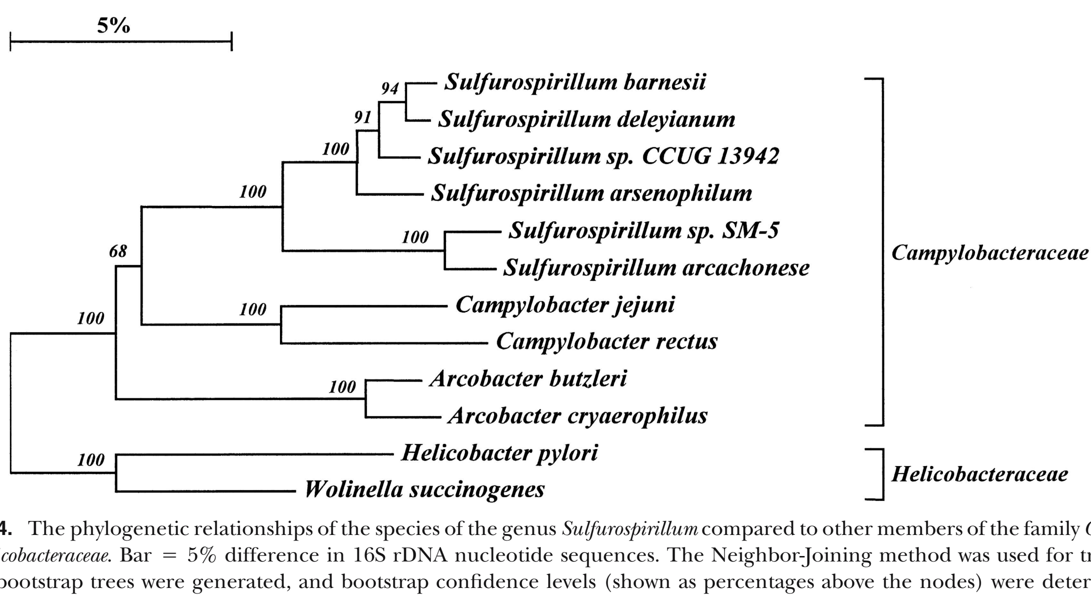

FIGURE BXII.ε.4. The phylogenetic relationships of the species of the genus *Sulfurospirillum* compared to other members of the family *Campylobacteraceae* and family *Helicobacteraceae*. Bar = 5% difference in 16S rDNA nucleotide sequences. The Neighbor-Joining method was used for tree construction. One hundred bootstrap trees were generated, and bootstrap confidence levels (shown as percentages above the nodes) were determined.

List of species of the genus Sulfurospirillum

1. **Sulfurospirillum deleyianum** Schumacher, Kroneck and Pfennig 1993, 188[VP] (Effective publication: Schumacher, Kroneck and Pfennig 1992, 292.)
de.ley.ia′ num. M.L. neut. n. *deleyianum* named after J. De Ley, for his contributions to genetic analysis in bacterial systematics.

Slender, vibrioid to spirally curved rods, 0.3–0.5 × 1.0–3 μm. Colonies in deep agar cultures are lens-shaped with a yellowish color due to the presence of a flexirubin-type pigment. Anoxic growth occurs with hydrogen or formate as electron donor; acetate and hydrogen carbonate as the carbon source; and nitrate, nitrite, sulfite, thiosulfate, S^0, fumarate, malate, and aspartate as electron acceptors. Sulfate is not reduced. S^0 is reduced to sulfide. Nitrate and nitrite are reduced to ammonia. Fumarate and malate can be fermented.

Microaerobic growth occurs with 1–4% oxygen, utilizing succinate, fumarate, malate, aspartate, pyruvate, oxoglutarate, and oxaloacetate as substrates. Glycerol and acetate are not oxidized.

Exogenous source of reduced sulfur needed. No vitamins or amino acids required. Grows at temperatures from 20 to 36°C, but not at 42°C.

Isolated from anoxic mud from a forest pond near Heiningen, Germany.

The mol% G + C of the DNA is: 38.4 (T_m), 40.6 (HPLC).

Type strain: Spirillum 5175, ATCC 51133, DSM 6946.

GenBank accession number (16S rRNA): Y13671.

2. **Sulfurospirillum arcachonense** Finster, Liesack and Tindall 1997d, 1216[VP]
ar.ca.cho.nen′ se. M.L. adj. *arcachonense* pertaining to the city of Arcachon, France, from where the strain was isolated.

Curved cells 0.3 × 1–2.5 μm. Colonies in deep agar are white, round, and filamentous when grown on S^0. Colonies are lens-shaped and yellowish-brown when grown with oxygen or fumarate. Temperature range is 8–30°C with optimal growth at 26°C. Grows with 0.6–4% NaCl and at least 0.1% $MgCl_2 \cdot 6H_2O$ is required.

Microaerobic growth occurs with up to 15% oxygen when agitated. Oxidase positive. Oxygen and S^0 can be used as an electron acceptor. Formate, acetate, proprionate, succinate, alanine, fumarate, lactate, α-ketoglutarate, citrate, malate, and yeast extract are oxidized with oxygen. Hydrogen, formate, lactate, pyruvate, α-ketoglutarate, glutarate, and yeast extract can be oxidized with S^0 as the electron acceptor.

Fatty acid composition $C_{14:0}$ (2.7%), $C_{14:1}$ (3.2%), $C_{16:0}$ (31.0%), $C_{16:1}$ (40.8%), $C_{18:0}$ (20.8%), and $C_{18:1}$ (0.6%), with $C_{15:0}$, $C_{17:0}$, and $C_{14:0\ 3OH}$ in trace amounts. Polar lipids are phosphatidylglycerol, phophatidylethanolamine, and lysophosophatidylethanolamine.

Isolated from oxidized surface sediment in an intertidal mud flat near Archachon, France.

The mol% G + C of the DNA is: 32 (HPLC).

Type strain: F1F6, DSM 9755.

GenBank accession number (16S rRNA): Y11561.

3. **Sulfurospirillum arsenophilum** Stolz, Ellis, Switzer Blum, Ahmann, Lovley and Oremland 1999, 1179[VP]
ar.sen.o′phi.lum. L. v. *arsenicum* yellow pigment of gold; Gr. comb. form *philos* loving; N.L. adj. *arsenophilum* arsenic loving.

Vibrioid to spiral-shaped cells, 0.3 × 1–2 μm. Motile by single polar flagellum. Distinguished by the ability to respire arsenate. Grows at 20°C and as high as 30°C but not at 37°C or above. Grows in the presence of 0.1% NaCl but 1% NaCl is inhibitory. Hydrogen and formate can serve as electron donors when acetate is used as the carbon source. Lactate, pyruvate, and fumarate can be used as electron donors. Arsenate, nitrate, and fumarate can serve as terminal electron acceptors. Nitrate is reduced to ammonia. Can ferment fumarate. Isolated from arsenic-contaminated watershed sediments in eastern Massachusetts, USA.

The mol% G + C of the DNA is: 40.9 (HPLC).

Type strain: MIT-13, ATCC 700056, DSM 10659.

GenBank accession number (16S rRNA): U85964.

4. **Sulfurospirillum barnesii** Stolz, Ellis, Switzer Blum, Ahmann, Lovley and Oremland 1999, 1179[VP]
barnes′i.i. M.L. gen. n. *barnesii* of Barnes, named after I. Barnes, of the U.S. Geological Survey, who recognized the environmental significance of selenium.

Vibrioid to spiral-shaped cells, 0.3 × 1–2 μm. Motile by polar flagella. Growth optimal 33°C, pH 7.5, and 0.05% NaCl. Selenate, arsenate, thiosulfate, S^0, trimethylamine oxide, Fe(III), nitrate, fumarate, aspartate, and manganese dioxide can all be used as a terminal electron acceptor when grown under anoxic conditions with lactate as the electron donor. Capable of microaerobic growth. Selenate is reduced through selenite to elemental selenium. Nitrate is reduced to ammonium. Lactate and H_2 can serve as electron donors. When grown with hydrogen, acetate is required as the carbon source.

The periplasmic nitrate reductase (NapA) from *S. barnesii* shares a 72% identity and 91% similarity with the NapA homolog from *Campylobacter jejuni*.

SES-3 is sensitive to ampicillin (10 μg/disk), carbenicillin (100 μg/disk), tetracycline (30 μg/disk), and erythromycin (30 μg/disk), showing complete inhibition at those concentrations, but only moderately sensitive to chloramphenicol (30 μg/disk) and naladixic acid (30 μg/disk), with only a small zone of inhibition at the given concentrations.

Isolated from a selenium-contaminated Massie Slough, western Nevada, USA.

The mol% G + C of the DNA is: 40.8 (HPLC).

Type strain: SES-3, ATCC 700032, DSM 10660.

GenBank accession number (16S rRNA): AF038843 and U41564.

Other Organisms

A marine sulfur-reducing bacterium, designated strain SM-5, was isolated by Coleman et al. (1993) and implicated as the organism involved in the formation of ferrous nodules. The 16S rRNA sequence (U85965) of SM-5 indicated that it is the fifth member of the genus *Sulfurospirillum* (Lonergan et al., 1996). It has yet to be fully characterized.

A free-living strain, *Sulfurospirillum* sp. DSM 806, (CCUG 13942), that is capable of aspartate fermentation, was isolated from activated sludge (Laanbroek et al., 1977; Laanbroek and Veldkamp, 1979) and has been reassigned as a strain of *S. deleyianum*. However, phylogenetic analysis of the 16S rRNA gene sequence of this strain indicates that it may represent a separate species, most closely related to *S. deleyianum*. Growth between 15°C and 41°C, with an optimal growth temperature of 37°C.

The mol% G + C of the DNA is: 41.5 (T_m).

Family II. **Helicobacteraceae** *fam. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

He.li.co.bac.ter.a′ce.ae. M.L. masc. n. *Helicobacter* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Helicobacteraceae* the *Helicobacter* family.

The family *Helicobacteraceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Helicobacter* (type genus), *Thiovulum*, and *Wolinella*.

Microaerophilic or anaerobic. Morphologically, metabolically, and ecologically diverse. Includes human and animal pathogens.

Type genus: **Helicobacter** Goodwin, Armstrong, Chilvers, Peters, Collins, Sly, McConnell, Harper 1989a, 403,[VP] emend. Vandamme, Falsen, Rossau, Hoste, Segers, Tytgat and De Ley 1991a, 100.

Genus I. **Helicobacter** *Goodwin, Armstrong, Chilvers, Peters, Collins, Sly, McConnell, Harper 1989a, 403,VP emend. Vandamme, Falsen, Rossau, Hoste, Segers, Tytgat and De Ley 1991a, 100*

Stephen L.W. On, Adrian Lee, Jani L. O'Rourke, Floyd E. Dewhirst, Bruce J. Paster, James G. Fox and Peter Vandamme

He.li.co.bac'ter. Gr. n. *helix* a spiral; M.L. masc. n. *bacter* a staff; M.L. masc. n. *Helicobacter* a spiral rod.

Cells may be **curved, spiral, or fusiform rods**, 0.2–1.2 × 1.5–10.0 μm. **Spiral cells may be tightly or loosely wound** depending on the species, and on the age and condition of the culture examined. Cells in old cultures or those exposed to air become coccoid. Ultrastructural studies show that **periplasmic fibers may be observed on the cell surface** of a few taxa and an electron-dense glycocalyx- or capsule-like layer has been observed on the cell surface of some species. Nonsporeforming. Gram negative. **Motile with a rapid corkscrew- or slower wave-like motion** due to flagellar activity. **Multiple sheathed flagella are seen in most species**, frequently with a bipolar distribution. Typical cell morphologies of various *Helicobacter* species are shown in Figs. BXII.ε.5 and BXII.ε.6.

In the laboratory, **strains grow under microaerobic conditions at 37°C** and show a respiratory type of metabolism. **Chemoorganotrophs. Asaccharolytic when sugar catabolism is tested by standard method**; however, recent studies have indicated that **glucose oxidation occurs in at least one species (*H. pylori*)** (Chalk et al., 1994; Tomb et al., 1997). Gelatin, starch, casein, and tyrosine are not hydrolyzed. Methyl red- and Voges–Proskauer negative. **Oxidase activity in all species.** Strains of most species produce catalase. **Many species produce urease and/or alkaline phosphatase.** Pigments are not produced; bacterial growth of some species demonstrates a blue-gray hue when cultured on blood agar. **Many species are pathogenic for humans and animals. Found in the intestinal tract, oral cavity, and internal organs of man and animals.**

Internal transcribed spacers or intervening sequences have been described in the 16S ribosomal RNA genes of *H. canis* (Linton et al., 1994b), *H. typhlonius* (Franklin et al., 2001), and *H. bilis* (Fox et al., 1995). Intervening sequences have been described in the 23S rRNA gene of *H. canis*, *H. mustelae*, and *H. muridarum* (Hurtado et al., 1997). The length of intervening elements in the 16S rRNA gene ranges from 166 bp (*H. typhlonius*) to 235 bp (*H. canis*), with those found in the 23S rRNA gene ranging from 93 bp (23S rRNA spacer, *H. mustelae*) to 377 bp (*H. muridarum*).

The mol% G + C of the DNA is: 24–48.

Type species: **Helicobacter pylori** (Marshall, Royce, Annear, Goodwin, Pearman, Warren, Armstrong 1984) Goodwin, Armstrong, Chilvers, Peters, Collins, Sly, McConnell, Harper 1989a, 403 (*Campylobacter pylori* Marshall, Royce, Annear, Goodwin, Pearman, Warren, Armstrong 1984, 87.)

Further descriptive information

The genus *Helicobacter* currently comprises 23 validly published species. Two candidate (*candidatus*) species have also been proposed. At least 10 other taxa have been designated as potentially novel species. The closest phylogenetic relatives of the genus *Helicobacter* include *Wolinella* and *Thiovulum* spp., and members of the family *Campylobacteraceae* (encompassing the genera *Campylobacter*, *Arcobacter*, *Sulfurospirillum*, and the generically misnamed *Bacteroides ureolyticus*). *Helicobacter* is phylogenetically diverse in comparison with the aforementioned genera, although most species associated with the gastric tract of different animals (*H. pylori*, *H. nemestrinae*, *H. acinonychis*, *H. felis*, *H. bizzozeronii*, and *H. salomonis*) form a distinct subcluster (Fig. BXII.ε.7). Significant levels of DNA–DNA hybridization (11–52%) have been reported between (i), *H. pylori* and *H. mustelae* (Fox et al., 1989); (ii), *H. cinaedi*, *H. fennelliae*, and *H. canis* (Stanley et al., 1993b); and (iii) *H. felis*, *H. bizzozeronii*, and *H. salomonis* (Jalava et al., 1997). The DNA–DNA relatedness of *H. acinonychis*, *H. pametensis*, *H. cholecystus*, *H. muridarum*, *H. hepaticus*, *H. trogontum*, *H. bilis*, *H. aurati*, *H. canadensis*, *H. ganmani*, *H. mesocricetorum*, *H. typhlonius*, and *H. rodentium* to other species has not been determined, but numerical analysis of whole-cell protein profiles show *H. acinonychis* and *H. pylori* to be closely related (Costas et al., 1993).

Electron micrographs of thin sections of *H. pylori*, *H. mustelae*, *H. felis*, *H. muridarum*, and *H. rodentium* cells show a distinct electron-dense glycocalyx-like or capsular structure external to the cell wall unit membrane (Goodwin et al., 1989a; Paster et al., 1991; Lee et al., 1992a; Shen et al., 1997). In these species, the glycocalyx is up to 40 nm thick and has a radial periodicity of approximately 14 nm. Periplasmic fibers may be coiled around the cells of *H. felis*, *H. muridarum*, *H. bilis*, *H. trogontum*, *H. aurati*, and *"H. rappini"*. In *H. muridarum* the structure of the fibers has been determined as circular and hollow with a diameter of 28–32 nm. Electron-dense granular bodies have been observed in *H. pylori* (Bode et al., 1993) and *H. rodentium* (Shen et al., 1997). In *H. pylori* these bodies are known to be aggregates of polyphosphate and may serve as a reserve energy source.

Helicobacter species have a respiratory metabolism. By means of conventional bacteriological methods, neither oxidation nor fermentation of carbohydrates is observed. However, detailed studies of metabolic pathways in *H. pylori* have demonstrated catabolic pathways for glucose, the sole carbohydrate source. The glycolysis-gluconogenesis metabolic axis probably comprises the principal means of energy production as well as the starting point for many biosynthetic pathways. In addition, glucose may also be oxidized by means of the Entner–Doudoroff pathway (Chalk et al., 1994; Tomb et al., 1997); enzymes for the pentose phosphate pathway are also present but may be involved principally in biosynthesis. Metabolic pathways for pyruvate and the amino acids serine, alanine, arginine, and glutamine (Chalk et al., 1994; Mendz and Hazell, 1995; Tomb et al., 1997) are also extant. Sequence analysis of the whole genome of *H. pylori* indicates that the tricarboxylic acid (TCA) cycle is incomplete, the glyoxylate shunt is absent, and that several substrates, including urea and ammonia, serve as important nitrogen sources for *H. pylori* (Tomb et al., 1997). The characteristically high degree of urease production in this species probably serves both as a mechanism for survival in the acid conditions of the stomach and as a means of providing nitrogen for essential cell functions (Chalk et al., 1994). Proton translocation is mediated by dehydrogenase NDH-1, and various cytochromes. Four respiratory electron-generating dehydrogenases have also been identified.

All validated *Helicobacter* spp. grow in a microaerobic (3–7% O_2) atmosphere. No growth is observed in aerobic conditions;

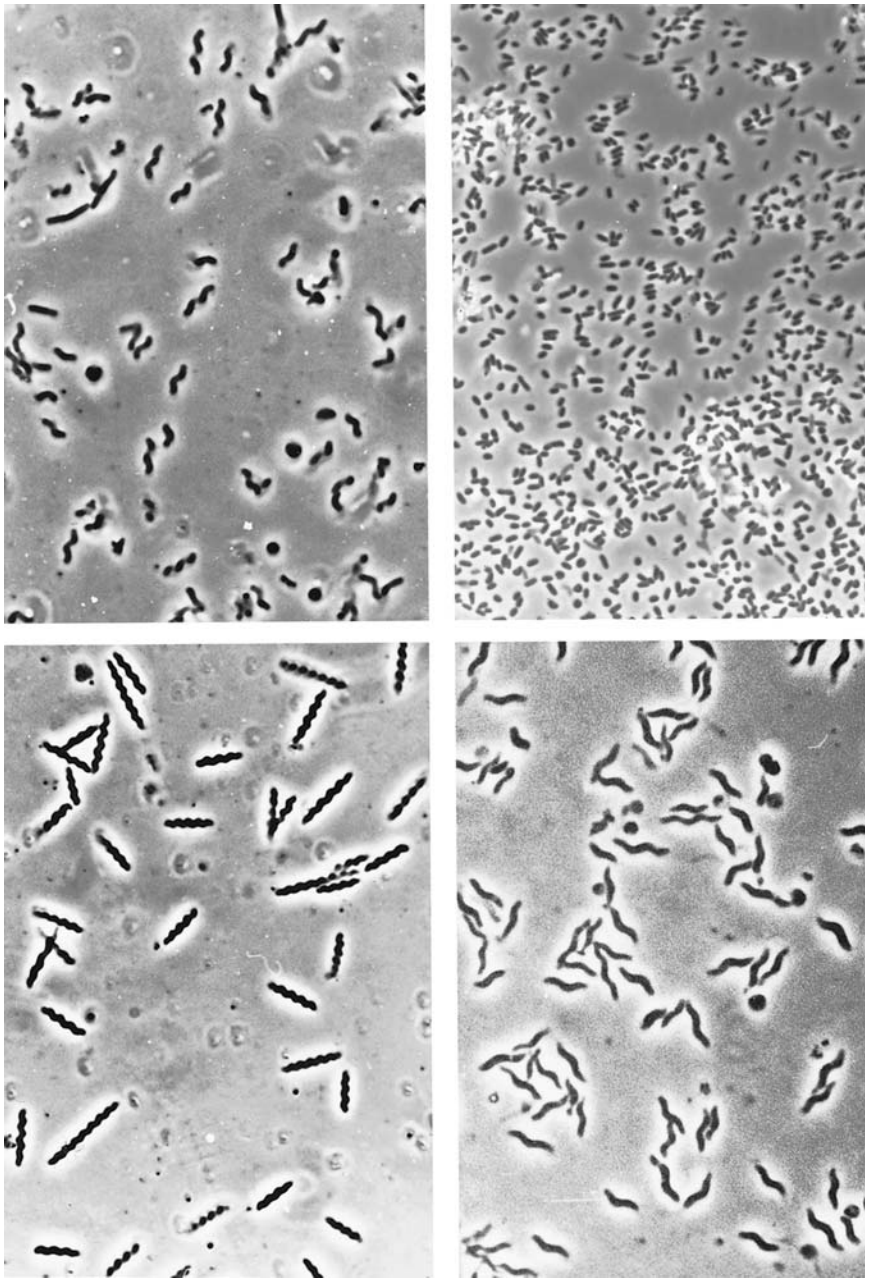

FIGURE BXII.ε.5. Phase contrast micrographs showing various morphologies of the *Helicobacter* spp. (*a*) Rod to S-shape of *H. pylori*; (*b*) short rod shape of *H. mustelae*; (*c*) tight helical shape of *H. felis*; and (*d*) S-shape of *H. muridarum*. (× 1000). (Micrographs courtesy of J. O'Rourke and A. Lee.)

some strains of certain species grow, usually poorly, in anaerobic conditions. *H. pylori*, *H. mustelae*, *H. nemestrinae*, and *H. acinonychis* do not require atmospheric hydrogen for growth in microaerobic conditions. The remaining species have all been cultured under microaerobic conditions containing hydrogen, and it is not known if this is an essential atmospheric component (as with certain *Campylobacter* species) or simply enhances growth on culture media. The metabolism of pyruvate by *H. pylori* reflects its microaerophilic nature since neither of the enzymes used in aerobic, or strictly anaerobic, processes are present. Instead, pyruvate is converted to acetyl CoA by pyruvate ferrodoxin oxidoreductase, previously found only in hyperthermophilic organisms. Oxidase activity is detected in all *Helicobacter* species; *H. pylori* is known to contain cytochromes *b* and *c* but not *a* or *d* types. Most helicobacters produce catalase. Superoxide dismutase is present in *H. pylori*.

Major cellular fatty acids reported for *Helicobacter* species include tetradecanoic acid ($C_{14:0}$); most species contain moderate-to-high levels of hexadecanoic acid ($C_{16:0}$) and also octadecanoic acid ($C_{18:1}$) (Lambert et al., 1987; Goodwin et al., 1989a; Haque et al., 1996). The presence of 19-carbon cyclopropane fatty acid ($C_{19:0\ cyclo}$) is highly species dependent but appears to be associated principally with species for which the natural ecological niche is the gastric mucosa (Haque et al., 1996). The polar lipid profile of many species is characterized by the presence of relatively high levels of various cholesteryl glucosides (between 9.7

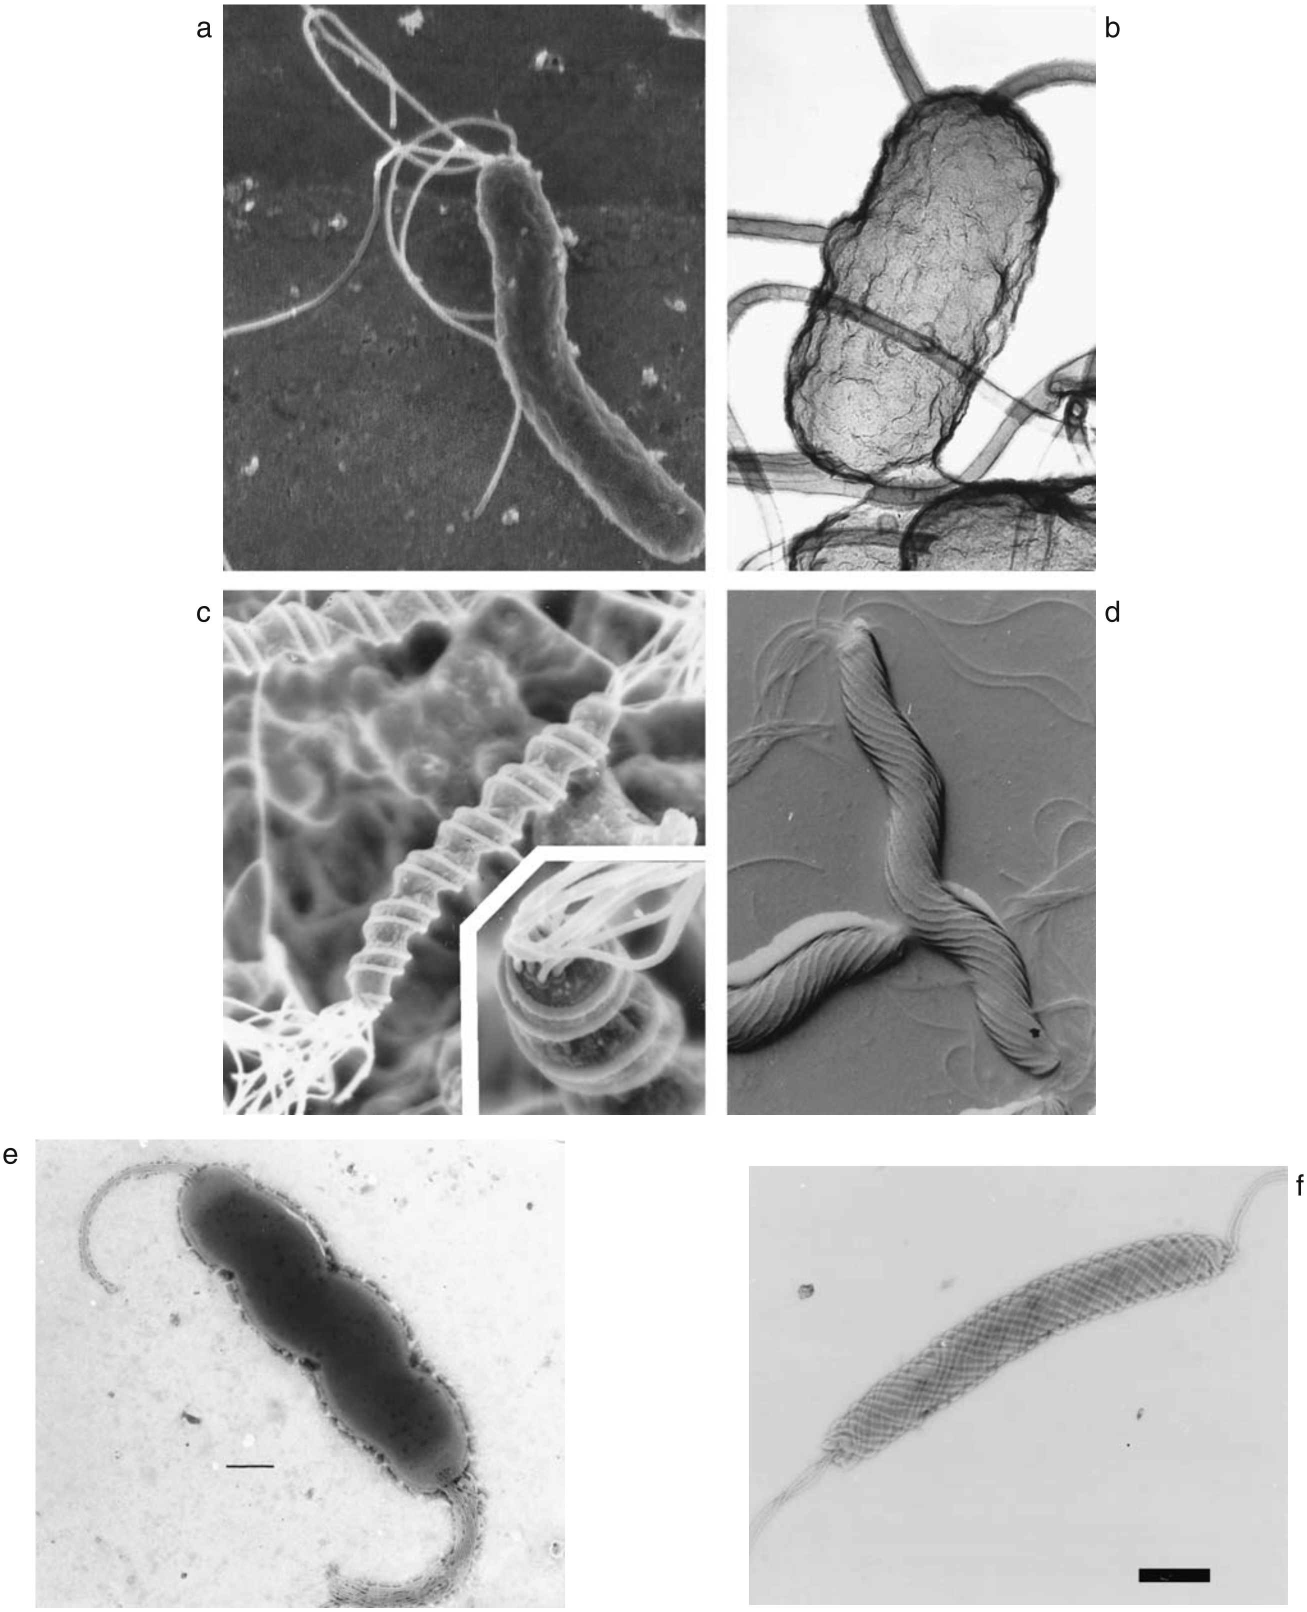

FIGURE BXII.ε.6. Detailed morphology of examples of *Helicobacter* species. (*a*) *H. pylori* showing S-shape and unipolar sheathed flagella (× 21,000). FIGURE BXII.ε.7. Phylogenetic relationships among *Helicobacter* species and close taxonomic relatives as evaluated by 16S rRNA gene sequence comparisons. Bar = 5% difference in nucleotide sequences as determined by measuring the lengths of the horizontal lines connecting two species.

and 33.1% total lipid content); these compounds have not been detected in *H. cinaedi* or *H. pametensis* (Haque et al., 1995, 1996). The isoprenoid quinone content of *H. pylori*, *H. cinaedi*, and *H. fennelliae* has been determined and includes menaquinone-6 (2-methyl-3-farnesyl-farnesyl-1,4-naphthoquinone) and an unidentified quinone (un-MK-6) as major respiratory quinones (Moss et al., 1990b).

Plasmids in the size range of 3.7 to >148 kb may be found in 35–58% of *H. pylori* strains (Tjia et al., 1987; Graham et al., 1988; Penfold et al., 1988). The plasmids do not contain any known virulence determinant. Kiehlbauch et al. (1995) demonstrated plasmids in the size range 1.8–45.0 kb in 14 of 42 strains of *H. cinaedi*, 1 of 5 strains of *H. fennelliae*, and one *H. cinaedi*/*H. fennelliae*-like strain from humans and animals. Of 14 *H. felis* strains tested, all contained more than one plasmid, and these ranged in size from 2 to >16 kb (Jalava et al., 1999a).

A wide range of phenotypic and genotypic methods for epidemiological typing of *H. pylori* has been described. These include biotyping; serotyping; whole-cell protein electrophoretic typing; plasmid profiling; restriction enzyme analysis of DNA with frequent- or rare-cutting (the latter resolved by pulsed-field gel electrophoresis, PFGE) restriction enzymes; ribotyping; restriction fragment length polymorphism (RFLP) analysis of DNA using species-specific probes; PCR-RFLP analysis of urease, vacuolating toxin (*vac*A), and adhesin genes; and other PCR-based fingerprinting methods using repetitive (REP-PCR), random (RAPD), or restriction halfsite-specific (AFLP) sequences as primers (Morgan and Owen, 1990; Owen and Desai, 1990; Simor et al., 1990; Costas et al., 1991; Foxall et al., 1992; Taylor et al., 1992a; Desai et al., 1993; Li et al., 1993; Evans et al., 1995; Forbes et al., 1995; Vandamme et al., 1995b; Simoons-Smit et al., 1996; Shortridge et al., 1997; Gibson et al., 1998; Salaun et al., 1998; van Doorn et al., 1998a, b). Application of the genetic methods in particular has demonstrated that *H. pylori* is a highly diverse species; the same genotype is usually only present within members of a single family. The extensive genetic diversity in *H. pylori* is due to a range of genetic phenomena, including point mutations, genomic rearrangements, and transformation, and a panmitic population genetic structure which has been proposed for the organism (Salaun et al., 1998). By contrast, *H. mustelae* (the species closest to *H. pylori* in terms of DNA relatedness) is genetically highly conserved, with few types discernible by biotyping, ribotyping, or RFLP analysis of genomic DNA with frequent- or rare-cutting enzymes (Morgan and Owen, 1990; Owen and Desai, 1990; Taylor et al., 1994b). *H. hepaticus* strains can be differentiated by PFGE analysis, with most strains from the United States demonstrating less diversity than European strains (Saunders et al., 1997). In addition, PCR-RFLP of the urease gene identifies just three types, indicating this gene to be highly conserved in *H. hepaticus* (Shen et al., 1998). PFGE analysis of 24 *H. felis* strains distinguished up to 20 distinct types; strains found to be indistinguishable were isolated from different animals at distinct times. Similar results for *H. felis* were obtained with plasmid profiling and ribotyping (Jalava et al., 1999a). *H. cinaedi* and *H. fennelliae* strains from humans, hamsters, cats, dogs, and macaque monkeys are differentiated by ribotyping, with strains from different hosts clearly distinct (Kiehlbauch et al., 1995).

Helicobacter species may be associated with three types of disease, generally related to their natural ecological niche. Of the species found in the gastric mucosa, *H. pylori* is well established as the leading microbiological cause of gastric and duodenal ulcers in humans (Dunn et al., 1997). *H. pylori* infection is also associated with the development of atrophic gastritis, and subsequent progression to gastric cancer; MALT lymphoma and adenocarcinoma of the distal stomach; and Ménétrièr' s disease, a rare disorder in which the gastric folds become hypertrophic. An association of *H. pylori* with nonulcer dyspepsia has been suggested but as yet remains unproven. The O-specific chain of the lipopolysaccharide in *H. pylori* mimics Lewis blood group antigens of the host and may serve as an immunoprotective "camouflage" mechanism or may contribute directly to the patho-

genesis of autoimmune disease. The CagA protein is another major antigenic component in many strains. CagA is 120–140 kDa in size and serves as a marker for the *cag* pathogenicity island, which is ca. 35–40 kb in size. Although the function of the CagA protein and most of the *cag* pathogenicity island has not yet been determined, *cagA*-positive strains have been correlated with an increased risk of development of duodenal ulcers and adenocarcinoma of the distal stomach (Dunn et al., 1997).

Of the other gastric species, *H. mustelae*, *H. acinonychis*, *H. felis*, and *H. bizzozeronii* have all been observed in natural and/or experimental infections in host animals showing signs of gastric disease (Lee et al. 1993; Skirrow, 1994; Jalava et al., 1998). *H. felis* has been occasionally described as a possible cause of human gastritis (Germani et al., 1997; also see comments in *H. felis* species description), while a cultured strain of *"Helicobacter heilmannii"* (Andersen et al., 1996), a taxon associated with approximately 1% of human gastritis cases (Dunn et al., 1997), has been identified as *H. bizzozeronii* (Jalava et al., 2001). Experimental infection of mice with *H. muridarum* (a urease-producing species normally found in murine intestinal mucosa) also induces atrophic gastritis in aging animals (Lee et al., 1993).

Several species associated with the lower gastrointestinal tract (including *H. pullorum*, *H. fennelliae*, *H. cinaedi*, *H. canis*, and *"H. rappini"*) have been isolated from cases of gastroenteritis in humans and/or animals (Skirrow, 1994; On, 1996); severe diarrhea in laboratory mice co-infected with *H. bilis* and *H. rodentium* has been noted (Shen et al., 1997). Inflammatory bowel disease in immunodeficient rats has been observed with natural and/or experimental infections using *H. bilis* and *H. typhlonius* (Haines et al., 1998; Fox et al., 1999). In immunocompromised human patients, complications such as septicemia and meningitis may occur. These enteric helicobacters are infrequently reported as agents of disease in humans, but their incidence could be significantly underestimated because of inadequate isolation and identification procedures (Skirrow, 1994; On, 1996).

Other enteric species (*H. hepaticus*, *H. cholecystus*, *H. bilis*, some strains of *H. pullorum*, *H. canis*, and *"H. rappini"*) have been isolated from hepatitis, cholangiofibrosis, and pancreatitis lesions in host animals (Kirkbride et al., 1985; Fox et al., 1994b, 1996a; Stanley et al., 1994b; Franklin et al., 1996). PCR-based analysis of bile and gallbladder samples from humans afflicted with chronic cholecystitis indicated the presence of *H. bilis*, *H. pullorum*, and *"H. rappini"* (Fox et al., 1998a). A soluble factor toxic to liver cells has been demonstrated in strains of *H. hepaticus*, *H. felis*, *H. acinonychis*, *H. pylori*, and *H. mustelae*, but not in *H. muridarum* or *"H. rappini"* (Taylor et al., 1995). This hepatotoxic activity may represent different cytotoxic factors produced by these species with activity against liver, and other cells.

Enrichment and Isolation Procedures

There is no ideal method for the isolation of all *Helicobacter* species, irrespective of the sample under consideration. Recovery is optimized by the concurrent use of selective and nonselective methods to examine the freshest possible samples. In particular, for species colonizing the gastric or intestinal mucosae, it is recommended that specimens be processed within 1 hour of sampling (Hänninen et al., 1996; Jalava et al., 1998). Fresh mucosal scrapings, or tissue biopsy material crushed in a small volume of suitable medium (brain heart infusion (BHI) broth + serum is often used), have proven to be suitable for the isolation of species from gastric or intestinal mucosae or extragastrointestinal tissue such as liver. Enteric species may be recovered from fecal samples and/or carcass washings by direct culture methods. Enrichment media commonly used to enhance the recovery of thermophilic *Campylobacter* species rarely have a similar effect on enteric helicobacters. *H. pametensis* was isolated by examining feces within 3 hours of collection (Seymour et al., 1994), and *H. pullorum* was only recovered from fresh, not chilled or stored, chicken carcass washings (Atabay et al., 1998b).

Selective media are frequently based upon the antibiotic supplement first described by Skirrow (1977) for the isolation of *C. jejuni* and *C. coli*, which includes vancomycin, trimethoprim, and polymixin B; amphotericin B may also be included to further restrict the growth of fungi. It is known that *H. pullorum* and some *H. pylori* strains cannot be cultured in the presence of polymixin B (Dent and McNulty, 1988; Atabay et al., 1998b). Cefsulodin has been used to replace polymixin B in some media for isolating *H. pylori* (Dent and McNulty, 1988; Tee et al., 1991). Most enteric species can be recovered on media incorporating cefoperazone, amphotericin B, and vancomycin (Burnens et al., 1993).

A range of solid media has been evaluated for isolating *H. pylori* (Hachem et al., 1995). BHI and *Brucella* agars supplemented with 5–10% blood are often used for isolating this, and other *Helicobacter* species. However, *Brucella* agar does not support the growth of *H. bizzozeronii* (Jalava et al., 1998), and certain formulations contain bisulfite compounds that inhibit the growth of *H. pylori* (Hawrylik et al., 1994). Nonselective growth media may be inoculated directly with the test sample, but this procedure normally results in an overgrowth of contaminating microflora. Instead, the sample may be passed through membrane filters with a pore size of 0.45, 0.65, or 0.8 μm onto the medium of choice. All plate cultures must be incubated for 3–10 d at 37°C under microaerobic conditions typically containing $CO_2/N_2/O_2/H_2$ (5:88:5:2). The latter enhances, and is sometimes essential for, helicobacterial growth. The isolation of several species, notably *H. bizzozeronii* and *H. salomonis*, has proven to be especially problematic. Special recommendations for the growth of these species, including the periodic addition of nutrient broth to plate cultures to inhibit surface dehydration (Jalava et al., 1998) have been made.

Maintenance Procedures

Stock cultures of *Helicobacter* species can be maintained under microaerobic conditions by transfer onto common blood agar bases every 4–7 d. Cultures may be stored for many years by freezing at −80°C, or in liquid nitrogen. Cryoprotective agents such as 10% glycerol or DMSO should be added to cultures before freezing, and heavy cell concentrations should be used. Many species can also be stored as lyophilized samples in 5% inositol serum, but more suitable methods for preserving fastidious species (*H. felis*, *H. muridarum*, *H. bizzozeronii*, *H. salomonis*) by this method require development.

Taxonomic Comments

The formation of the genus *Helicobacter* from the reclassification of *Campylobacter pylori* and *C. mustelae* by Goodwin et al. (1989a) reconciled substantial phenotypic and phylogenetic differences observed between these two species and members of the genera *Campylobacter* and *Wolinella*. The subsequent transfer of *C. cinaedi* and *C. fennelliae* to *Helicobacter* by Vandamme et al. (1991a) was also made on the basis of polyphasic taxonomic data and established the ecological divergence of the genus. Since this time, the classification of *Helicobacter* has been based principally on

phylogenetic relationships as determined by analyses of the 16S rRNA gene. In phylogenetic terms, the genus is readily distinguished from other members of the *Epsilonproteobacteria*. Moreover, the natural ecological niche of helicobacters appears to be fairly conserved (the gastric tract or lower intestine), but considerable diversity in the morphological characteristics and DNA base ratios of different species is observed.

It is feasible to propose that *Helicobacter* and the monotypic genus *Wolinella* be included in a single bacterial family. Phylogenetic analyses based upon both $T_{m(e)}$ values of DNA–rRNA hybrids and sequence comparisons of the 16S rRNA gene consistently demonstrate that *Helicobacter* and *Wolinella* are at least as closely related as members of the family *Campylobacteraceae* (*Campylobacter*, *Arcobacter*, *Sulfurospirillum*, and the generically misnamed *Bacteroides ureolyticus*) (see Fig. BXII.ε.10; Vandamme et al., 1991a). The phenotype, morphology, natural habitat and DNA base ratio of *Wolinella* and *Helicobacter* appear similarly compatible, given the diversity in the latter genus.

Phylogenetic distinctions aside, there are presently no absolute defining features for the genus *Helicobacter* that distinguish it from the genus *Campylobacter*. Early studies indicated that flagellar sheathing and resistance to polymixin B were consistent features and served to differentiate helicobacters from campylobacters (Han et al., 1989; Burnens and Nicolet, 1993). It is now clear that certain species (*H. pullorum*, *H. rodentium*, *H. canadensis*, *H. ganmani*, and *H. mesocricetorum*) give atypical results in at least one of these unifying characteristics. Other chemotaxonomic markers (cellular fatty acid composition, presence of steryl glucosides) similarly serve as useful distinguishing features for most, but not all, species, and there is a need for phenotypic characters that accurately reflect the overall phylogenetic coherence of the genus.

Elucidation of the whole genome sequence of *H. pylori*, combined with the intensive and wide-ranging studies made on this medically important organism, demonstrated its ability to metabolize glucose. This was a surprising discovery, since by all conventional methods no such activity has been detected. This finding may clarify, or further confound, the issue of generic consistency. It is not yet known whether similar metabolic pathways for glucose utilization are extant in other *Helicobacter* species. If present, then the characteristic would serve as an important taxonomic marker for the genus; if absent in certain, or all other, species, then the characteristics of the genus become even more divergent. It is however significant that comparison of the inferred metabolic pathways for *C. jejuni* from whole-genome sequence analysis (*C. jejuni* sequencing group at the Sanger Center, 1998) with those for *H. pylori* (Tomb et al., 1997) indicate that these phylogenetically related, but distinct bacteria share several important features, including elements of the TCA cycle and gluconeogenesis pathways. Thus, it is possible that all helicobacters, and not just *H. pylori*, have the ability to metabolize glucose. Furthermore, comparison of the whole-genome sequences of *C. jejuni* and *H. pylori* suggests salient differences in the metabolic pathways of the two species. For example, the Entner–Doudoroff pathway is absent in *C. jejuni*, and only *C. jejuni* appears able to operate a complete tricarboxylic acid cycle (Kelly, 2001). Such features may eventually prove useful characteristics for distinguishing these two distinct, but highly related genera.

There are a number of outstanding nomenclatural and taxonomic problems, principally at the species level. Strains described as *"Flexispira rappini"* are clearly *Helicobacter* species by phylogenetic analysis, and several workers already refer to these bacteria as *"H. rappini"*. However, the taxonomic status of *"H. rappini"* requires clarification. The name *"Flexispira rappini"* was first proposed by Bryner et al. (1986) for a group of ultrastructurally distinct, urease-producing strains isolated from aborted lambs, dog, and human feces, and subsequently from pig intestines (Bryner et al., 1986; Bryner, 1987). Archer et al. (1988) examined human, canine, and ovine strains using biochemical tests and whole-cell protein analysis and concluded all strains were similar, although some distinction between the ovine strain and fecal isolates was made. Since these first studies, strains have been identified as *"H. rappini"* by 16S rRNA gene sequence comparisons, despite notable morphologic and/or phenotypic differences (Tee et al., 1998). Such results may be due, in part, to errors made in the 16S rRNA gene sequence determination for a human strain often used as a study reference (ATCC 43879 CCUG 23435, GenBank no. M88137) as a consequence of strain mislabeling. This error has since been corrected by one of us (F.E. Dewhirst, personal communication). A subsequent study using the corrected sequence of M88137 (=M88138), and that of a different pig strain (ATCC 43968, GenBank no. U96300), shows that these strains are 95.6% similar by 16S rRNA gene sequence comparison and assigns these strains to radically different branches in a phylogenetic analysis (Shen et al., 1997). Considerable diversity in the 16S rRNA gene sequence of 36 strains exhibiting *"H. rappini"*-like morphology has since been observed (Dewhirst et al., 2000a). In addition, *"H. rappini"*-like strains from canine gastric mucosa resemble, but are phenotypically different from CCUG 23435, including their protein electrophoresis profiles (Jalava et al., 1998). Moreover, *H. bilis*, *H. aurati*, and *H. trogontum* bear a striking ultrastructural and phenotypic resemblance to *"H. rappini"* strains studied by Bryner et al. (1986), Bryner (1987), and Jalava et al. (1998). A polyphasic investigation of the relationships between all these strains is required to clarify the taxonomic position and status of this complex group. Available data strongly suggest that urease-positive bacteria with the complex, fusiform ultrastructure first associated with this taxon represent more than one species, of which three (*H. bilis*, *H aurati*, and *H. trogontum*) have standing in nomenclature. However, the phylogenetic classification of many *"H. rappini"* strains, along with the formal description of *"H. rappini"* for one of the major groups observed (Dewhirst et al., 2000a), will provide a useful basis for examining interstrain relationships in more detail.

Similar nomenclatural and taxonomic problems exist for the group of gastric bacteria often referred to as *"Gastrospirillum"* spp. and/or *"H. heilmannii"* (hereafter referred to as gastrospirilla). These organisms are principally characterized by their cell morphology (large, tightly coiled rods) and such cells have been observed in gastric biopsies of many hosts including humans, cats, dogs, pigs, monkeys, rats, and various captive exotic carnivores (Salomon, 1898; McNulty et al., 1989; Mendes et al., 1990; Jakob et al., 1997; Jalava et al., 1998). Gastrospirilla are also typified by their highly fastidious growth requirements, and much of the uncertainty concerning their taxonomic status has arisen because most investigators have failed to culture the strains *in vitro*. Phylogenetic analyses clearly identify all gastrospirilla as helicobacters, with names proposed for pig (*"Gastrospirillum suis"*, *Candidatus* Helicobacter suis), lemur (*"G. lemur"*), and human (either *"G. hominis"*, of which two phylogenetically distinct types have been described, or *"H. heilmannii"*) strains (McNulty et al. 1989; Mendes et al., 1990; Dewhirst et al., 1992; Solnick et al., 1993). The taxonomic status of these strains as distinct species

has been largely assumed by the position of their 16S rDNA sequences in phylogenetic trees. However, studies of successfully cultured gastrospirilla-like strains from cats, dogs, and a human, indicate complex taxonomic relationships among these strains. *H. felis*, *H. bizzozeronii*, and *H. salomonis* represent a group of highly related species from domestic pets, with 16S rRNA gene sequences showing greater variation between strains of a single species than comparable differences between strains of different species (Jalava et al., 1998). Subsequent phylogenetic analysis clearly identifies these validly described species as being related to the two sequences representing *"G. hominis"*, although the latter are somewhat distinct from the *H. felis–H. bizzozeronii–H. salomonis* group. Nevertheless, a study examining phenotypic characters, protein profiles, and DNA relatedness of a human strain initially described as *"H. heilmannii"* (Andersen et al., 1996) has identified the isolate as *H. bizzozeronii* (Jalava et al., 1999c). As the former name has no standing in nomenclature, this human isolate should be named *H. bizzozeronii*. It should not however be assumed that all human gastrospirilla are in fact *H. bizzozeronii*. The 16S rRNA gene sequence of *"H. heilmannii"* type 1 (Solnick et al., 1993) is 95.9– 97.0% similar to those of the *H. felis–H. bizzozeronii–H. salomonis* group and *"H. heilmannii"* type 2 (Solnick et al., 1993), but 99.5% similar to *"G. suis"* from pigs (Mendes et al., 1994). The relatively low level of phylogenetic similarity between *"H. heilmannii"* type 1 and the *Helicobacter* spp. from cats and dogs suggests that *H. bizzozeronii* may represent only part of the human strains. The high degree of sequence relatedness between *"H. heilmannii"* type 1 and *"G. suis"* certainly indicates an additional animal reservoir. Nevertheless, although available data suggest that human gastrospirilla may represent more than one species, further polyphasic taxonomic studies on cultured gastrospirilla from each of the sources in which they have been observed, are required to clarify the taxonomic status of these bacteria.

In the case of many recently described or putative *Helicobacter* species, considerable weight has been placed on the position of 16S rRNA gene sequences of representative strains in phylogenetic analyses. Although this method is presently unsurpassed for determining broad evolutionary relationships, its efficacy in delineating taxa at or below the species level is now known to be limited (Stackebrandt and Goebel, 1994; Clayton et al., 1995). Recent studies on *H. bizzozeronii*, *H. salomonis*, and *H. felis* have shown that these taxa cannot be unequivocally separated by 16S rRNA gene sequence analysis (Jalava et al., 1997) although their status as discrete, albeit closely related, species is substantiated by phenotypic and genotypic data (Jalava et al., 1997, 1998). The identification of *Helicobacter* sp. strain Mainz and *"H. westmeadii"* as *H. cinaedi* isolates (Vandamme et al., 2000), and of a *"H. heilmannii"* isolate as *H. bizzozeronii* (Jalava et al., 1999c), is similarly relevant, since these taxa have been postulated as potentially novel species on the basis of 16S rRNA gene sequence data. It is impossible to predict whether the taxonomic status of other helicobacters for which extensive polyphasic characterization has not been performed will be similarly amended. It is however clear that descriptions of putative new species should consider the present view that interstrain relationships should be circumscribed by means of a polyphasic taxonomic analysis. The provision of a set of minimal standards for describing new *Helicobacter* species will also prove valuable for future descriptions (Dewhirst et al., 2000b).

Since the initial revision of this chapter, *Candidatus* Helicobacter bovis and *Candidatus* H. suis have been described (De Groote et al., 1999a, b). These are noteworthy since they represent the first descriptions of *Helicobacter* species assigned to the provisional taxonomic status *Candidatus*. The designation *Candidatus* was first proposed by Murray and Schleifer (1994) to record the properties of putative new species of procaryotes that cannot be cultured at present under standard laboratory conditions. This proposal was recommended for implementation by the International Committee on Systematic Bacteriology (ICSB) and formal guidelines for its practice published (Murray and Stackebrandt, 1995). The provisional *Helicobacter* species listed were described in accordance with these guidelines.

Acknowledgments

We gratefully thank all those who allowed the citation of data that were, at the time of writing, unpublished. K. Jalava (University of Helsinki, Finland) is also thanked for the electron micrograph of *H. salomonis*.

Differentiation of the species of the genus *Helicobacter*

Phenotypic characteristics useful for differentiating the validly described *Helicobacter* species are given in Table BXII.ε.5. It should be noted that *H. pullorum* bears a close resemblance to certain *Campylobacter* species (notably *C. lari*), with which it also shows similarities in host range and disease associations. Several pairs of species, notably *H. pylori* and *H. acinonychis*, and *H. felis* and *H. bizzozeronii*, cannot be differentiated with conventional phenotypic tests.

A variety of different methods has been applied to identify *Helicobacter* species (reviewed by On, 1996). Of the phenotypic methods described thus far, standardized whole-cell protein profile analysis has proven to be consistently effective in species identification (Costas et al., 1993; Jalava et al., 1998). Of the genetic methods described to date, restriction profile analysis of PCR amplicons derived from the 23S rRNA gene (Hurtado and Owen, 1997b) was shown to differentiate 13 species (including *"H. rappini"*) but could not unequivocally discriminate *H. felis*, *H. bizzozeronii*, and *H. salomonis* from each other (Jalava et al., 1999b). Specific oligonucleotide probes and/or PCR assays for *H. pametensis* (and the related, but unnamed taxa *Helicobacter* bird-B and bird-C), *H. pylori*, *H. hepaticus*, *H. pullorum*, *H. bilis*, *H. trogontum*, and *H. canis* (Dewhirst et al., 1994; Fox et al., 1995; Mendes et al., 1996; On, 1996) have been described. It should be noted that, due to constant developments in the taxonomy of *Helicobacter*, none of the aforementioned genetic methods have been fully evaluated for all species thus far described.

List of species of the genus Helicobacter

1. **Helicobacter pylori** (Marshall, Royce, Annear, Goodwin, Pearman, Warren, Armstrong 1984) Goodwin, Armstrong, Chilvers, Peters, Collins, Sly, McConnell, Harper 1989a, 403[VP] (*Campylobacter pylori* Marshall, Royce, Annear, Goodwin, Pearman, Warren, Armstrong 1984, 87.)
py.lo′ri. Gr. masc. n. *pyloros* gate keeper; L. masc. n. *pylorus* lower part of the stomach; L. gen. n. *pylori* of the pylorus.

Cells are helical or curved, 2.5–5 × 0.5 μm, with rounded ends and spiral periodicity. Polyphosphate granules seen in cells under certain conditions (Bode et al., 1993). Cells transform to coccoid forms with age (Jones et al., 1985). Motile by means of four to seven unipolar sheathed flagella with distinctive terminal bulbs. Nutritionally fastidious, translucent colonies 1–2 mm in diameter are produced on blood agar bases. Will grow in defined media (Reynolds and Penn, 1994) or liquid culture using brain–heart infusion or *Brucella* broth, growth enhanced by shaking the culture and the addition of serum or cyclodextrins (Olivieri et al., 1993). Grows microaerophilically and in the presence of air enriched with 10% CO_2. Some strains grow poorly at 30°C and no growth is obtained at 25°C. A few strains from rhesus monkeys grow at 42°C. Initial growth obtained after 4–5 d but will grow in 2 d on subsequent subculture. No growth in the presence of 1% glycine and 1.5% NaCl. Urease, catalase, and oxidase positive. Does not reduce nitrates or hydrolyze hippurate. Exhibits leucine arylamidase, alkaline phosphatase, and gamma-glutamyl-transpeptidase activities. Major fatty acids are tetradecanoic acid ($C_{14:0}$) and 19-carbon cyclopropane fatty acid ($C_{19:0\ cyclo}$) (Goodwin et al., 1989b). The major isoprenoid is MK-6; methylated MK-6 is absent (Moss et al., 1990b). Has a requirement for amino acids (arginine, histidine, isoleucine, leucine, methionine, phenylalanine, and valine). Some strains require alanine or serine (Nedenskov, 1994; Reynolds and Penn, 1994). The amino acids may be deaminated to provide carbon and energy to the cell. Amino acids may be the primary energy source of the species. Excess amine nitrogen may be removed from the cell via the urea cycle. Limited metabolism of carbohydrates. Able to take up and metabolize glucose via the pentose phosphate and the Entner–Doudoroff pathways. Glucose may be fermented to mixed acid products or provide metabolites to the TCA (Krebs) cycle (Mendz et al., 1994). Alcohol dehydrogenase activity reported (Kaihovaara et al., 1994). May use oxygen as the terminal receptor in aerobic respiration or fumarate in anaerobic respiration (Hazell and Mendz, 1997).

Resistant to nalidixic acid, trimethoprim, sulfonamides, and vancomycin, and sensitive to penicillin, ampicillin, cephalothin, kanamycin, gentamicin, rifampin, and tetracycline. Variable resistance to metronidazole and clarithromycin. FDA-approved treatment regimens include the use of metronidazole (250 mg) and tetracycline (500 mg), together with bismuth subsalicylate (262 mg; bismuth subcitrate often used outside of the USA), all taken four times daily for 14 d, or clarithromycin (500 mg three times daily) with either omeprazole (40 mg once daily) or ranitidine bismuth citrate (400 mg twice daily) for 14 d (Dunn et al., 1997).

Strains show a high level of genetic diversity with variable genome sizes, gene order, and nucleotide sequences (Langenberg et al., 1986; Akopyanz et al., 1992; Go et al., 1996). Evidence of gene mosaicism, e.g., six possible allelic versions of the *vacA* gene (Atherton et al., 1995). However, comparison of two complete genome sequences from geographically distinct locations indicated considerable conservation at the gene level (Alm et al., 1999).

Plasmids ranging in size from 3.7 to >148 kb found in 35–58% of strains (Tjia et al., 1987; Graham et al., 1988;

Penfold et al., 1988). Bacteriophages observed (Schmid et al., 1990).

Approximately 60% of strains possess a pathogenicity island (PAI), 40 kb in size with a mol% G + C content very different from the mean chromosomal average, associated with virulence factors and found in conjunction with the *cagA* gene (Censini et al., 1996). The 31 genes of *cag* encode for a new type IV secretion system (Salmond, 1996). The genome of strain 26695 has been completely sequenced (Tomb et al., 1997). This strain has a circular genome with 1590 predicted coding regions, 1091 of them matching identified database entries. The average mol% G + C content of strain 26695 from the sequence data was 39%, with five regions within the genome showing significantly different mol% G + C compositions.

The principal reservoir of *H. pylori* is the human, with infection occurring mainly in childhood (Mitchell et al., 1992). *H. pylori* has been found in rhesus monkeys, certain macaque species, and in a closed colony of barrier-maintained cats (Fox and Lee, 1997). The latter instance appears to be a unique report in domestic pets, and human-to-animal transmission has been suggested as the most likely explanation (El-Zaatari et al., 1997). Subsequent investigations have not detected *H. pylori* in either cats (Jalava et al., 1998) or dogs (Eaton et al., 1996a) from random sources. The presence of *H. pylori* in pigs is poorly documented. However, one strain of porcine origin is widely available (NCTC 11916). It is not known if this strain is derived from an experimental or natural infection. Costas et al. (1993) determined that this pig isolate, and strains from humans and rhesus monkeys, could be discriminated by whole-cell protein profiles and that strains from each source were also phenotypically distinguishable.

Pathogenic. Widespread infection causing gastritis in all infected humans and most naturally or experimentally infected animals (monkeys, pigs, cats, dogs), but is usually asymptomatic. Symptomatic diseases include peptic ulcers and gastric malignancy. Causes up to 95% of duodenal ulcers and 70–80% of gastric ulcers in humans (Dunn et al., 1997). Classified as a class 1 carcinogen by the International Agency for Research in Cancer of the World Health Organization (Anonymous, 1994). In association with other factors such as a high-salt diet and lack of vitamin C, *H. pylori* causes the majority of cases of gastric adenocarcinoma (Correa et al., 1998). The evidence is primarily epidemiological (Forman, 1998) although gastric cancer is induced in Mongolian gerbils (Watanabe et al., 1998). Causes low-grade B-cell gastric lymphomas (MALTomas), the majority of which regress on anti-*H. pylori* therapy (Isaacson, 1996). Urease enzyme activity is an essential colonizing factor allowing survival in gastric acid (Eaton et al., 1991a; Scott et al., 1998). Motility is also essential for colonization (Eaton et al., 1992). Severity of gastritis dependent on possession of the pathogenicity island via induction of proinflammatory cytokines such as IL-8 (Crabtree, 1998). No other specific virulence factors have been conclusively defined although many strains produce a vacuolating cytotoxin (Cover, 1996). Host factors most likely contribute to pathogenesis (Lee, 1997). Infection induces autoantibody to gastric tissue (Negrini et al., 1991). Molecular mimicry observed with the LPS structure (Appelmelk et al., 1996). Lewis antigens also shown to be possible adhesins (Boren et al., 1993).

The mol% G + C of the DNA is: 36–39 (T_m).

Type strain: ATCC 43504, DSM 4867, JCM 7653, LMG 7539, NCTC 11637.

GenBank accession number (16S rRNA): Z25741, M88157, U01330; genome sequence, strain 26695: AE000511.

2. **Helicobacter acinonychis** Eaton, Dewhirst, Radin, Fox, Paster, Krakowa, Morgan 1993, 105[VP] (*Helicobacter acinonyx* (sic) Eaton, Dewhirst, Radin, Fox, Paster, Krakowa, Morgan 1993, 105.)
ac.i.non.y′ chis. L. gen. n. *acinonychis* referring to the feline species *Acinonyx jubilatus*, from which the organism was isolated.

Cells are short spiral or curved rods, 0.3 × 1.5–2.0 µm. Motile by means of 2–5 multiple sheathed flagella, which exhibit a monopolar arrangement and possess terminal bulb-like structures. Colonies on blood agar are small, round (1–2 mm in diameter), colorless, and translucent. Swarming is not observed. Strains do not grow at 37°C in anaerobic conditions. Growth obtained on blood agar media containing 32 mg/l nalidixic acid, but not 32 mg/l cephalothin, after 3 d microaerobic incubation. Alpha-hemolytic after three days growth on 5% horse blood agar. Catalase, alkaline phosphatase, and urease produced. Nitrate is not reduced.

Numerical analysis of whole-cell protein profiles and sequence analysis of the 16S rRNA gene identify an especially close relationship between *H. acinonychis* and *H. pylori* (Costas et al., 1993; Fig. BXII.ε.7). These species are phenotypically indistinguishable (On et al., 1996). DNA–DNA hybridization studies between these species have not been performed, but differences in the mol% G + C content of their DNA have been noted (Eaton et al., 1993).

Pathogenicity undetermined. Isolated from mucosal lesions in cases of severe lymphoplasmacytic gastritis in a single colony of captive cheetahs (*Acinonyx jubilatus*). Restriction endonuclease analysis of genomic DNA indicated all strains to be an outbreak clone (Eaton et al., 1991b). However, protein profiles and extensive phenotypic testing identify one of the four strains available in international culture collections to differ from the others (Costas et al., 1993; On and Holmes, 1995).

Resistant to sulfamethoxazole, trimethoprim, and vancomycin. Sensitive to penicillin, ampicillin, nitrofurazone, erythromycin, gentamicin, chlortetracycline, and chloramphenicol.

The mol% G + C of the DNA is: 29.9 (T_m).

Type strain: 90-119, ATCC 51101, CCUG 29263.

GenBank accession number (16S rRNA): M88148.

Additional Remarks: Name corrected to *H. acinonychis* by Trüper and De' Clari, 1997.

3. **Helicobacter aurati** Patterson, Schrenzel, Feng, Dewhirst, Paster, Thibodeau, Versalovic and Fox 2002, 3[VP] (Effective publication: Patterson, Schrenzel, Feng, Dewhirst, Paster, Thibodeau, Versalovic and Fox 2000, 3727.)
au.ra′ ti. L. gen. masc. n. of the golden one, named after the golden Syrian hamster, *Mesocricetus auratus*, from which it was isolated.

Cells are fusiform, 0.6 × 4–5 μm. Periplasmic fibers are coiled around the cell body, which gives a crisscross appearance to the bacterial surface. In older cultures, large coccoid forms are observed. Motile by means of tufts of 7–10 sheathed flagella in a bipolar arrangement. Culture on agar media containing 5% sheep blood or 5% fetal calf serum under microaerobic conditions does not result in single colonies; growth occurs as a thin spreading film. Catalase, urease, and γ-glutamyl transpeptidase produced. Indoxyl acetate hydrolyzed. No growth under anaerobic conditions. Sensitive to nalidixic acid (30 μg) but resistant to cephalothin (30 μg) in disk diffusion tests.

Pathogenicity unknown. Isolated from inflamed stomachs and ceca of the Syrian hamster *Mesocricetus auratus*.

Helicobacter aurati shares the same distinctive ultrastructure as *H. bilis* and *H. trogontum*, and thus these species represent distinct phylotypes of bacteria frequently referred to as *"Flexispira rappini"*. As discussed in more detail above (see Taxonomic Comments), the genetic relationship of *H. aurati* to the wide range of *"Flexispira rappini"* phylotypes described from other sources (Dewhirst et al., 2000a) is presently unknown. It remains to be seen if *H. aurati* is host-specific, or if it possesses a broader host range.

The mol% G + C of the DNA is: not determined.
Type strain: Type strain: MIT 97-5075c.
GenBank accession number (16S rRNA): AF297868.

4. **Helicobacter bilis** Fox, Yan, Dewhirst, Paster, Shames, Murphy, Hayward, Belcher and Mendes 1997b, 601[VP] (Effective publication: Fox, Yan, Dewhirst, Paster, Shames, Murphy, Hayward, Belcher and Mendes 1995, 453.)
bi'lis. L. n. *bilis* relating to the bile, referring to the bodily fluid from which it was isolated.

Cells are fusiform to slightly spiral, 0.5 × 4–5 μm. Periplasmic fibers are coiled around the cell body, which gives a crisscross appearance to the bacterial surface. Occasionally, loosening of the fibers results in the appearance of paired filaments. In older cultures, coccoid forms predominate; periplasmic fibers and flagella are usually seen. Motile by means of 3–14 sheathed flagella arranged in tufts at both ends of the cell body. Colonies are initially punctiform but often spread out as thin layers on the surface of agar media after 3–5 d microaerobic incubation at 37°C. Catalase and urease produced. Strains will grow on media containing up to 20% bile but not 1.5% NaCl. Sensitive to metronidazole (4 mg) but resistant to cephalothin (30 mg) and nalidixic acid (30 mg) in disk diffusion tests.

Pathogenicity unknown. First isolated from colonic crypts and ceca of mice, and the bile and livers of mice with hepatitis. Also causes a condition resembling inflammatory bowel disease (inflammation and hyperplasia of the lower gastrointestinal tract) in immunodeficient rats (Shomer et al., 1997; Haines et al., 1998).

Strains from human bile and gallbladder samples, and from a canine gastric biopsy, have also been identified as *H. bilis* by 16S rRNA gene sequence comparisons (Eaton et al., 1996a; Fox et al., 1998a). However, the close ultrastructural resemblance and taxonomic proximity of *H. bilis*, *H. trogontum*, *H. aurati*, and *"H. rappini"* (see Taxonomic Comments), and absence of other chemotaxonomic data that would clarify the relationships among these taxa, makes it difficult to be certain that dog and human strains are indeed *H. bilis*.

The mol% G + C of the DNA is: not determined.
Type strain: Hb-1, ATCC 51630.
GenBank accession number (16S rRNA): U18766.

5. **Helicobacter bizzozeronii** Hänninen, Happonen, Saari and Jalava 1996, 165[VP]
biz.zo'zer.o.ni.i. L. gen. n. *bizzozeronii* named in honor of Guilio Bizzozero, an Italian pathologist who was one of the first scientists to describe spiral organisms in the canine gastric tract.

Cells are tightly coiled helical rods, 0.3 × 5–10 μm. Coccoid forms are observed in aging cultures. Cells demonstrate a rapid, corkscrew-like motility achieved by means of multiple sheathed flagella in a bipolar arrangement. Culture of the bacteria is difficult and best achieved on freshly prepared, moist media. Consequently, individual colonies have not been observed and bacterial growth appears as a thin spreading film on agar media. All strains produce urease when tested *in situ* in mucosal tissue samples and when first isolated, but may spontaneously lose this activity after subcultivation. Most strains (80%) are resistant to 5-fluorouracil (100 U/l), but do not grow in the presence of 1% bile or metronidazole (4 mg/l). Variable results for alkaline phosphatase production and ability to hydrolyze indoxyl acetate have been reported.

H. bizzozeronii and *H. felis* share 2–30% DNA relatedness in optical DNA–DNA reassociation studies and 99.3–99.9% sequence homology in the 16S rRNA gene. Conventional phenotypic tests do not discriminate between these two species. Ultrastructural studies show that most *H. felis* strains exhibit periplasmic fibrils encircling the cell body, a feature absent in all *H. bizzozeronii* isolates examined to date. The two species can also be differentiated by whole-cell protein analysis and by dot-blot DNA–DNA hybridization assays.

H. bizzozeronii is morphologically indistinguishable from strains found in humans which are referred to as either *"H. heilmannii"* or *"Gastrospirillum hominis"*. By 16S rRNA gene sequence comparisons, *H. bizzozeronii* and *"H. heilmannii"* appear closely related (96.7–98.7% similarity), but taxonomic studies to clarify the relationship between these taxa have been impaired due to the failure of most workers to culture the human strains. One successfully cultured strain of *"H. heilmannii"* (Andersen et al., 1996) has been identified as *H. bizzozeronii* by phenotypic, protein electrophoretic, and DNA–DNA hybridization experiments (Jalava et al., 2001). However, it is likely that *H. bizzozeronii* does not account for all such observations (see Taxonomic Comments and Other Organisms).

Pathogenicity unknown. Isolated from the canine gastric mucosa of healthy animals, and those showing signs of upper gastrointestinal dysfunction (vomiting or abdominal discomfort). One strain isolated from a gastric biopsy of a human with gastritis.

The mol% G + C of the DNA is: not determined.
Type strain: Storkis, CCUG 35545.
GenBank accession number (16S rRNA): Y09404.

6. *Candidatus* Helicobacter bovis De Groote, van Doorn, Ducatelle, Verschuuren, Tilmant, Quint, Haesebrouck and Vandamme 1999b, 1713[VP]
bo'vis. L. n. *bos* the cow; L. gen. n. *bovis* of the cow.

Cells are helical rods showing 1–3 complete spiral turns with a wavelength of ~750 nm, 0.3 × 1.5–2.5 μm. Cells possess at least four flagella at one end of the cell, but further details of the flagellar arrangement and presence or absence of a flagellar sheath are not clear at this time. Urease activity was detected in all pyloric samples in which bacteria were seen. The species has not yet been cultured *in vitro*.

Pathogenicity unknown. Found in the gastric crypts of the pyloric part of the bovine abomasal stomach.

Comparison of 16S rRNA gene sequences shows that *Candidatus* H. bovis occupies a distinct branch in the genus. Its closest validly published phylogenetic neighbor is *H. bilis* (level of similarity, 92.8%), although clustering of sequences by the neighbor-joining method places *Candidatus* H. bovis with the majority of gastric *Helicobacter* species (De Groote et al., 1999b). A specific PCR assay and oligonucleotide probe is available for diagnostic purposes (De Groote et al., 1999b). Cross-reactivity with polyclonal *H. pylori*-derived antibodies is observed.

The mol% G + C of the DNA is: not determined.
Type strain: Not yet cultured.
GenBank accession number (16S rRNA): AF127027.
Additional Remarks: Candidate (*Candidatus*) species.

7. **Helicobacter canadensis** Fox, Chien, Dewhirst, Paster, Shen, Melito, Woodward and Rodgers 2002, 3^{VP} (Effective publication: Fox, Chien, Dewhirst, Paster, Shen, Melito, Woodward and Rodgers 2000, 2549.)
can.ad.en.sis. L. n. from Canada, the country of original isolation.

Cells are curved to spiral (1–3 turns) rods, 0.3 × 1.5–4 μm. Motile by means of single unipolar or bipolar unsheathed flagella. Culture on agar media containing 5% sheep blood under microaerobic conditions does not result in single colonies; growth occurs as a thin spreading film. Catalase, but not urease, alkaline phosphatase, or γ-glutamyl transpeptidase produced. Indoxyl acetate hydrolyzed. Nitrate reduced. Resistant to nalidixic acid (30 μg) and cephalothin (30 μg) in disk diffusion tests.

Pathogenicity unknown. Isolated from human diarrhea.

In both phylogenetic and phenotypic analyses, *H. canadensis* is similar to *H. pullorum* although the inability of the latter species to hydrolyze indoxyl acetate is a useful distinguishing feature. The close resemblance of these two species led Fox et al. (2000) to ponder the prospect of *H. canadensis* sharing similar animal reservoirs. With the discovery of strains from wild birds sharing >99.1% similarity in their 16S rDNA sequences with that of *H. canadensis* and with a phenotype closely resembling the latter species (S.L.W. On and J. Waldenström, unpublished data), it seems *H. canadensis* and *H. pullorum* also share the ability to colonize the avian gut. The wider zoonotic potential of these enteric species should be a subject for careful consideration.

The mol% G + C of the DNA is: not determined.
Type strain: NLEP-16143, MIT 98-5491, ATCC 700968.
GenBank accession number (16S rRNA): AF262037.

8. **Helicobacter canis** Stanley, Linton, Burnens, Dewhirst, Owen, Porter, On and Costas 1994c, 370^{VP} (Effective publication: Stanley, Linton, Burnens, Dewhirst, Owen, Porter, On and Costas 1993b, 2502.)
ca′nis. L. n. *canis* dog, after source of first isolation.

Curved or helical rods, typically 0.25 × 4 μm. Motile by means of two sheathed flagella showing a bipolar distribution. Colonies are pinpoint, translucent, and nonpigmented after 2 d microaerobic incubation on blood agar.

Neither catalase nor urease produced. Strains grow at 42°C and on media containing up to 1.5% ox-bile and 100 U/l 5-fluorouracil. No growth on media containing 0.032% methyl orange.

Insertion sequences ranging from 181 to 320 bp in size have been detected in the 16S and 23S rRNA genes of some strains (Linton et al., 1994b). The two 23S rRNA operons in *H. canis* may be polymorphic with respect to the presence of such insertion sequences.

In semi-quantitative DNA–DNA hybridization experiments, *H. canis* shares 30% and 52% DNA relatedness, respectively, with the species *H. fennelliae* and *H. cinaedi*. 16S rRNA gene sequence analyses identify the latter species, and *H. bilis* and *"H. rappini"* also, as reasonably close relatives (>97.8% sequence similarity). All these taxa are known to inhabit the lower intestinal tract of their hosts and have been associated with gastrointestinal disease; several (including *H. canis*, *H. bilis*, and *"H. rappini"*) have been isolated from hepatic disorders in humans or animals.

Pathogenicity unknown. Isolated from diarrhea in dogs and humans, and from the liver of a dog suffering from multifocal necrotizing hepatitis (Stanley et al., 1993b; Fox et al., 1996a).

The mol% G + C of the DNA is: 48.2–48.8 (T_m).
Type strain: ATCC 51401, NCTC 12739.
GenBank accession number (16S rRNA): L13464.

9. **Helicobacter cholecystus** Franklin, Beckwith, Livingston, Riley, Gibson, Besch-Williford and Hook 1997, 601^{VP} (Effective publication: Franklin, Beckwith, Livingston, Riley, Gibson, Besch-Williford and Hook 1996, 2957.)
cho.le′cyst.us. N.L. n. *cholecyst* gallbladder; L. gen. n. *cholecystus* relating to the gallbladder.

Cells are straight or curved rods, 0.5–0.65 × 2–5 μm. Motile by means of a single sheathed flagellum. Colonies are pinpoint and nonpigmented after 3 d microaerobic incubation on blood agar. Catalase, arginine aminopeptidase, and L-arginine arylamidase produced. Nitrate is reduced. Urease is not produced and indoxyl acetate is not hydrolyzed. Strains grow at 42°C and on media containing up to 5% bile salts. Growth observed under anaerobic conditions. Resistant to 30 mg/l cephalothin.

Syrian hamsters have been identified as a natural host of *H. cholecystus*. A number of helicobacters occur naturally in rodents and, of these, *H. bilis* and *H. hepaticus* are possibly closely related by 16S rRNA gene sequence comparisons (>96% similarity) to *H. cholecystus*. All of these species have been associated with various hepatic diseases in their respective hosts, possibly suggesting a common evolutionary origin.

Pathogenicity unknown. Isolated from the gall bladder of Syrian hamsters afflicted with cholangiofibrosis and pancreatitis.

The mol% G + C of the DNA is: not determined.
Type strain: Hkb-1, ATCC 700242.
GenBank accession number (16S rRNA): U46129.

10. **Helicobacter cinaedi** (Totten, Fennell, Tenover, Wezenberg, Perine, Stamm and Holmes 1985) Vandamme, Falsen, Ros-

sau, Hoste, Segers, Tytgat and De Ley 1991a, 100[VP] (*Campylobacter cinaedi* Totten, Fennell, Tenover, Wezenberg, Perine, Stamm and Holmes 1985, 138.)
ci.nae.di. L. gen. n. *cinaedi* of a homosexual.

Cells in 48 h old cultures are predominantly slender spiral rods, 0.3–0.5 × 1.5–5.0 μm. Rapid corkscrew-like motility by means of a single polar, sheathed flagellum. Single curved, S-shaped, and straight rods are occasionally seen. Coccoid forms develop in old cultures.

Colonies that are 48 h old are pinpoint and translucent. On freshly prepared or moist media, growth often occurs as a flat and spreading zone and discreet colonies may be rare. No distinct odor.

Grow in microaerobic conditions at 37°C, but not at 25°C or 42°C. Hydrogen stimulates or is essential for growth. No growth in aerobic or anaerobic conditions. Catalase is produced. Nitrate is reduced. No urease activity. Growth in 1% glycine, but not in 2% NaCl. Strains grow on media containing 0.04% triphenyl-tetrazolium chloride. No hydrolysis of indoxyl acetate.

Susceptible to ampicillin, gentamicin, doxycycline, tetracycline, ceftriaxone, rifampin, spectinomycin, nalidixic acid, and chloramphenicol. Most strains are susceptible to sulfamethoxazole (<4 μg/ml) and trimethoprim-sulfamethoxazole (<8 μg/ml), and resistant to 64 μg/ml of cefoperazone. Resistant to trimethoprim. Varying levels of resistance towards clindamycin, erythromycin, streptomycin, and metronidazole.

Pathogenicity unknown. Isolated from rectal swabs and blood of homosexual men. Associated with gastroenteritis, proctitis, proctocolitis, cellulitis, and arthritis with or without accompanying HIV infection. Rarely isolated from blood, cerebrospinal fluid, or feces of women and children without risk factors for HIV infection. Isolated from normal or diarrhetic feces of hamsters, cats, dogs, and foxes (Stanley et al., 1993b; Vandamme et al., 2000).

Campylobacter cinaedi was first described by Totten et al. (1985) in a taxonomic study of *Campylobacter*-like organisms from homosexual men with enteric disease. This species was proposed by these authors to encompass two genetic groups (CLO-1a and CLO-1b), although DNA hybridization values between CLO-1a and CLO-1b ranged from 42 to 51%. Comparable values between group CLO-2 strains (proposed as *C. fennelliae*) and the single (still unnamed: see below) CLO-3 isolate were, however, far lower (<7%). These results and the absence of phenotypic differences between CLO-1a and CLO-1b groups led Totten et al. (1985) to include both in a single species. *H. cinaedi* is thus known to be genotypically diverse, comprising at least two genomospecies. It is also noteworthy that *H. cinaedi* isolates from humans, dogs, and hamsters formed distinct ribotype pattern groups according to their host source, despite DNA–DNA hybridization values to the type strain exceeding 77% (Kiehlbauch et al., 1995). *H. cinaedi* is genetically most closely related to *H. canis* (52% DNA relatedness; Stanley et al., 1993b) and *H. fennelliae* (3–10% DNA relatedness; Totten et al., 1985). Phylogenetically, *H. cinaedi* forms a tight cluster with strains of *H. canis* and a human *"H. rappini"* strain. The three validly described species are phenotypically very similar and few tests unequivocally differentiate these species (see Table BXII.ε.5).

The mol% G + C of the DNA is: 37–38 (T_m).
Type strain: ATCC 35683, CCUG 18818, DSM 5359.
GenBank accession number (16S rRNA): M88150.

11. **Helicobacter felis** Paster, Lee, Fox, Dewhirst, Tordoff, Fraser, O'Rourke, Taylor and Ferrero 1991, 36[VP]
fe'lis. L. gen. n. *felis* of a cat.

Cells are tightly coiled helical cells, 0.4 × 5–7.5 μm. Cells transform to coccoid forms (diameter 2–4 μm) with age. Rapid corkscrew-like motility by means of 10–17 sheathed flagella (25 nm thick) with a bipolar distribution. The flagella are positioned slightly off center at each end of the cell. Cells of most strains are surrounded by periplasmic fibers, which appear as concentric helical ridges on the cell surface, either in pairs, threes, or singly. Highly fastidious. Grows as a thin, translucent film on enriched blood agar and does not readily form colonies. Colonies when observed are pinpoint and colorless after 3 d growth. Can be cultured using serum-enriched broths (brain-heart infusion and *Brucella* broths have been used), in which growth is enhanced by shaking the culture.

Some strains can grow on solid media under anaerobic conditions. Optimal growth is achieved at 37°C in a microaerobic atmosphere. Initial growth obtained after 4–5 days, will grow in 2 days on subsequent subculture. Some strains grow at 42°C; no growth obtained at 25°C. Urease produced, but spontaneous loss of this enzyme activity in a few strains after subcultivation may be observed (Jalava et al., 1998). Arginine aminopeptidase, leucine aminopeptidase, and gamma-glutamyl transpeptidase activities are detected. Most strains have histidine and leucine aminopeptidase activity. No production of *N*-acetylglucosaminidase, α-glucosidase, α-arabinosidase, β-glucosidase, α-fucosidase, α-galactosidase, β-galactosidase, proline aminopeptidase, pyroglutamic acid amylamidase, tyrosine aminopeptidase, alanine aminopeptidase, phenylalanine aminopeptidase, glycine aminopeptidase, or arginine dihydrolase. Nitrate is reduced to nitrite. Neither hippurate nor indoxyl acetate is hydrolyzed. In tests requiring growth on solid media, *H. felis* is typified by its unreactivity, a trait shared with its closest relatives *H. bizzozeronii* and *H. salomonis* (On et al., 1996; Jalava et al., 1998). Most strains are resistant to 5-fluorouracil (100 U/l).

Strains are genetically heterogeneous with no association to host species or country of origin. Most strains have multiple plasmids, 2 to >16 kb. Genome size 1.6 Mb (Jalava et al., 1999a). Pathogenicity island not detected.

Helical bacteria have been observed in canine and feline gastric mucosal samples for over a century (Bizzozero, 1893; Salomon, 1898). Such bacteria are known to be present in virtually all adult cats and dogs and three *Helicobacter* species (*H. felis*, *H. bizzozeronii*, *H. salomonis*) have been described from the gastric tract of domestic pets. These taxa are closely related, with DNA–DNA hybridization experiments indicating intraspecific DNA relatedness values of 11–39%. Phylogenetic analysis using 16S rRNA gene sequence comparisons shows strains of these species are so highly related that individual species cannot be clearly distinguished (Jalava et al., 1997). Similar results are inferred using restriction fragment length polymorphisms of the 23S rRNA gene, which cannot discriminate these species (Jalava et al., 1999a).

The relative prevalence and distribution of each species

in domestic pets is difficult to estimate since isolation and identification of the bacteria is extremely problematic (Eaton et al., 1996a; Jalava et al. 1998). Of 51 *Helicobacter* strains isolated from 95 dogs, 10 were *H. felis* (Jalava et al. 1998). The same study isolated only three strains from 22 cats examined; all were *H. felis*. This result may reflect the observation that this species was easiest to isolate.

Isolated from the gastric mucosa of cats and dogs (Lee et al., 1988). A human gastric biopsy strain identified as *H. felis* (99.5% similar to type strain sequence) by sequence comparison of a 967 bp segment of the 16S rRNA gene to similar data held in GenBank and EMBL databases, and by a PCR assay based on the urease gene sequence described as specific for *H. felis* (Germani et al., 1997). The result should however be treated with some caution due to the subsequent description of *H. salomonis* and *H. bizzozeronii*, which show up to 99.6% sequence homology in the 16S rRNA gene to other *H. felis* strains and which have not been examined with the urease gene assay applied by Germani et al. (1997).

Infection associated with lymphoid follicles in experimentally infected dogs. (Lee et al., 1992a). Colonizes the gastric mucosa of mice (Dick-Hegedus and Lee, 1991; Fox et al. 1991) and may cause a persistent chronic gastritis of approximately 1 year in duration in germ-free mice and their conventional non-germ-free counterparts (Fox et al., 1993). Widely used as an experimental model, including for vaccine studies (Lee, 1998).

The mol% G + C of the DNA is: 42.5 (T_m).
Type strain: CS1, ATCC 49179.
GenBank accession number (16S rRNA): M57398.

12. **Helicobacter fennelliae** (Totten, Fennell, Tenover, Wezenberg, Perine, Stamm and Holmes 1985) Vandamme, Falsen, Rossau, Hoste, Segers, Tytgat and De Ley 1991a, 100[VP] (*Campylobacter fennelliae* Totten, Fennell, Tenover, Wezenberg, Perine, Stamm and Holmes 1985, 138.)
fen.nel' li.ae. N.L. gen. n. *fennelliae* of C.L. Fennell, the person who first isolated this organism from rectal swabs of homosexual males.

Cells of 48 h old cultures are predominantly slender spiral rods, 0.3–0.5 × 1.5–5.0 μm. Rapid corkscrew-like motility by means of a single polar sheathed flagellum. Single curved, S-shaped, and straight rods are occasionally seen. Coccoid forms develop in old cultures.

Colonies of 48 h old cultures are pinpoint and translucent. On freshly prepared or moist media, growth often occurs as a flat and spreading zone, and discreet colonies may be rare. Strains may be characterized by an odor resembling that of hypochlorite cleaning powders.

Grow in microaerobic conditions at 37°C, but not at 25°C. Approximately one-third of strains grow at 42°C. Hydrogen stimulates or is essential for growth. No growth in aerobic or anaerobic conditions. Most strains produce catalase. No urease activity. Strains grow on media containing 0.04% triphenyl-tetrazolium chloride; reduction of this compound is concurrently observed and bacterial growth is of a metallic red sheen.

Susceptible to ampicillin, gentamicin, doxycycline, tetracycline, ceftriaxone, rifampin, spectinomycin, nalidixic acid, chloramphenicol, clindamycin, erythromycin, and metronidazole. Resistant to 5-fluorouracil, trimethoprim, and streptomycin. Most strains are susceptible to sulfamethoxazole (<4 μg/ml) and trimethoprim-sulfamethoxazole (<8 μg/ml).

DNA–DNA hybridization experiments indicate the closest taxonomic relatives to *H. fennelliae* to be *H. canis* (30% DNA relatedness) and *H. cinaedi* (3–10% DNA relatedness). By 16S rRNA gene sequence comparisons, *H. fennelliae* appears rather distinct (Fig. BXII.ε.7); Shen et al. (1997) showed the type strain of *H. pullorum* (NCTC 12824) was phylogenetically most closely related to *H. fennelliae* (95.9% sequence similarity).

Pathogenicity unknown. Isolated from rectal swabs and blood of homosexual men. Associated with proctitis and proctocolitis with or without accompanying HIV infection. Isolated from blood and feces of children with diarrhea.

The mol% G + C of the DNA is: 37–38 (T_m).
Type strain: 231, ATCC 35684, CCUG 18820, DSM 7491.
GenBank accession number (16S rRNA): M88154.

13. **Helicobacter ganmani** Robertson, O'Rourke, Vandamme, On and Lee 2001, 1888[VP]
gan.man' i. N.L. gen. n. *ganmani* an arbitrary name derived from *ganman*, which, in the language of the Gadigal people (indigenous Australians who live in the Sydney Harbour area), means "snake finder". Thus *ganmani* is intended to refer to both the spiral, snake-like morphology of the organism and to the area in Australia from which it was first described.

Cells are curved to spiral (2 turns per cell) rods 0.3 × 2.5 μm. Motile by means of single bipolar unsheathed flagellum. Culture on agar media containing 5% horse blood under anaerobic conditions occasionally results in translucent, irregular, and unpigmented colonies < 1 μm in diameter. However, growth is more frequently seen as a thin spreading film. Nitrate and triphenyl-tetrazolium chloride (TTC) reduced. Urease and alkaline phosphatase activity not detected. Weak catalase activity observed in a few strains. Indoxyl acetate not hydrolyzed. Resistant to cephalothin (32 μg/l), carbenicillin (32 μg/l), and cefoperazone in agar dilution tests.

Pathogenicity unknown. Isolated from the ceca, large and small bowels, and livers of laboratory mice.

Phenotypic, protein electrophoretic, and phylogenetic analyses indicated *Helicobacter ganmani* and *H. rodentium* were closely related, but distinct species. In addition, both species occupy the same ecological niche. All *H. ganmani* and 2/3 *H. rodentium* strains tested by Robertson et al. (2001) grew only under anaerobic conditions, a feature not observed with other *Helicobacter* species, although since *H. rodentium* had been isolated under microaerobic conditions (Shen et al., 1997), methodological differences may account for this anomaly. These species, along with *H. canadensis*, *H. mesocricetorum*, and *H. pullorum* are atypical from all other *Helicobacter* species in lacking flagellar sheathing. The significance of this is unknown. *H. ganmani* is the tenth validly described *Helicobacter* species isolated from the rodent intestine. This emphasizes the diversity of species that naturally occur in rodents and has wider implications for workers employing laboratory rodents for pathogenicity, immunological and other studies. The routine screening of laboratory rodents for indigenous *Helicobacter* species has been suggested (Shen et al., 1997; Robertson et al., 2001).

The mol% G + C of the DNA is: not determined.
Type strain: CMRI H02, CCUG 43526.
GenBank accession number (16S rRNA): AF000221.

14. **Helicobacter hepaticus** Fox, Dewhirst, Tully, Paster, Yan, Taylor, Collins, Gorelick and Ward 1994c, 595[VP] (Effective publication: Fox, Dewhirst, Tully, Paster, Yan, Taylor, Collins, Gorelick and Ward 1994c, 1243.)
he.pa′ ti.cus Gr. adj. *hepatikos* relating to the liver.

Cells are slender, curved to spiral rods, 0.2–0.3 × 1.5–5 μm. Coccoid forms are found in older cultures. Motile by means of a sheathed, single bipolar flagellum. Colonies are pinpoint, but cultures often appear as a thin spreading layer on agar media after two to three days incubation at 37°C in microaerobic conditions. The spreading growth is either translucent or light blue-gray in color. Growth also obtained under anaerobic, but not aerobic conditions. Hemolytic. Catalase and urease produced. Strains grow on media containing 0.04% triphenyl-tetrazolium chloride; reduction of this compound is concurrently observed and bacterial growth is of a metallic red sheen. Strains also grow on media containing 0.1% sodium deoxycholate. Sensitive to metronidazole (4 mg/l) but resistant to 5-fluorouracil (100 U/l) and carbenicillin (32 mg/l).

H. hepaticus causes a chronic active hepatitis in certain strains of mice and, in A/JCr and B6C3F1 varieties, infection is linked to the development of hepatic adenoma and hepatocellular carcinoma (Fox et al., 1994b, 1996b, c; Ward et al., 1994; Whary et al., 1998). In some immunodysfunctional mice, the organism can cause severe inflammation of the colon and cecum, causing a condition closely resembling inflammatory bowel syndrome (Cahill et al., 1997). The organism colonizes the crypts of the cecum and colon, and, in susceptible strains of mice, the bile canaliculi of the liver. The prevalence of *H. hepaticus* in laboratory mice (including strains used in carcinogenesis bioassays) has been estimated from 47–100% among different vendors (Shames et al., 1995; Fox et al., 1998b).

The mol% G + C of the DNA is: not determined.
Type strain: Fox Hh-2, ATCC 51448.
GenBank accession number (16S rRNA): U07574.

15. **Helicobacter mesocricetorum** Simmons, Riley, Besch-Williford and Franklin 2000b, 1699[VP] (Effective publication: Simmons, Riley, Besch-Williford and Franklin 2000a, 1816.)
me′ so.cric.et.or′ um. L. n. from the Syrian hamster *Mesocricetus auratus*, the original source of isolation.

Cells are loosely spiral rods, 0.3–4 × 2–3 μm. Motile by means of single bipolar unsheathed flagella. Culture on agar media containing 5% sheep blood under microaerobic conditions results in either pinpoint colonies or a thin spreading film. Catalase and alkaline phosphatase, but not urease produced. No growth on media containing 1.0% glycine or 1.5% sodium chloride. Resistant to cephalothin (30 μg) in disk diffusion tests.

Pathogenicity unknown. Isolated from the feces of asymptomatic Syrian hamsters (*Mesocricetus auratus*).

The species *Helicobacter mesocricetorum*, *H. ganmani*, and *H. rodentium* bear a striking phenotypic resemblance to each other and appear closely related in 16S rRNA gene sequence comparisons. These species also share a cellular morphotype uncommon among *Helicobacter* species, in that sheathing along the flagellar shaft is absent. Since these species appear to be indigenous to the rodent intestine, it is reasonable to presume they share a relatively recent common ancestor, although of these species only *H. mesocricetorum* has yet been recovered from Syrian hamsters. Nevertheless, *H. mesocricetorum* may be conveniently distinguished from the other taxa by its alkaline phosphatase activity and poor or no growth under anaerobic conditions.

The mol% G + C of the DNA is: not determined.
Type strain: MU 97-1514, ATCC 700932, CCUG 45420.
GenBank accession number (16S rRNA): AF072471.

16. **Helicobacter muridarum** Lee, Phillips, O' Rourke, Paster, Dewhirst, Fraser, Fox, Sly, Romaniuk, Trust and Kouprach 1992b, 35[VP]
mu.ri.da′ rum. L. n. *Muridae* family name for Old World rats and mice; L. gen. n. *muridarum* of the *Muridae*.

Cells are helical rods, 3.5–5 × 0.5–0.6 μm with two to three spiral turns. Cells transform to coccoid forms with age. Rapid, darting motility by means of 10–14 bipolar sheathed flagella. Cells surrounded by 9–11 periplasmic fibers, which appear as concentric helical ridges on the cell surface. Highly fastidious. Grows as a fine, translucent spreading film on media enriched with blood or serum. Optimal growth occurs on a moist agar surface after 2–3 d incubation at 37°C in a microaerobic atmosphere (1–16% oxygen, with added 5–10% CO_2). Single colonies rarely obtained due to the preference of the bacterium for moist agar surfaces. Catalase, urease, and arginine aminopeptidase produced. No production of leucine aminopeptidase and γ-glutamyl transpeptidase. Nonhemolytic. No growth under aerobic or anaerobic conditions, or at 25°C or 42°C. No growth in the presence of 1.5% NaCl, >1% bile, or 0.1% sodium fluoride. Sensitive to cefoperazone and metronidazole. Indole and H_2S not produced. Gelatin, casein, starch, tributyrin, and hippurate are not hydrolyzed.

Isolated from the intestinal mucosa of rats and mice, mainly colonizing the mucus in the ileal crypts. In germfree animals colonizes the cecal pits in large numbers (Phillips and Lee, 1983). Invades small intestinal tissue in immunologically compromised mice (Quastler and Hampton, 1962; Hampton, 1967). In older animals may colonize the gastric mucosa in large numbers (Lee et al., 1993).

The mol% G + C of the DNA is: 34 (T_m).
Type strain: ST1, ATCC 49282.
GenBank accession number (16S rRNA): M80205.

17. **Helicobacter mustelae** (Fox, Taylor, Edmonds and Brenner 1988) Goodwin, Armstrong, Chilvers, Peters, Collins, Sly, McConnell and Harper 1989a, 403[VP] (*Campylobacter mustelae* (Fox, Taylor, Edmonds and Brenner 1988) Fox, Chilvers, Goodwin, Taylor, Edmonds, Sly and Brenner 1989, 303; *Campylobacter pylori* subsp. *mustelae* Fox, Taylor, Edmonds and Brenner 1988, 370.)
mus.te′ lae. L. gen. n. *mustelae* of a ferret.

Cells of 3–5 d old cultures are 0.5–1 × 3–5 μm. Coccoid forms predominate in older cultures. Colonies on blood agar are nonpigmented, translucent, and 1 mm in diameter. Straight or curved rods, 0.5–0.65 × 2–5 μm. Motile by means of multiple sheathed flagella with terminal bulb-like

structures demonstrating a peritrichous arrangement. Catalase and urease produced. Urease activity can be spontaneously lost during subcultivation on artificial culture media (Costas et al., 1991). Grows in anaerobic conditions in the presence of 10% CO_2. Does not exhibit leucine arylamidase activity. Resistant to cephalothin (32 mg/l) and 5-fluorouracil (100 U/l), sodium fluoride (0.1%). Sensitive to metronidazole (4 mg/l).

Major fatty acids are $C_{16:0}$. Moderate amounts (given as % total fatty acid content) of $C_{14:0}$ (13–17%), $C_{18:1}$ (14–23%), and $C_{19:0\ cyclo}$ (8–15%) detected.

In a taxonomic investigation to determine the relationship between *Campylobacter pylori* and a bacterium isolated from ferret gastric mucosa, DNA–DNA hybridization values between these organisms were found to exceed 85%. Phenotypic differences between the ferret and human strains were noted, and these data used to propose that ferret isolates represented a subspecies of *C. pylori*, named by the authors *C. pylori* subsp. *mustelae* (Fox et al., 1988). Almost a year later, Fox et al. (1989) reported that subsequent DNA–DNA hybridization experiments using three different methods indicated a much lower level of DNA relatedness between the two taxa (1–49%) and the two subspecies were subsequently elevated to species status, the ferret isolates being assigned to *C. mustelae*. The subsequent issue of the *International Journal of Systematic Bacteriology* saw the transfer of both species to the new genus *Helicobacter* (Goodwin et al., 1989a). Although *H. mustelae* and *H. pylori* are closely related genetically and both are associated with gastric disease in their natural hosts, they occupy different clades in phylogenetic analyses based on 16S rRNA gene sequences (Fig. BXII.ε.7). In further contrast with *H. pylori*, *H. mustelae* appears to be genomically conserved (Taylor et al., 1994b).

H. mustelae is frequently used as an animal model of *H. pylori* infection and a number of important virulence traits have been characterized. Isogenic mutants lacking urease activity, as well as those without flagella, are unable to colonize gastric mucosa of ferrets (Andrutis et al., 1995, 1997).

Pathogenic in ferrets (*Mustela putorius furo*). Causes chronic gastritis and is clinically associated with gastric and duodenal ulcers as well as gastric adenocarcinoma and gastric MALT lymphoma (Fox et al., 1990, 1997a; Erdman et al., 1997). Isolated from the gastric mucosa and feces of infected ferrets and from the gastric mucosa of mink.

The mol% G + C of the DNA is: 36–41 (T_m).

Type strain: R85-13-6, ATCC 43772, CCUG 25715, NCTC 12198.

GenBank accession number (16S rRNA): M35048.

18. **Helicobacter nemestrinae** Bronsdon, Goodwin, Sly, Chilvers, Schoenknecht 1991, 150[VP]
ne.mes.tri.nae. N.L. gen. n. *nemestrinae* of the macaque species *M. nemestrina*, from which the organism was isolated.

Cells are helical or curved rods, 0.2–0.3 × 2.0–5 µm. Cells appear as loosely coiled wave-forms and small curved rods under light microscopy. Under certain culture conditions cells may demonstrate a high degree of pleomorphism and appear as bizarre twisted or knotted forms. Coccoid forms are observed in aging cultures. Motile by means of multiple sheathed flagella which exhibit a monopolar arrangement and possess terminal bulb-like structures.

Colonies on blood agar are small, round (0.5–1.0 mm in diameter), colorless, and translucent. Swarming is not observed but colonies may develop irregular edges after 3–5 d of incubation on moist growth media. Strains will grow at 42°C in a microaerobic atmosphere and at 37°C in anaerobic conditions. Weak growth obtained on blood agar media containing 32 mg/l nalidixic acid and 100 U 5-fluorouracil after 3 d microaerobic incubation. Weakly alpha-hemolytic after three days growth on 5% calf blood agar. Catalase, alkaline phosphatase, and urease produced. Indoxyl acetate not hydrolyzed.

Major cellular fatty acids are $C_{18:1}$ and $C_{16:0}$. Small amounts of $C_{14:0\ 3OH}$ and $C_{15:0}$ present but no $C_{19:0\ cyclo}$ or $C_{16:0\ 3OH}$.

At present, the type strain is the only known representative of the species. The DNA base composition is highly atypical for the genus, but phylogenetic analysis, overall phenotype, and the ecological niche of the organism are consistent with those recorded for other *Helicobacter* spp. Bronsdon et al. (1991) recorded very low levels of DNA relatedness between *H. nemestrinae* and the type strains of *H. pylori* (<10%) and *H. mustelae* (<1.0%). *H. nemestrinae* was found to be distinct from *H. felis* and *H. mustelae*, but not from all strains of *H. pylori*, when examined for restriction fragment length polymorphisms in the copper-transporting ATPase gene *copA* (Ge et al., 1996).

Sequence comparisons of nine housekeeping and flagellar genes of the type strain held at ATCC (ATCC 49396) suggest it to be a strain of *H. pylori* (Suerbaum et al., 2002). The status of the equivalent strains held at other international culture collections is at present unknown. Although current data suggest *H. nemestrinae* should be considered a junior synonym of *H. pylori*, DNA–DNA hybridization studies are required to confirm the genetic relationship between these two taxa.

Pathogenicity unknown. Isolated from the gastric mucosa of a pigtailed macaque monkey (*Macaca nemestrina*). No abnormal pathology was seen in naturally infected tissue samples, and infection was not associated with any morbidity or mortality of the animal.

Resistant to nalidixic acid, trimethoprim, sulfamethoxazole, and vancomycin. Sensitive to penicillin, ampicillin, erythromycin, gentamicin, cephalothin, cefoperazone, tetracycline, polymyxin, furoxone, rifampin, metronidazole, and chloromycetin.

The mol% G + C of the DNA is: 24 (T_m).

Type strain: T81213-NTB, ATCC 49396, CCUG 32350, DSM 7492.

GenBank accession number (16S rRNA): X67854.

19. **Helicobacter pametensis** Dewhirst, Seymour, Fraser, Paster and Fox 1994, 559[VP]
pa.me.ten′ sis. N.L. of the Pamet River, Truro, Mass.

Cells are small curved rods, approximately 0.4 × 1.5 µm with rounded ends. Motile by means of two sheathed flagella, one at each end of the cell. Occasionally cells possess a third flagellum adjacent to one of the other flagella. Flagella are inserted subterminally. Colonies are pinpoint to 0.5 mm in diameter, translucent, colorless and weakly hemolytic after 3 d growth on 5% blood agar in microaerobic conditions at 37°C. Will also grow at 42°C and poorly under anaerobic conditions, but not at 25°C or in air. Catalase and

arginine beta-naphthylamide aminopeptidase activity. Urease, gamma glutamyl transpeptidase, lysine, and ornithine decarboxylase, and proline, pyroglutamate, tyrosine, alanine, phenylalanine, and glycine beta-naphthylamide aminopeptidases are not detected. Nitrate and selenite reduced. Sensitive to nalidixic acid (32 mg/l) but resistant to cephalothin (32 mg/l) in disk diffusion and agar dilution assays.

Pathogenicity unknown. *H. pametensis* has been isolated from tern, gull, and swine feces and from a feline gastric biopsy (Seymour et al., 1994; Neiger et al., 1998). No disease manifestations have been recorded.

The mol% G + C of the DNA is: 38 (T_m).
Type strain: B9, ATCC 51478, CCUG 29255.
GenBank accession number (16S rRNA): M88147.

20. **Helicobacter pullorum** Stanley, Linton, Burnens, Dewhirst, On, Porter, Owen and Costas 1995, 418[VP] (Effective publication: Stanley, Linton, Burnens, Dewhirst, On, Porter, Owen and Costas 1994b, 3448.)
pul.lo′ rum. L. gen. n. *pullorum,* derived from *pullus*, chicken, after source of first isolation.

Cells are slightly curved rods, 0.3–0.5 × 3–4 μm. Motile by means of a single, unsheathed, polar flagellum. Colonies are pinpoint to 1 mm in diameter, nonpigmented, smooth, and translucent after 3 d incubation on blood agar at 37°C. Alpha-hemolytic. Most strains produce catalase (88%) and reduce nitrate (91%). Hydrogen sulfide production in triple sugar iron has been detected in many strains (76%); the use of freshly prepared media (≤3 days old) and a hydrogen-containing atmosphere may favor development of this trait. Urease is not produced and indoxyl acetate is not hydrolyzed. Most strains grow at 42°C (88%) and on 1% bile (79%) media under microaerobic conditions. Most strains (94%) are resistant to cephalothin (32 mg/l) and cefoperazone (64 mg/l) but not to nalidixic acid (18%).

H. pullorum is an unusual *Helicobacter* species in several respects. It is one of only four species (*H. rodentium*, *H. ganmani*, and *H. mesocricetorum* are the others) in which the flagellum is not sheathed. The fact that *H. pullorum* is also sensitive to polymixin B (to which all other *Helicobacter* spp. tested thus far are resistant) makes the phenotype of *H. pullorum* more consistent with members of the genus *Campylobacter*. This is noteworthy since several important *Campylobacter* species (e.g., *C. lari*, *C. jejuni* subsp. *jejuni* and *C. coli*) are, like *H. pullorum*, of enteric origin and occur in poultry. There is thus a risk that *H. pullorum* could be misclassified as *Campylobacter* spp. in routine laboratories. However, the use of appropriate isolation and identification methods showed *H. pullorum* to be present in 60% of poultry samples (Atabay et al., 1998b). A species-specific PCR assay to facilitate its identification has been described (Stanley et al., 1994b), but cross-reacts with *H. canadensis* (Fox et al., 2000).

The avian origin of *H. pullorum* is also atypical of *Helicobacter* spp., most of which are found in mammalian hosts. Interestingly, the closest phylogenetic relative to *H. pullorum* is *H. pametensis.* At present, these species are the only validly described helicobacters from birds. Finally, *H. pullorum* has been associated with hepatitis in some host animals, an association shared by *H. hepaticus*, *H. cholecystus*, and *"H. rappini"*. The natural ecological niche of all three of these taxa is considered the lower gastrointestinal tract and thus an invasive capability, at least of some strains, is suggested.

Pathogenicity unknown. Isolated from the ceca of asymptomatic broiler chickens, the liver and intestinal contents of chickens suffering from vibrionic hepatitis, and from human diarrhea.

The mol% G + C of the DNA is: 33.8–35.1 (T_m).
Type strain: NCTC 12824.
GenBank accession number (16S rRNA): L36141.

21. **Helicobacter rodentium** Shen, Fox, Dewhirst, Paster, Foltz, Yan, Shames and Perry 1997, 633[VP]
ro.den′ ti.um. L. gen. n. *rodentium* of gnawing animals, referring to the first reported source (mice).

Cells are curved to spiral rods, 0.3 × 1.5–5 μm. Motile by means of two sheathed flagella showing a bipolar distribution. After 4–7 d of incubation under microaerobic conditions, colonies are 1–2 mm in diameter, but growth on solid media is frequently observed as a thin spreading film. Catalase, but not urease or γ-glutamyl transpeptidase, produced. Strains will grow under anaerobic conditions. Nonhemolytic.

Pathogenicity unknown. Isolated from the feces and intestinal tissue samples of healthy mice. Diarrhea was seen in *scid* mice coinfected with *H. bilis.*

The mol% G + C of the DNA is: not determined.
Type strain: MIT 95-1707, ATCC 700285.
GenBank accession number (16S rRNA): U96296.

22. **Helicobacter salomonis** Jalava, Kaartinen, Utriainen, Happonen and Hänninen 1997, 981[VP]
sa.lo.mo′ nis. L. gen. n. *salomonis* in honor of Hugo Salomon, a German scientist who was one of the first workers to describe three morphologically distinct spiral organisms in canine gastric mucosa.

Cells are loosely helical or curved rods 0.8–1.2 × 5–7 μm. Coccoid forms predominate in aging cultures. Cells exhibit a more pronounced corkscrew-like appearance when studied *in situ* in mucosal tissue samples. Cells exhibit a relatively slow, wave-like motility that is attained by means of multiple sheathed flagella arranged at one or both ends of the cell body. Culture of the bacteria is difficult and best achieved on freshly prepared, moist media. Consequently, individual colonies have not been observed and bacterial growth appears as a thin spreading film on agar media. All strains produce catalase and urease. Strains do not grow in the presence of 1% bile or cefoperazone (<60 mg/l). A few strains (17%) tolerate 5-fluorouracil (100 U/l). Variable results for alkaline phosphatase production and ability to hydrolyze indoxyl acetate have been reported.

H. salomonis shares 11–34% DNA relatedness with *H. bizzozeronii* and 26–39% DNA relatedness with *H. felis* in optical DNA–DNA reassociation studies. Similarly, *H. salomonis* shares 98.2–99.2% sequence similarity in the 16S rRNA gene with *H. bizzozeronii* and *H. felis.* 16S rRNA gene sequence similarity between two *H. salomonis* strains was found to be 98.4%. Unequivocal differentiation of *H. salomonis* from its two closest taxonomic relatives cannot be achieved by conventional phenotypic tests, but the cell morphology and motility of cultured strains, and inability to grow at 42°C or on 5-fluorouracil (100 U/l)-containing media serve as broadly distinguishing features. These species

can also be differentiated by whole-cell protein analysis and by dot-blot DNA–DNA hybridization assays.

Pathogenicity unknown. Isolated from the gastric mucosa of healthy dogs.

The mol% G + C of the DNA is: not determined.

Type strain: Inkinen, CCUG 37845.

GenBank accession number (16S rRNA): U89351.

23. *Candidatus* Helicobacter suis De Groote, van Doorn, Ducatelle, Verschuuren, Haesebrouck, Quint, Jalava and Vandamme 1999a, 1775.
su'is. L. n. *sus* the pig; L. gen. n. *suis* of the pig.

Cells are tightly coiled helical rods, 0.6 × 2.5–3.5 μm. Cells possess 1–5 flagella in a bipolar arrangement. Presence or absence of a flagellar sheath is not clear at this time. Urease activity was detected in all pig stomach samples in which bacteria were seen. The species has not yet been cultured *in vitro*.

Pathogenicity unknown. Found in the gastric and pyloric crypts of the pig stomach.

Comparison of 16S rRNA gene sequences shows *Candidatus* H. suis and *"H. heilmannii"* type 1 are 99.5% similar (De Groote et al., 1999a). This is in agreement with a similar analysis performed on sequences representing *"Gastrospirillum suis"* and *"H. heilmannii"* type 1 (Mendes et al., 1994). Since the ultrastructure and host source of *Candidatus* H. suis and *"G. suis"* are the same, these taxa are highly likely to represent the same species. The former name is validly published and should take nomenclatural precedence over the latter. Although present data suggest that *Candidatus* H. suis and *"H. heilmannii"* type 1 represent the same species with a potential for zoonotic transmission, the relationship between these taxa can be determined only when strains of both taxa are cultured (De Groote et al., 1999a). A specific PCR assay and oligonucleotide probe for diagnostic purposes is available (De Groote et al., 1999a). Cross-reactivity with polyclonal *H. pylori*-derived antibodies is observed.

The mol% G + C of the DNA is: not determined.

Type strain: Not yet cultured.

GenBank accession number (16S rRNA): AF1270278.

Additional Remarks: Candidate (*Candidatus*) species.

24. **Helicobacter trogontum** Mendes, Queiroz, Dewhirst, Paster, Moura and Fox 1996, 920^{VP}
tro.gon'tum. Gr. part. adj. *trogon* gnawing; M.L. gen. pl. n. *trogontum* of gnawing animals, referring to source of first isolation.

Cells are fusiform to slightly spiral with pointed ends that measure 0.6–0.7 × 4–6 μm. Cells also have periplasmic fibers coiled around the protoplasmic cylinder, which gives a crisscross appearance to the bacterial surface. In older cultures, coccoid forms with overlapping periplasmic fibers are common. Motile by means of tufts of 3–7 sheathed flagella at each end of the cell. Colonies are initially punctiform but often spread out as thin layers with a blue-gray hue on the surface of agar media after 3–5 d microaerobic incubation. Catalase, urease, gamma-glutamyl transpeptidase, and ornithine decarboxylase produced. Some strains produce alkaline phosphatase. Nitrate not reduced. No growth on agar media containing >1.5% NaCl. Sensitive to metronidazole (4 mg/l) but resistant to cephalothin (32 mg/l).

The complex cellular ultrastructure of *H. trogontum* bears a striking resemblance to that exhibited by *H. bilis* and ovine, porcine, murine, and human isolates that have been referred to as *"Flexispira"* or *"Helicobacter rappini"*. 16S rRNA gene sequence comparisons indicate the phylogenetic positions of all these taxa to be distinct, with similarity values between *H. trogontum* and *H. bilis* and human and porcine *"H. rappini"* strains ranging from 95.5–96.1% (Shen et al., 1997). Since the taxonomic status of *"H. rappini"* is unclear (see Taxonomic Comments) and the level of DNA–DNA relatedness among the aforementioned taxa has not been determined, it is likely that *H. trogontum* represents a murine subset of strains that at one time would have been referred to as *"H. rappini"*. Indeed, strains from laboratory mice were identified by Schauer et al. (1993) as *"F. rappini"* by their distinctive cell ultrastructure and 16S rRNA gene sequence identity (98.0–99.3% similarity) to human and ovine *"F. rappini"* strains studied by Bryner et al. (1986, 1987) and Archer et al. (1988).

Pathogenicity unknown. Isolated from colonic mucosa of rats. No abnormal pathological changes in the colonized tissue have yet been noted.

The mol% G + C of the DNA is: not determined.

Type strain: LRB 8581, ATCC 700114.

GenBank accession number (16S rRNA): U65103.

25. **Helicobacter typhlonius** Franklin, Gorelick, Riley, Dewhirst, Livingston, Ward, Beckwith and Fox 2002, 686^{VP} (Effective publication Franklin, Gorelick, Riley, Dewhirst, Livingston, Ward, Beckwith and Fox 2001, 3925.)
ty.phlo'ni.us. Gr. n. *typhlon,* cecum; N.L. adj. *typhlonius* pertaining to the cecum, site of original isolation.

Cells are filamentous spiral or curved rods, 0.3 × 2–5 μm. Motile by means of single bipolar sheathed flagella. Culture on agar media containing 5% sheep blood under microaerobic conditions results in pinpoint colonies. No growth under anaerobic conditions. Catalase, but not alkaline phosphatase or urease produced. Indoxyl acetate not hydrolyzed. Weak growth on media containing 1.0% glycine. Resistant to cephalothin (30 μg) but sensitive to nalidixic acid (30 μg) in disk diffusion tests.

Pathogenicity uncertain. Causes typhlocolitis, hepatitis, and inflammatory bowel disease in immunodeficient mice, but can also be recovered from mice without abnormal gastrointestinal pathology. Isolated from feces and ceca of laboratory mice.

In 1999, two independent research groups described novel helicobacters associated with gastrointestinal lesions of various strains of immunodeficient mice (Fox et al., 1999; Franklin et al., 1999); the latter group proposed the name *"Helicobacter typhlonicus"* for their isolates. A subsequent collaboration between the two research groups determined that the strains studied by each respective group represented a distinct species, *Helicobacter typhlonius.* This specific epithet *typhlonius* was used in preference to the initial designation *"typhlonicus"* for nomenclatural reasons relating to use of Latin adjectives.

In 16S rRNA gene sequence comparisons, *Helicobacter typhlonius* forms a clade with other murine helicobacters *H. hepaticus* and *H. muridarum.* However, many features differ-

entiate these species, including presence of periplasmic fibrils and multiple flagella on the cell body of *H. muridarum*, absence of urease in *H. typhlonius* and alkaline phosphatase activity in *H. muridarum* only. All strains of *H. typhlonius* examined have demonstrated an intervening sequence of 166 bp in their 16S rDNA amplicons (Franklin et al., 2001). Thus, this species is one of only three species at present (including *H. bilis* and *H. canis*) in which such insertions have been detected in the 16S rRNA gene.

The mol% G + C of the DNA is: not determined.

Type strain: MIT 97-6810, ATCC BAA-367.

GenBank accession number (16S rRNA): AF127912.

Other Organisms

Helicobacter sp. strain CLO-3 was originally described by Fennell et al. (1984) in their study of *Campylobacter*-like organisms (CLO) isolated from homosexual males. The groups CLO-1 and CLO-2 were later formally classified as *Campylobacter* species by Totten et al. (1985), and reclassified as *Helicobacter cinaedi* and *Helicobacter fennelliae*, respectively, by Vandamme et al. (1991a). Only a single strain belonged to CLO-3, and the CLO-3 taxon was not formally named pending the isolation and characterization of additional strains belonging to the same species. This single isolate is well-characterized and has been included in a variety of taxonomic studies.

Cells of 48 h old cultures in microaerobic conditions at 37°C are predominantly slender spiral rods, 0.3–0.5 × 1.5–5.0 µm. Rapid corkscrew-like motility by means of a single, polar, sheathed flagellum. Single curved, S-shaped, and straight rods are occasionally seen. Coccoid forms develop in old cultures.

Colonies of 48 h old cultures are pinpoint and translucent. On freshly prepared or moist media, or in older cultures, growth usually occurs as a flat and spreading zone with a blue-gray hue and discreet colonies may be rare. No distinct odor.

No growth in aerobic or anaerobic conditions. Catalase is produced. Nitrate is not reduced. No urease activity. Growth in 1% glycine, but not in 2% NaCl. Grows on media containing 0.04% triphenyl-tetrazolium chloride; reduction of this compound is concurrently observed and bacterial growth is of a metallic red sheen. Hydrolysis of indoxyl acetate is weakly positive.

The mol% G + C of the DNA is: 45 (T_m).

Deposited strain: CLO-3, CCUG 14564.

GenBank accession number (16S rRNA): M88151.

In their study of *Helicobacter* strains from wild bird feces, Seymour et al. (1994) distinguished three biochemical groups of strains, referred to as "Bird-A", "Bird-B", and "Bird-C" strains. Strains belonging to the Bird-A taxon were formally classified as *Helicobacter pametensis* by Dewhirst et al. (1994); the Bird-B and Bird-C taxa were not formally classified.

Biochemically, Bird-C and Bird-B strains differed only in the degree of susceptibility towards nalidixic acid (the Bird-C strain was susceptible while Bird-B strains were only moderately susceptible); Bird-B and Bird-C strains were distinguished from Bird A strains by the absence of urease activity and susceptibility to cephalothin, which are characteristic for the latter. Bird-B and Bird-C strains produced urease, alkaline phosphatase, catalase, and oxidase, reduced nitrate, and hydrolyzed indoxyl acetate; they did not produce gamma-2-glutamyl transpeptidase. They were resistant to cephalothin but susceptible to nalidixic acid. They grew at 42°C and in the presence of 1% glycine, but not in the presence of 3.5% NaCl.

Old cultures of cells of Bird-B and -C strains 48 h old are predominantly slender spiral rods, 0.3–0.5 × 1.5–5.0 µm. Rapid corkscrew-like motility by means of a single, bipolar, sheathed flagellum. Coccoid forms develop in old cultures.

The 16S rRNA genes of *H. pametensis*, *H. mustelae*, and the Bird-B and Bird-C strains are more than 97% similar. The presence of several differential biochemical characteristics suggests that the Bird-B and Bird-C strains represent distinct species, but DNA–DNA hybridization experiments have not yet been performed.

Both Bird-B strains were isolated from tern feces; the Bird-C strains were isolated from feces of a house sparrow.

The mol% G + C of the DNA is: 31 and 30 (T_m) (Bird-B and -C strains, respectively).

Deposited strain: Bird-B, CCUG 29256, M88139; Bird-B, CCUG 29254, M88146; and Bird-C, CCUG 29261, M88144.

GenBank accession number (16S rRNA): Bird-B, M88139, M88146; Bird-C, M88144.

The name *"Flexispira rappini"* was proposed by Bryner (Bryner et al., 1986; Bryner, 1987) to denote a group of distinctive bacteria from enteric or genital tract samples of sheep, humans, and pigs. The organisms closely resembled strains observed by Rappin (1881) in dog feces and had a fusiform cell body encircled by spiral periplasmic fibers with bipolar tufts of sheathed flagella. In 1991, analysis of 16S rRNA gene sequences and DNA–rRNA hybridization experiments (Paster et al., 1991; Vandamme et al., 1991a) revealed that two human *"Flexispira rappini"* strains belonged to the genus *Helicobacter*. Since these studies, additional *"H. rappini"* strains have been identified, primarily based on their cell morphology and phylogenetic position. Moreover, there is increasing evidence indicating that strains named *"H. rappini"* represent more than one species. Indeed the murine species *H. aurati*, *H. bilis*, and *H. trogontum* closely resemble *"H. rappini"*. A fuller description of the problems concerning the taxonomic status of these strains is given in the Taxonomic Comments section above. Validation of the name *"H. rappini"* (proposed for certain human, dog, and mouse strains that form a closely related phylogenetic group) is pending (Dewhirst et al., 2000a).

Biochemical characteristics of individual *"F. rappini"* strains have been described in various studies cited above. Bryner (1987) reported that seven *"F. rappini"* strains had an average DNA base ratio of 33 mol% G + C (thermal denaturation method). Vandamme et al. (1991a) reported that the DNA base composition of strains ATCC 43879 and ATCC 43880 was 33.7 and 34.3 mol% G + C (thermal denaturation method), respectively, confirming data reported by Bryner (1987).

Strains tentatively identified as *"F. rappini"* have been isolated from a variety of sources including the gastrointestinal mucosa and feces of humans and animals including dogs, mice, and pigs. Strains have also been isolated from human blood and from aborted ovine fetuses. It should however be emphasized that it is unclear whether these strains represent a single species. It is certainly possible that rodent strains represent either *H. bilis* or *H. trogontum*, which are ultrastructurally indistinguishable from *"F. rappini"*.

Deposited strain: ATCC 43966, ATCC 43968, ATCC 43879.

GenBank accession number (16S rRNA): M88137, U96300, M88138.

The name *"H. westmeadii"* was proposed by Trivett-Moore et al. (1997) for two strains isolated from blood cultures of AIDS

patients. The authors presented a formal description for this novel species but did not denote a type strain. Thus far, the name has not been validated and has no standing in nomenclature. Recently, detailed phenotypic, protein-electrophoretic, and DNA–DNA hybridization analyses have identified these strains as *H. cinaedi* (Vandamme et al., 2000).

Cells of 48 h old cultures are predominantly slender spiral rods, 0.5 × 1.5–2.0 μm. Rapid corkscrew-like motility by means of a single, unipolar, sheathed flagellum.

Colonies of 48 h old cultures are pinpoint and translucent. On freshly prepared or moist media, growth occurs as a fine, translucent, spreading zone, and discreet colonies are rare.

Although originally reported as an anaerobic organism, optimal growth is obtained in a microaerobic atmosphere containing hydrogen. Growth at 37°C, but not at 25°C or 42°C. No growth in aerobic conditions. Catalase, alkaline and acid phosphatase, C4 esterase, C8 ester lipase, leucine arylamidase, and naphthol-AS-BI-phosphohydrolase activities, but not lysine or ornithine decarboxylase, or arginine dihydrolase activity. Nitrate is reduced. No urease activity. Indole and hydrogen sulfide are not produced. Resistant to cephalothin but sensitive to nalidixic acid.

Isolated from blood cultures of HIV-positive males with AIDS.

Deposited strain: None designated.

GenBank accession number (16S rRNA): U44756.

Additional Remarks: Both strains were reported to have identical 16S rRNA gene sequences, but strain numbers were not specified.

Helicobacter sp. strain Mainz (CCUG 33804) was isolated from an effusion of a knee joint of an AIDS patient with septic arthritis (Husmann et al., 1994). The strain produces catalase but does not hydrolyze indoxyl acetate. Alkaline phosphatase and urease activity are absent. The strain was susceptible to cephalothin (30 μg), tetracycline (30 IU), and clindamycin (2 IU), and resistant to nalidixic acid (30 μg), ciprofloxacin (5 μg), and erythromycin (15 IU) (as determined by a disc diffusion assay). Analysis of the 16S rRNA gene sequence revealed a 97.7% similarity with *H. fennelliae*, its closest phylogenetic neighbor. The authors suggested that the strain may represent a novel species, but subsequent phenotypic, protein electrophoretypic, and DNA–DNA hybridization analyses identified the strain as *H. cinaedi* (Vandamme et al., 2000).

Deposited strain: CCUG 33804.

GenBank accession number (16S rRNA): X81028.

The name *"Gastrospirillum hominis"* was proposed by McNulty et al. (1989) to refer to tightly coiled spiral bacteria that were clearly distinct from *H. pylori* in human gastric biopsy samples. The organisms were not cultured. A subsequent study by Solnick et al. (1993) clearly identified *"G. hominis"* strains as helicobacters by 16S rRNA gene sequence comparisons, and also designated two phylogenetically distinct types. As a result of their findings, Solnick et al. (1993) proposed the name *"H. heilmannii"* to supercede *"G. hominis"* for reference to the human strains; some workers have referred to strains observed in domestic pets as *"H. heilmannii"* (Dieterich et al., 1998; Neiger et al. 1998). It should be noted that neither *"G. hominis"* nor *"H. heilmannii"* have been formally described (until recently, their cultivation has eluded most workers, with one exception) and neither at present has nomenclatural precedence over the other. The name *"Gastrospirillum"* is still used to designate large, tightly helical, uncultivable bacteria from the gastric mucosa of a wide variety of animals. Strains from pigs and lemurs have been referred to as *"G. suis"* and *"G. lemur"*, respectively (Mendes et al., 1990; Dewhirst et al., 1992).

The taxonomic and nomenclatural problems surrounding the gastrospirilla are discussed more completely in the Taxonomic Comments section above. The identification of a cultured human *"H. heilmannii"* strain (Andersen et al., 1996) as *H. bizzozeronii* (Jalava et al., 1999c) has significant implications from taxonomic, applied, and epidemiological perspectives. It is, however, probable that the gastrospirilla represent a number of distinct species, some of which may be novel. Nonetheless, it is important to understand that *H. felis*, *H. bizzozeronii*, and *H. salomonis* are inherently difficult to isolate (Eaton et al., 1996a; Jalava et al., 1998) and strains of these species that are not cultured are, by existing criteria, gastrospirilla. The close phylogenetic associations of all these strains make unequivocal differentiation of these taxa impossible by current methods. Results from PCR-based assays based on urease gene sequences (Germani et al., 1997; Dieterich et al., 1998; Neiger et al., 1998) require validation as to their species specificity. However, comparisons of urease gene sequences do differentiate *H. bizzozeronii*, *H. felis*, *H. salomonis*, and *Candidatus* H. suis (J.L. O'Rourke and A. Lee, personal communication); nevertheless, it is likely the gastrospirilla will remain a difficult and controversial group for some time.

Although there is no formal description, generally *"Gastrospirillum"* cells are large spiral rods, 0.4–0.9 × 4–10 μm with polar bundles of sheathed flagella. Cells have 3–8 spiral turns and some strains have periplasmic fibers, but these are not detectable using common light microscopy. The presence of gastrospirillum cells is always associated with urease activity in gastric biopsy samples.

Deposited strain: Not yet cultured.

GenBank accession number (16S rRNA): type 1, L10079, type 2, L10080.

The name *"Helicobacter suncus"* was proposed by Goto et al. (1998) to describe a group of 27 strains (of which five were characterized) recovered from the stomach of house musk shrews (*Suncus murinus*) suffering from chronic gastritis. Based on the biochemical and phylogenetic data presented, a close relationship with *H. mustelae* and the unnamed *Helicobacter* sp. Bird-B, described above, was indicated. *H. suncus* differs from the latter taxa in being resistant to nalidixic acid and failing to hydrolyze indoxyl acetate. A type strain was not designated, and as yet, the name has not been validated.

Cells are curved rods, typically 0.5 × 3.5–5 μm. Coccoid forms are predominant in 5–7 d old cultures. Motile by means of two sheathed flagella showing a bipolar distribution. Bacterial growth is described as transparent and mucoid by the authors after 5–7 d of incubation under microaerobic conditions. Catalase, urease, and alkaline phosphatase activity is observed. Nonhemolytic.

Pathogenicity unknown. Isolated from stomach homogenates of house musk shrews (*Suncus murinus*) suffering from chronic gastritis.

The mol% G + C of the DNA is: not determined.

Deposited strain: Kaz-1, Kaz-2.

GenBank accession number (16S rRNA): AB006147, AB006148.

In order to determine whether ulcerative colitis-like disease in cotton-top tamarins (*Saguinus oedipus*) was associated with infection with *Helicobacter* spp., eight strains representing a putative new species were isolated (Saunders et al., 1999). The ultrastructure and overall phenotype of the strains closely resembled that of *"H. rappini"*, *H. aurati*, *H. bilis*, and *H. trogontum*. However, in contrast to these four taxa, the cotton-top tamarin isolates were found to be urease negative. The 16S rRNA gene sequences of two representative tamarin strains were identical to one another,

contained an intervening sequence of 350 bases, and were most similar to *H. canis*, although the analysis presented by the authors placed *H. fennelliae* as the closest phylogenetic relative.
